The out-door photographer who works with wet plates has to contend with many difficulties. Landscape scenery does not come to him to be photographed; he must go where it is; and in doing so he must take his traps with him, which, to say the least, is enough to spoil the pleasure of a day out. And this is not all. Arrived at the scene of action, he has sometimes to go a quarter of a mile for water to wash his plates, and more if he fixes up his tent on the road, which is often the case, on account of the difficulty he finds in getting into out-of-the-way places with so much luggage. He is perpetually annoyed with dust, and, what is worse, plenty of prying people, who congregate about anything they do not understand; and any body who has tried it knows how seldom they can get a view without some one wishing to improve it by standing gazing into the camera, and that such an acquisition to the view does improve it who can doubt? Again, the difficulty in removing from one place to another is so great that the wet-plate photographer often carries camera and stand two or three hundred yards around his tent, returning each time to develop his plates, the result being that he returns home thoroughly exhausted, and often with little success.

Let us now accompany two ardent photographers into the country. They are going together for a day's pleasure. The weather is beautiful. What a lovely change from working in the operating room, on a hot summer's day, to a ramble in the country, where they can, for one day at least, inhale the pure country air, instead of the poisonous fumes of the smoky town! Both have with them their apparatus. One carries a tripod in one hand and a small parcel in the other, and walks along as though he were empty-handed; the other carries in one hand a parcel (or, rather, a large box, containing camera, chemicals, &c.), in the other, and also suspended by a strap round his neck, a still larger box. Their journey is about three miles, and as they cannot go by rail, of course they must walk. The first mile or so is got over pretty easily, and the man carries his luggage and complains not; nay, he thinks he can manage very nicely. His parcels are not over heavy, but as they near their destination he begins to think the weight increases. They arrive at last, however, and pick out a view, agree upon a place of meeting, in time to return home.

The dry-plate man has exposed a plate before the wet-plate man has cleaned his first plate, and, if he has plates enough with him, can take two views for the wet-plate man's one the day through. I will not dwell upon the difficulties experienced by the wet-plate man, as most of you are aware of them; let it suffice that he meets the dry-plate man, who has exposed his plates with little or no trouble, and has enjoyed himself amazingly. When they are returning home they meet a friend, who desires to know how far he has carried those things. "Not far," says the wet-plate man; "only about four miles, and two to go." The friend jogs along, and the wet-plate man hears, floating along the breeze, the lovely words, "Britons never shall be slaves!"

Many of you may say you are aware that it is less work to take landscape scenery with dry plates than with wet; but you know not until you return home what you have got. But I tell you a person accustomed to dry-plate work knows, when he has exposed his plates, what sort of pictures he will have; he has seen the view he wants on his ground glass, exposed his plate, and takes it home with as much confidence as if it were already developed.

The formula I use is the one given by Mr. England, or near it; you have all seen it in some of the photographic papers or YEAR-BOOK. But, to remind you of it, I will here state it:—Pour collodion on a clean plate, and sensitize in a 30-grain bath, as for wet plates, then wash until all greasiness disappears; next pour on a solution of albumen containing a few drops of liquid-ammonia; let it flow over the plate like collodion, and return to the bottle. Repeat this two or three times; wash moderately. Now carefully pour

\* Read before the Oldham Photographic Society, April 30th.

over the plate a 20-grain solution of nitrate of silver containing a few drops of acetic acid to one ounce of solution. Let this stay on a few seconds; pour off into another bottle: this must not be used over again. This is the backbone of the process, as every plate gets the benefit of a new bath, and is thereby equally good. After this the plate only wants thoroughly washing, and you have a plate which, when dry, is capable of producing the best results (equal to wet plates), and should it fail, the development or exposure is to blame. To develop, pour on a 3-grain solution of pyrogalllic acid, and, when the picture is faintly but thoroughly out, intensify in the usual manner with pyro and silver; fix with hypo of soda. I never use distilled water for any of the washings, but use it for silver baths and pyro for developing solutions.

I think nothing more need be said in favour of this process than that Mr. England uses it in preference to the wet.

## Recent Patents.

### PRODUCING TRANSPARENT DESIGNS ON PAPER.

BY WALTER B. WOODBURY AND R. H. ASHTON.

THE object of this invention, which is simply one of the variously ramified applications of the photo-relief printing process, is to produce by pressure on paper, with a relief photographically obtained, designs resembling the ordinary water-mark, with the object of preventing forgery in bank notes, cheques, &c. The method is also applicable for producing images on lithographic stones, by placing thin paper charged with a greasy substance between the relief and a lithographic stone. The operations are described in the specification as follows:—

In carrying out our invention a relief is first obtained in gelatine by the process described in the specification of letters patent granted to Walter Bentley Woodbury, and dated 23rd September, 1864, No. 2338, or by any other analogous means. This relief is mounted or laid on a plate of hard metal, and the paper to be impressed is rolled or passed through a press in contact therewith, by which means the paper will be rendered transparent at those parts where it has been pressed in contact with the relief parts of the design. On looking at the paper by reflected light a positive picture will be seen (the transparent parts appearing darker than the surface), but upon viewing the same by transmitted light it will appear as a negative; if the reverse effect be desired it will be necessary to replace the ordinary negative by a transparent positive in the production of the gelatine relief; or a metal relief or intaglio may be obtained from the gelatine (by pressure or by the electrolytic process) and used with the ordinary paper machinery for producing the water-mark. Either line subjects or those bearing half-tints may be thus impressed on the paper; in the latter case the different amounts of pressure given to the paper by the varying heights of the relief will produce the effect of the middle tints as well as the extremes of light and shade. In place of using the relief direct as obtained to produce the water-mark in the paper, a reverse of this relief may be obtained by means already known, and a number of casts of it may be made in gelatine on the surface of a steel or zinc plate, and when dry these plates may be used for pressing the paper, or a sheet of highly pressed paper may take the place of the steel or zinc plates. Where the reliefs obtained by light are used, having for their support collodion, these may be cut to any shape, and mounted on the zinc or copper plate by means of india-rubber or other varnish or cement. It will be evident that if (while the paper is undergoing pressure in contact with the gelatine relief) a piece of fine paper charged with a coloured greasy material similar to the carbonized paper used for copying letters is interposed between the relief and the sheet of unsized paper, a design bearing half-tones, according to the variations of the relief, will be impressed upon the latter, which may be transferred to stone, and used to print lithographic impressions in the ordinary manner; or the image may by the same means be impressed at once on the stone without transferring.

Having now described the nature and object of our said invention for "Improved Means of Producing Designs upon Paper," together with the manner in which the same is to be or may be performed or carried into practical effect, we would remark in conclusion that we claim as our invention the peculiar method hereinbefore described of producing transparent designs or water-marks upon paper from reliefs or intaglios obtained by the aid of photography, and also of producing by the same means (with the interposition of paper charged with a greasy substance) of designs either directly upon stone, or which may be transferred on to stone for printing by the ordinary lithographic process.

### PRODUCING PRINTING SURFACES.

BY A. A. DISDERI.

THIS process, for which M. Disderi received provisional protection, is not very fully stated, as the patent was not completed. The provisional specification is as follows:—

This invention comprises two distinct features: first, the transformation of a photographic image into a matrix obtained by galvanoplasty; and, secondly, the production with this matrix either of impressions with inks or of any colour upon paper, textile fabric, glass, ceramic ware, wood, stone, and metal, or of counter-types in relief or in intaglio on any metal, or of engraved blocks for printing.

The invention consists—1st. In obtaining by means of a vehicle (say albumen, gelatine, or other analogous body) a coating or layer containing salts which modify under the action of luminous rays, such as nitrates, chlorides, bichromates, prussiates, and the like, double salts of different metals, gold, silver, copper, and the like. The said coating or layer gives a proof in relief by causing to dissolve, according to its nature, the parts not impressioned by light, by means of water at different temperatures, alcohol, ether, or acids, and thus leaving bare the parts gradually metallized. This coating, or layer, obtained in relief after the mode of an ordinary photographic negative, will give a positive proof by transparency with the blackest lines in relief and the whitest in intaglio.

2nd. In varnishing the contour of the glass bearing this positive proof with gutta percha, in order to avoid damage; in then employing the means ordinarily adopted in galvanoplasty in order to cause a deposit upon this image of a layer of gold, silver, copper, or other metal, and to obtain thus a matrix, the hollows of which will be formed by the black or dark parts and the relief by the white or light parts. The production of this matrix constitutes the first part of this invention. Now with the matrix I can obtain various artistic and industrial results, which constitute the second part of the invention.

Firstly, I can cover this matrix with an ink at the ordinary temperature, and apply it to printing upon glass, wood, stuffs, porcelain, paper, and other bodies. Dessication takes place; then, to detach the image easily from the matrix, and to leave it adherent to the body applied to receive the impression, I heat the matrix gently with a spirit lamp. I compound the ink by mixing therewith ingredients which melt under heat, such as gelatine and the like, and colouring ingredients to vary the effects; I also add vitrifiable matters if I wish to print on porcelain and to obtain enamels and the like. Finally, I can, by the process above-described, produce impressions on wood, metals, paper, glass, stuff, stone, plastic substances, and other surfaces.

Secondly, I can submit the matrix to a second galvanic operation to obtain proofs in relief in gold, silver, copper, or other metals, which, besides appearance, will give results the most favourable to great preservation. These proofs can also, by the known typographic processes, serve for printing, as with engravings in wood or metal.

### PORTABLE APPARATUS FOR THE FIELD.

BY HENRY COOK.

THIS portable laboratory or apparatus for working wet plates in the field was only provisionally protected. The specification is as follows:—

The photographic apparatus which forms the subject of the present invention has for its object the construction of a convenient form of portable apparatus for taking views without the necessity of carrying about a cumbersome and unwieldy quantity of apparatus.

The apparatus is composed of two main parts, consisting, firstly, of a circular box 6 inches in diameter and 2½ inches in thickness, constructed to contain fifty or any other convenient number of prepared and sensitized glasses, each 1½ inches square. These glasses are brought by means of the simple rotation of the case one after another directly over a door which opens and shuts automatically.

The second part of the invention consists of the photographic apparatus or camera itself, which forms the principal part of the invention. This apparatus is of the form, dimensions, and appearance of an ordinary opera glass. The glass plates used in the camera are exquisitely sensitive, and will keep so for twelve months, and the images taken may be developed at any interval after exposure. The two tubes of the opera glass are furnished with two lenses exactly similar in focus; one of these serves to project the image to be taken on to the ground focussing glass which occupies the large part of the tube, the other to produce the image on the prepared glass plate, which occupies a small dark chamber formed in the opposite tube. The circular box in which are arranged the prepared glass plates is pushed over an opening in this chamber provided with appropriate grooves; the doors of the box and of the dark chamber are simultaneously opened, and a prepared glass plate falls from the box into the dark chamber. When the view has been taken the apparatus is turned upside down, and the glass plate which has been exposed will fall back into its place in the box, which is then removed. The door of this latter closes, and a small movement to the right or left brings another prepared glass plate over the door and the opening in the camera. As the place of each prepared glass plate is numbered, all danger of using a glass twice over is avoided. The tube which contains the ground focussing glass is provided with a magnifying power to facilitate the finding of the focus; that which contains the dark chamber is provided with a spring and screw to hold the prepared glass in its place; this tube is likewise furnished with a very convenient stop or blind, which, when the instrument is fixed and the focus found, may be opened and closed according to the time of exposure. When all the prepared glass plates in the box have been exposed they may be removed in artificial light and placed in the supply box, from which an equivalent number of fresh glasses may be taken. Within the space or size, therefore, of an opera glass, a drinking cup, and a pistol case for extra glasses, a man may take and bring home with him two or three thousand views. If he be a photographer he will develop the views himself; if not, he will give them to a professional man, who for a trifling expense will complete and enlarge them for him. So great is the facility of enlargement, and so perfect are the results, that it is quite an undecided question whether it would not be wiser in all cases to adopt the system of taking small views. A very perfect stand has been devised uniting the requisite rigidity with great lightness; it is a simple socket and upright post provided with an universal joint of great simplicity, which permits of the rapid fixing and removal of the instrument.

#### METHOD OF ENLARGING.

BY JAMES SIMPSON.

This method of enlarging, or rather the arrangement of apparatus for carrying it out was only provisionally protected. The specification is as follows:—

My invention is designed for the purpose of facilitating the process of obtaining enlarged photographic pictures from small negatives, and also for producing from such negative a superior positive print than is obtained with the process now adopted: and the improvements consist in the employment and use of an ordinary photographic camera and lens in connection with an elongated conical dark tube or other shaped box, which may be constructed of one given length or arranged telescopically in order that it may be diminished or elongated in length. The camera or cameras are connected with the dark box so as to have the lens enclosed and embraced by the narrow end of the cone, or inserted in one side of the box, the opposite end or base being provided and enclosed with a slide or slides constructed like the ordinary dark slide of a camera, in order that it can receive a sheet of paper or other material having a previously prepared sensitized surface; the ordinary dark slide of the camera at the reverse end and outside the conical box is arranged so as to receive the negative to be printed from,

which thereby becomes the only medium through which the light entering the box will be allowed to penetrate, the rays of light so entering the box being diffused and governed according to the opacity or transparency of the negative, become in their passage through the lens gradually enlarged until they strike upon and are received by the previously sensitized surface placed at the base of the cone, the result of which is a direct enlarged positive print, the depth or intensity of which is regulated according to the time the sensitized surface is exposed to the action of light through the negative and lens. The conical dark box is provided with sliding doors, one near the adjusting screw of the lens, and the other for the operator to look through, in order that the greatest nicety of focus may be obtained before exposing the sensitized surface, the doors being closed before such exposure.

#### INSTANTANEOUS PHOTOGRAPHY A QUARTER OF A CENTURY AGO.

A DESCRIPTION of instantaneous photographic portraiture upwards of a quarter of a century ago seems at first sight somewhat startling, and might lead to the question, Have we really progressed? A little reflection would, however, leave little doubt on that subject, but would not deprive of interest an account of the operations in a photographic portraitist's establishment six-and-twenty years ago. A correspondent has called our attention to the following extract from the *Spectator* of April 16th, 1842, describing the late Mr. Claudet's operations at the Adelaide Gallery when photography itself was a novelty and a wonder.

It seemed sufficiently wonderful to have one's "portrait in little" limned by the sun in a few seconds, but now it is done instantaneously; a passing expression is transferred to a plate, and the "Cynthia of the minute"—or rather of the *moment*—is caught and clapped into a case in no time. This magical celerity in taking photographic likenesses by the Daguerreotype, at the Adelaide Gallery, is the result of some improvement in the process recently made by M. Claudet, who has also greatly improved the pictorial effect of the miniatures by the introduction of backgrounds, and he adopts a method of fixing the image peculiar to himself. The momentary quickness with which the likeness is taken prevents the necessity for retaining a fixed look and posture for a certain time; this is not only more agreeable to the sitter, but gives a life-like ease and vivacity to the photographic portraits: thus, the objections made to their stern and gloomy expression are obviated in a great degree, the most transient smile being reflected in the polished surface of the plate as in a mirror. The addition of a background of trees, architecture, or a library, takes away from the metallic effect of the plate, and gives to the miniature the appearance of an exquisitely finished mezzotint engraving seen through the wrong end of an opera glass. This addition is made by simply placing a scene, painted in distemper in neutral tint, behind the sitter, and arranging the focus of the lens of the camera so that the upper part of the figure is shown. By diminishing the size of the head, the defects arising from an exaggeration of facial peculiarities are got rid of, and the salient points of the physiognomy are, as it were, concentrated; the fixing process, too, imparts a warm brownish tinge to the miniature, substituting the tone of a sepia drawing for the livid coldness of the metallic surface. The roof of the Adelaide Gallery is the scene of these operations, on which a chamber glazed with blue glass is erected for use in cold and rainy weather. When it is fine the sitter is placed in the open air under an awning to screen the face from the glare of sunlight. Waiting your turn, and while away the time by trying to discern distant objects through the smoke, or looking at the steeple of St. Martin's Church that rises in bold relief before you, a courteous person invites your attention to a little square box that he holds, and, placing it on a stand directly opposite to you, begs you to remain steady for an instant. He lifts up the little dark curtain that veils one side of the cube-shaped box, and lets it drop directly. You suppose there is something wrong. Not at all; the thing is done. Whatever your look was at that moment it is transfixed on the plate, and you may go to the little laboratory where the process of "fixing" is performed, and, as the moisture of the preparation is evaporated from the surface, see what was the precise expression on your

face at the time. There is your image as though a diminishing glass had perpetuated the reflection, only without colour. But what a hand! Surely you have not got such a huge fist? No; you happened to thrust it forward before the plane of the picture, and hence it has been taken under a different angle. You don't like to present a portrait with such a fist to the fair one to whom you have offered your hand, and you hesitate, though the likeness is so striking. M. Claudet perceives your embarrassment, and, anticipating the objection, says: "Let us try again, if you please;" and the operation is repeated—ay, and a third time, if any accidental failure renders it necessary. Should you prefer it, a friend may share the operation, and, at the same moment, both phizzes will be transferred to the plate. We saw a loving couple taken in this way—nay, even groups of three; you may have a whole family enclosed in a couple of miniatures. The small size of the heads does not diminish the likeness; you might have a set of shirt-studs ornamented with portraits of your friends.

## Proceedings of Societies.

### SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE ordinary meeting was held in the City of London College on the evening of Thursday, May 14th, Mr. T. SEBASTIAN DAVIS in the chair.

The minutes of a previous meeting were read and confirmed.

Mr. HENDERSON exhibited some exceedingly fine enamels which he had produced by a process which he has recently discovered. The results were exceedingly fine.

Mr. WHARTON SIMPSON exhibited some examples of Marion's "Vitrified India-Rubber Sheet," which he explained did not, on examination, appear to be india-rubber. It was, most probably, made in the same way as Herr Grune's "leather collodion," made from collodion containing castor oil. He also exhibited some of a similar pellicle made by Mr. Woodbury, which was at the same time treated with iodized collodion, excited, and a preservative applied, forming, in fact, a dry collodion plate without glass. He also showed a negative produced on such a dry plate.

After some conversation on the subject,

The CHAIRMAN called attention to some fine examples of Mr. Rejlander's photography, consisting of the seven studies taken when he was producing the negative from which the presentation print of the Society, "A Night in London," was printed. It illustrated that in working out a good idea several attempts might be necessary before the highest result could be obtained. He also called attention to three charming studies from life by Mr. Rejlander, one of which was an admirable head, after the style of Guido's Beatrice Cenci.

No paper having been provided, in response to the Chairman's invitation to any member to introduce a subject of conversation,

Mr. Rejlander said he had often seen articles in which the advantages of clear glass in the shadows of a negative were claimed. He thought there was danger in aiming at this, unless much judgment were used. In a portrait with a dark background, it was a good rule to avoid having the deepest shadows in the figure as deep as the background, whilst with a light background they must of course be deeper. The effect of the shadows, being holes in which you could look through and see the background, should be carefully avoided. A negative with all the shadows represented by bare glass would not possess much gradation; a good picture should only have a very sparing amount of pure black or white.

A desultory conversation on the subject followed, and on the question whether a picture was better for the entire absence of any points of pure white. After which,

Mr. SIMPSON showed a number of Mons. Adam-Salomon's prints unmounted or finished in any way, to illustrate the amount of touching in the finished prints. They were much admired, and a general acknowledgment was made that touching was rarely needed, the photography being exceedingly perfect, and the pictures singularly full of half-tone and modelling.

The CHAIRMAN announced that the presentation print would be ready for issue at the next meeting.

The proceedings then terminated.

## Correspondence.

### MR. ENGLAND'S PROCESS.

SIR,—While perusing a recent number of one of the journals I was surprised to find that the application of nitrate of silver as a sensitizer to the coltodio-albumen film was attributed to Mr. England. This, sir, is not correct; for that fact was discovered by me in the summer of 1858, and the process laid before the North London Society on the 26th of June in the same year, and subsequently embodied in a paper which I read before the London Society, at King's College, on the 4th of December, 1860.

Now, sir, I do not wish in the least to charge Mr. England with taking to himself that which he believes to be another's; and therefore the only reason I can assign for so old a photographer not knowing that such a process did exist is, that while Mr. England gave his mind entirely to wet-plate photography, myself and others were engaged in endeavouring to discover a dry plate process available in the field, and certain in its results.

One word with regard to the keeping properties of the plate. If you finish it at once, the sooner it is exposed the better; but I would recommend that the film should be allowed to dry after the albumen has been washed off; because, in this state, it will keep any length of time, and it can be rendered sensitive at any time by redipping in the nitrate bath, or a solution of nitrate of silver poured over the plate, taking care to well wash afterwards.—I am sir, yours, &c., J. RYLEY, M.D.

48, Gibson Square, Islington, May 14, 1868.

### HONEY PROCESS.

DEAR SIR,—For the benefit of your readers who may not have seen the early numbers of the PHOTOGRAPHIC NEWS, I repeat the process, strongly recommending it to keep for any time within six or eight hours. When your plate is ready for the carrier, pour over it a solution of honey; pour off; again pour on from the opposite corner a fresh quantity. The second lot may be used for the first coating of next plate. Exposure not more than three to four seconds more than the wet plate. Develop with either iron or pyro (caution: beware of too much intensity in the sky). Flood the plate with developer. When detail is nearly out, add 2 to 3 m. of silver solution, wash, fix hypo, wash. To make the honey solution, buy the country honey, which in season may be purchased from 10d. to 1s. 4d per lb. Take 1 ounce by weight, add 2 ounces of distilled water, filter through cotton wool, neutralize with drops of a 10-m. solution of liquor ammonia. When neutral, add 1 or 2 m. of a 10-m. solution of nitric acid.

I believe the whole secret of the process lies in neutralizing and acidifying the honey, to get good clear results. If for keeping longer, wash the plates after they come from the bath before applying the honey, and report progress.—Yours respectfully, S.

### SULPHOCYANIDE TONING.

DEAR SIR,—I have for some time used the sulphocyanide of ammonium for toning, but from the first three or four lots of prints I toned in that way I perceive, that with all its advantages (and they are many), one great objection was the tendency they had to lose their purity in the whites. In some few cases, of course, this effect is an improvement; but in prints from negatives which have those delicate half-tones that all photographs ought to have, it deteriorates much from their beauty if the whites are not pure. To obtain my prints free from that defect, I wash them in the ordinary way, and then put them for a few minutes—or until I see them clear in the whites—into the following bath:—

Acetate of soda	...	...	...	4 drachms
Carbonate of soda	...	...	...	10 grains
Water...	...	...	...	20 ounces
Chloride of gold	...	...	...	2 grains.

After taking them from this bath, just give them one wash, and proceed in the ordinary way with the sulphocyanide.

I enclose two prints from the same negative—one toned with the sulpho bath only, and the other in the way I have described.

I would like to have your opinion of that.—I am, dear sir, yours truly,

GEORGE H. BRITTON.

10, High Street, Forest Hill, S.E.

[The tone of both prints is good, but that treated as above is purest in the whites.—Ed.]

## Talk in the Studio.

**ROYAL CORNWALL POLYTECHNIC SOCIETY.**—The prize list for the exhibition of the Society to be held this year is just issued. In photography the following prizes are offered to professional photographers:—For the best landscape, a silver medal; for the best portrait or group, a silver medal; for the second best landscape, a bronze medal; for the second best portrait or group, a bronze medal. Medals and prizes will be awarded to meritorious productions contributed by amateurs. In all cases the prints must be untouched; and of vignetted pictures, fully printed copies must also be sent for the inspection of the judges. All articles intended for exhibition should be sent to the Polytechnic Hall at Falmouth, not later than the 21st of September. Photographers desiring further information should communicate with Mr. J. C. Stephens, Falmouth.

**MORE PIRACY.**—A few days ago at Lambeth, Mr. Woolrych heard a number of summonses, taken out at the instance of Mr. Graves against Mr. Prince, a dealer in photographs, carrying on business in Holborn, and residing at Caroline Cottages, Brixton, for selling a number of photographs of which the complainant had the copyright. There were twenty-one alleged offences, and the penalties, at £10, would amount to £210. Mr. Lewis, Jun. (Lewis and Lewis), appeared in support of the summonses, and Mr. Brandt, barrister, was for the defendant. Several cases were taken. The evidence of Emil Kaltenbrunn, a German, in the employ of Mr. Graves, was to the effect that he went on several occasions to the defendant's place of business in Holborn and selected photographs from a bundle handed to him by the clerk. Mr. Boydell Graves, son of the complainant, stated that some years ago he went to the defendant's place of business, and when he came in he was recognized, and threatened to be kicked downstairs if he did not leave the place. Mr. H. Graves produced the certificates of registration. Mr. Brandt took several objections in the course of the discussion. The learned counsel said that under the Act of Parliament the penalties would amount to a large sum, and he urged that each case should be strictly proved. Mr. Graves said that many of the photographs were made in Berlin and Birmingham. Mr. Woolrych, after hearing a number of the cases, said the case was far too important for him to decide without consideration. He would consider the points urged, and the construction of the Acts of Parliament. His present impression was that the case had been established, but he would, before he gave his judgment, consider all the objections taken. As he was going to leave town for some time the case must stand over. Mr. Lewis mentioned that the Act required the penalties to be recovered within six months from the time of the offence, and several of the summonses were for offences committed in December last. Mr. Woolrych said he would give judgment on Saturday. Mr. Lewis asked for bail to be given for the defendant's appearance. Mr. Brandt objected. The defendant had appeared, and would appear again. The magistrate required bail from the defendant in £100, and his own recognizance in £200 for his appearance. On Saturday the case was further heard, the defence being conducted by Mr. Seaman, solicitor; Mr. George Lewis, Jun., again attended for Mr. Graves. Several further cases were brought forward, after which Mr. Woolrych said he had considered the objection urged and the construction of the Acts of Parliament, and was clearly of opinion that the offences had been established against the defendant. The first case was "Ordered on Foreign Service." The wrongful act of selling the photographs was made out, and he inflicted a penalty of £5 with costs, or the alternative of fourteen days' imprisonment. It was, in his opinion, a most daring and audacious infringement of a copyright which belonged to Mr. Graves, who had made large and liberal outlays to produce beautiful works of art, and was entitled to all the protection that the law afforded. Mr. Seaman reminded the learned magistrate that several purchases were

made on the same day. Mr. Woolrych said the Court of Queen's Bench had decided that each purchase, notwithstanding it was made on the same day, was an offence, and he should inflict the penalty in each. Then as to the photographs "Waiting for the Verdict," and "The Acquittal," the penalties would be the same, as also on "My First Sermon"—they were all spurious copies. As to the photographs "Morning before the Battle" and the "Evening after the Battle," he should award a similar penalty or fourteen days. The photographs of "Piper and Pair of Nutcrackers" would follow the same rule, as also "Home and its Treasures." There were nineteen convictions of £5 each, it would appear, or fourteen days' consecutive imprisonment on each, making some months. Mr. Lewis said he would not press for costs. Mr. Seaman said the object was to bring the matter under the Small Penalties Act, which he submitted did not apply. The penalties were ordered without costs. The defendant was locked up in default of the payment of then nineteen penalties.

**PHOTOGRAPHY IN ABYSSINIA.**—The photographs taken by the Abyssinian expedition which have hitherto come under our attention have not hitherto, with the exception of some large groups, consisted of portraits. Speaking of Theodore, one correspondent observes: "Mr. Holmes, of the British Museum, has taken an exceedingly good likeness of the dead monarch; indeed, I do not know that I ever saw a more striking resemblance. The engineers have also taken a photograph of him." The correspondent of the *Times* says: "Some facetious fellow-captive, with a curious quaver, however, in his voice, which makes the facetiousness give forth an uncertain sound, has just sternly ordered the ladies to come with their husbands and children, and 'have their heads taken off,' in a photograph, and, of course, I must presently go too, to have my first good look at so interesting a group, this being about the fiftieth interruption since I began this morning to try to make mental notes of what I had gone through in the last two days."

**POISONING BY CYANIDE.**—A sad accident occurred at Wadbridge last week, when a little boy, two years of age, son of Mr. C. Lobb, photographer, got into the dark room while his father was engaged talking to some customers, and drank from a bottle of cyanide that had just been in use. Death occurred in about ten minutes. The coroner's jury on the evidence laid before them returned a verdict of "Accidental Death."

**REMARKABLE MIRAGE AT DOVER.**—A mirage was strikingly conspicuous on Sunday afternoon and evening at Dover. The dome of the Cathedral and Napoleon's Pillar at Boulogne were to be seen from the Crescent Walk by the naked eye, but with a telescope of ordinary power, the entrance of the port, its lighthouse, its shipping, and the surrounding houses, the valley of the hillside of Capécure, and the little fishing village of Portel, were distinctly visible; whilst on the eastern side the principal features of the country—the lighthouse of Cape Grincez, the adjacent windmill, numerous farms and villages, with their windows illuminated by the setting sun—stood out with extraordinary clearness. Whilst these were under observation, a locomotive was seen to leave Boulogne and travel some miles in the Calais direction by its puffs and wreaths of white steam. Shortly after sunset the mirage subsided.—*Dover Chronicle*.

**UNEVEN DRYING OF SENSITIZED PAPER.**—To prevent the silver solution from collecting in drops on the albumen paper, buff the surface with a tuft of cotton before sensitizing.—*D. G. Munger, in Philadelphia Photographer*.

**STRENGTHENING NEGATIVES BY HEAT.**—A correspondent of the *Philadelphia Photographer* says:—"As the tendency of all intensifiers is to flatten and destroy the beauty of the photograph, it is desirable to omit them as much as possible. I often avoid their use by the following 'dodge.' If, after the negative is developed, fixed, and washed, it needs a little reinforcing, I dry it rapidly by the stove or otherwise, which usually brings it right for printing. Any one who will try the experiment will be surprised at the difference between a negative thus dried and one that is allowed to dry spontaneously. Negatives, after washing, should be flowed while wet with a solution of gum-arabic in water. This prevents the hard varnish from changing them."

**USING IMPERFECTLY CLEANED GLASSES.**—The Hon. Nassau Jocelyn writes: "I recently heard of a very good plan for using dirty glasses—not that any careful workman would do so willingly, but sometimes it is pleasant to be independent of a glass cleaner. Take of ether and alcohol 100 and 10 parts re-

spectively, and add to them 1 part of ordinary uniodized collodion, and 1-5th part of tincture of iodine. Spread this very thin film on the glass, and, when it has set, collodionize and sensitize as usual; this forming a perfectly chemically clean surface, it is natural that any dirt or stains which may lie beneath will not appear in the upper film. This proceeding is useful under certain circumstances, when the conditions of the atmosphere do not favour an easy cleaning of plates by the ordinary method.

## To Correspondents.

J. STOTHARD.—To have made an acetate toning bath properly, the gold salt should have had the acid driven off by evaporation at the outset; but by careful management of the solution you have, in the manner we indicated, you will get, as you have doubtless found, very good warm black tones, especially with vigorous prints. The object of the various additions to the chloride of gold solution is to induce a tendency to decomposition, liberating the chlorine, and precipitating the gold in a metallic form. The colour of gold precipitated in this way is modified by the size of the particles, and the size of the particles is modified by the substances used to effect the decomposition. If the decomposition be rapid, as when carbonate of soda is used, and the prints be immersed at once whilst there is nascent chlorine in the solution, the prints are attacked and become mealy and grey. If from imperfect evaporation of the acids in making the gold salt, as in your case, hydrochloric acid, or chlorine, is present in the solution, a similar result ensues. 2. For a strong developer for short exposures, avoid gelatine. Use a strong iron solution with a small portion of acetic acid. Try 40 grains of protosulphate of iron and 20 minims of acetic acid. Gelatine promotes vigour and cleanness, and, in short exposures, often tend to hardness. Thanks for your reminder as to the method of copying. We shall describe, shortly, your application of it.

DUFFER.—It is legal to copy a picture in which there is no copyright. The registration at Stationers' Hall does not confer copyright, it is only a necessary record of the existence of copyright. If you possess the copyright of a picture it is necessary to register it at Stationers' Hall, but such registration would not give you a copyright in something belonging to another. If your object be to ascertain whether by registering your copy of a non-copyright picture you acquire a copyright, the answer is, that you acquire a copyright in your copy, but that would not deprive anyone else, who had opportunity, of the right to copy the original picture. 2. If you send a description of the photograph in the form we have often described, together with fifteen stamps, to our Publisher, he will duly register it for you and pay the fee. 3. The printing bath turning white and turbid indicates that it is getting weak, and is dissolving the albumen and chloride from the paper floated thereon. 4. Excess of salt will redissolve a portion of the chloride of silver in the washing water, instead of precipitating it; but no proportion of salt can be given, because the proportion of silver present is unknown. Take care to add a little at a time for safety; or, better still, use hydrochloric acid to precipitate the chloride, in which case there is no danger of adding excess.

AN AMATEUR.—It is very probable that the cause you suggest may have operated in your case, and that the use of excess of silver in your collodio-bromide may have been the cause of practical insensitiveness. We scarcely agree with you that a process which is rendered worthless by want of precision in carrying it out is not worth pursuing. Precision is one of the first requisites in successful photography. However, there is large choice of excellent dry processes open, and the gum process we know to be excellent. Thanks for your experience confirming the value of permanganate solution for rectifying the bath.

SILEX.—The occasional uneven tinging of collodio-chloride prints is due to the use of a repellent horny collodion, which prevents ready and even permeation of aqueous solutions. The white opaque effect in the shadows is also due to unsuitable collodion. The plain collodion used should dry quite clear and transparent when tried on a glass plate; some samples dry dull, opaque, or opalescent, and such will give dull, grey, opaque shadows when employed for collodio-chloride. We explained the reason why your questions frequently do not reach us. We never neglect to answer questions which do not seem important, because we know that the most trivial difficulty is important to one suffering under it.

X. Y.—Spirits of wine 56 over-proof is not sufficiently highly rectified for making collodion; it should not be less than 60 over-proof at weakest; it is usually used stronger than that. Spirit of 56 over-proof is about 837 sp. gr.; spirit of 60 over-proof is about 830 sp. gr.; and spirit of 63 over-proof is about 823 sp. gr.

W. F. MORGAN.—You are right in your statement of Mr. England's practice; but as very little more silver solution need be used than is necessary to cover the plate, and as the solution poured off may be added to the residues, there need be little waste. The results are, as you observe, exceedingly perfect.

W. H. PAYNE sends us a good 10 by 8 architectural photograph, to show how perfect a result may be obtained with a Jamini quarter-plate lens. He does not state the focus of the lens; but the result is certainly good.

II. W.—Mr. England generally uses distilled water for the first and final washes, using common water for the copious washing. In his last Continental trip he wet with good rain water, which answered every purpose. 2. In mixing iodides or bromides with plain collodion, the quality of the latter determines the mode of proceeding. If it be too thick for use, then the salts must be dissolved in a proper quantity of alcohol, and added; but if a collodion of considerable body be required, and the plain collodion be of the desired thickness, the salts must be added direct, and dissolved by frequent agitation. For such a purpose, the most soluble salts, such as those of cadmium, should be chosen.

S.—The formation of oxide of silver by the addition of lime water to nitrate of silver solution might be useful to the photographer; but, on the whole, we prefer the method we usually recommend; namely, the addition of a little caustic potash to a solution of nitrate of silver. Thanks.

II. S.—The residue you describe as obtained after boiling your bath to dryness and fusing, which you sent a week or two ago, we find to consist for the most part of reduced metallic silver, the appearance of which was, however, much altered by the presence of sulphate of silver, together with some crystallized nitrate. Upon applying heat, we found no difficulty in dissolving the precipitate in nitric acid.

W. J. A. G.—As a rule, the use of strong hyposulphite solution and short immersion is safer and better than the use of weak solution and long immersion. In some cases, especially in prints from weak negatives or with highly salted paper, the prints are somewhat reduced and weakened by using very strong hypo; but we never like to use less than a quarter of a pound to a pint of water. The use of a warm hypo bath, except in extremely cold weather, is not desirable, as it will impoverish the prints and reduce the tone more, and heat facilitates decomposition in the hypo bath. 2. In the studio you describe you will find the use of a black or dark blue blind over half the top very desirable for securing shadow. See our recent notice of the studio of Mr. Williams. Much depends on the size of the room as to the best mode of sliding. If the room be small, let it slide from side to side; if large, and two or three blinds will be necessary to cover the skylight, let them slide from eaves to ridge, using one or more down at a time as necessity may require. 3. Mr. England's Rhine views were produced from dry plates. You can obtain them of Marion, Solio Square.

P. S.—The heat of a common fire, unless kept up very high with bellows, is not sufficient for reducing residues. The best plan will be to break up the slag, add more flux, and apply the heat of a proper furnace. 2. The term "Ivorytype" has been given to several forms of photograph which have been made transparent; but generally with colour. Several such processes have been patented, but we believe that none of the patents are maintained. We have published several such processes in the News at different times; but we cannot, without more definite information as to which process you want, give details here. If you can let us know more precisely, we can probably refer you to the information you require.

R. GILLO and KENT.—Received. Thanks. In our next.

### MR. McLACHLAN'S DISCOVERY.

WE shall now endeavour briefly to state what appears to us to be the suggestions to be derived from Mr. McLachlan's experiments. The chief feature of his operations appears to consist in his care to produce a neutral bath. In stating this, it is only fair to say, however, that he himself very emphatically denies that the issue of his treatment of the nitrate of silver solution simply results in the production of a neutral bath. He insists that some unknown, unrecognized change is effected by the action of light on the neutral silver solution, by which it acquires new properties quite distinct from those of any bath, either acid, alkaline, or neutral, hitherto known. We must decline, however, to refer to occult causes results which can be assigned to known agencies; and pending the further test of experiment, which it is always fair to Mr. McLachlan to hold in reserve, we may without impropriety consider how far the good results he has described may be consistent with much that is already known, but the importance of which is possibly not sufficiently recognized.

Mr. Spiller's experiments lead him to believe that the results described by Mr. McLachlan are due to the presence of a trace of chloride of silver present as an impurity in the nitrate used, and this view is strengthened by an examination of the sample of Mr. McLachlan's favourite nitrate, details of which will be found on another page. Whether this be the explanation or not, Mr. Spiller's experiments have shown that a 20-ounce bath to which 1 grain of chloride of sodium had been added, after sunning for some weeks, and treating with caustic potash, as directed by Mr. McLachlan, gave, with a collodion rendered colourless and neutral by treatment with a potash solution, perfectly brilliant and clean pictures, without any trace of fog, as an example now before us proves. Thirty drops of a solution containing half a grain of caustic potash in an ounce of water were added to the pint of nitrate solution, which was, according to Mr. Spiller, rendered quite neutral, and according to Mr. McLachlan decidedly alkaline. We may here, by the way, remind Mr. McLachlan of a fact which seems to have escaped his attention, and may have misled him in some of his conclusions. He assumes that the bath is necessarily in an alkaline condition, because it slowly restores the blue colour to reddened litmus paper. He should remember that a solution of perfectly pure nitrate of silver will restore the blue tint of reddened litmus paper.

We return, however, to the fact that a bath so free from any trace of free acid as to slowly restore reddened paper, and a collodion rendered colourless by caustic potash, did give clean brilliant negatives. This is, of course, not absolutely novel, but it is certainly rare. The tendency of working in late years has been to a decided increase in the use of nitric acid in the negative bath. The neutral bath and freshly

mixed simply iodized collodion in a colourless neutral state, which many years ago were regarded as securing the perfection of conditions, are now almost unknown. When simply iodized collodions were employed, the least trace of nitric acid in the bath was fatal to sensitiveness, and it was never employed; but, since the use of bromo-iodized collodion for negatives has become universal, nitric acid—which, when bromides are present, interferes little with sensitiveness—has been largely used as a means of preventing fog in a bath which would otherwise give dirty negatives. The free use of nitric acid has, in fact, often permitted the use of a bath containing considerable impurity.

Now, we are by no means sure that the use of nitric acid in tolerably large proportion is an evil. We have used it freely for many years without suffering any serious inconvenience which we can trace to its use. But there are certain evils which may result from its use which are worth considering. In the first place, if a collodion containing a very small proportion of bromide be employed, nitric acid will impair sensitiveness. In the next place, under many circumstances it tends to the formation of a thin grey metallic-looking image, instead of the dense brown image desirable in a negative. In the next place, its presence in the nitrate solution will tend to oxidize the alcoholic bodies accumulating in the bath, and to cause the formation of aldehyde, and so gradually induce the fog it was added to prevent. And finally, the presence of nitric acid increases the tendency of the bath to dissolve iodide of silver, which will, therefore, more rapidly increase in the bath the greater the proportion of nitric acid present, and so promote the accumulation of one source of pinholes.

Having regard to these considerations it may be well worth while to consider whether the system, the practicability of which Mr. McLachlan's experiments suggest, of working with a perfectly neutral bath, and a collodion without any trace of free iodine, by which nitric acid would be liberated in the bath, may not possibly tend to diminish or eliminate many of the evils which are occasionally troublesome in the ordinary mode of working. Confirmatory experience is not found wanting. Many photographers have stated that a nitrate bath neutralized and sunned often works admirably without any addition of acid. Mr. Blanchard has more than once stated this fact in our pages. Mr. England, who works with a nearly neutral silver bath, also works with a perfectly colourless collodion; and the practice of some other authorities tend in the same direction.

The fact that the iron developer yields cleaner and brighter results when it contains a trace of a persalt is not new, but has long been held by the majority of the practical photographers. Mr. McLachlan's somewhat roundabout mode of securing the oxidation of the iron salt does not, so far as we can at present see, possess any advantage over the simpler known methods.

To his condemnation of the use of bromides in collodion we cannot attach any weight, inasmuch as it is not sustained either by any statement of reasons or of experience. On the contrary, we find that he prefers, and in his own practice employs, a commercial sample of collodion well known to contain a bromide.

That some uncertainty in working should occasionally arise in the practice of the ablest and most experienced men is, as before pointed out, inevitable from the inherent nature of the wet collodion process; but we believe by far the most fertile cause of troubles is one which was suggested in the course of the discussion at the Photographic Society by more than one speaker: we mean the over-working of baths. In many cases one or two baths of not much larger capacity than is required for sensitizing the size of plates employed will be worked incessantly without replenishment and without rest, day after day in constant practice. Sometimes collodions of different constitutions are excited in such baths. Ether, alcohol, iodide of silver, the bases of different iodides and bromides, and occasionally the traces of plate-cleaning mixtures on the edges of the glass, are accumulating in the bath, whilst every plate abstracts silver, which is the one essential element the bath requires. It is not surprising that working conditions should often be impaired, and sometimes entirely break down.

We will conclude by describing the practice recently detailed to us by one of our ablest and most experienced professional portraitists, a practice in the course of which troubles with the nitrate bath are almost unknown. Six 40-ounce baths are continually kept in use, one for each day in the week. The quantity remaining of each bath is, at the close of each day, emptied into a wide-mouthed bottle, and set aside, loosely covered with a piece of paper to preserve it from dust, but not stoppered to prevent the escape of ether and alcohol. After five days' rest, it is filled up to its full quantity with a fresh 50-grain solution without any iodide of silver, filtered, and again brought into use; when, as might be expected, it is found to work in all respects satisfactorily. The plan of filling up with fresh plain solution, it will be seen, prevents the rapid accumulation of iodide of silver, whilst it prevents the weakening of the bath. The accumulation of ether and alcohol is checked by the facility for evaporation, and the well-known advantages of rest are secured to every bath. Under such a system the photographer is never placed *hors de combat* by the sudden (and as some fancy) inexplicable, although really very natural, complete break down of perhaps the only nitrate bath he has to rely upon for his daily practice.

#### THE RETOUCHING OF M. ADAM-SALOMON'S PICTURES.

It is somewhat late to revive the question of the retouching of the marvellous portraits produced by M. Adam-Salomon, inasmuch as the majority of photographers taking interest in the matter have had opportunity in one way or other of personally examining some of the prints, and confirming our repeated statement of the case, to the effect that whilst some of the prints are more or less retouched, a large number, and these the finest, are quite untouched. As we have some confirmatory evidence to add on the subject, it may be worth while once more briefly to refer to the question. M. Salomon has recently favored us with a number of unmounted prints rough from the washing trough, chiefly duplicates of those we exhibited some months ago in Conduit Street, and permitting, therefore, of the most minute comparison between the finished print and the rough unmounted. The test is a most satisfactory one, and proves that those prints in which a little touching is manifest owe very much less to the pencil than even the most careful observers would imagine, being for the most part perfect in detail, in modelling, and a brilliancy without any touch whatever, and every one distinguished by that exquisite ren-

dering of texture and colour in which a perfect distinction is maintained between the tint of flesh and of white linen, a distinction which so many photographers, in their aim to secure factitious brilliancy, contrive so often to destroy.

One especial fact is worth noting. A correspondent of one of the journals affected some time ago to describe an analysis or examination of one of the prints described as "The Lady with the Riding-whip," and stated that after removing the encaustic and sponging the print, all the retouching being removed, a hard black-and-white picture, destitute alike of detail and modelling, remained, proving M. Salomon, although a good artist, a bad photographer. Now we have both the finished and the unmounted print of this negative before us, and we find in the latter as well as the former an exceedingly fine photograph, possessing much very perfect and delicate half-tone, as well as the greatest richness and brilliancy. We can only come to one of two conclusions, therefore: either that the writer in question stated what was not true, or that he had performed a work like that of some unskilled cleaners of oil paintings, who contrive to remove not only dirt and dirty varnish, but also half the work of the painter, and, having done so, descant on the want of skill in the artist. It is possible, of course, by dint of resolute friction, to scrub away parts of the surface of an albuminized print, and so destroy part of the picture.

We shall have pleasure in showing these unmounted prints to any of our readers who may desire to see them, and who have opportunity to call at our residence for the purpose.

#### MR. McLACHLAN'S NITRATE OF SILVER.

BY JOHN SPILLER, F.C.S.

On the 12th instant, Mr. McLachlan was kind enough to give me a sample of the nitrate of silver which he found to be peculiarly well fitted for the preparation of the bath according to his recent instructions. The crystals have a distinct violet tinge (or "dirty bluish-looking appearance," according to the published description), which is, however, confined to the surface, for if they be momentarily washed with water all the colour is at once removed, and the pure white (or colourless) nitrate underneath, if then taken out, dried, and sunned, does not appear to be in any way affected. The aqueous solution obtained by washing the crystals was discoloured as though by the presence of blackened chloride, sulphide of silver, or other dark matter in suspension, and on filtering the solution it came through bright and clear. The insoluble portion left on the filter was, however, exceedingly small, and I am only able to say of it that its bulk was diminished by treatment with ammonia as though by partial solution. I found, also, that the discoloured crystals gave a clearer liquid when dissolved in dilute ammonia than when pure water was employed as a solvent. Nitric acid added to either of these ammoniacal solutions produced a faint turbidity, as though chloride of silver in small quantity was precipitated. I tested the clear aqueous solution of the crystals, for metallic and other impurities, by adding hydrochloric acid in slight excess to throw down the silver, separating this by means of a filter of Swedish paper, and evaporating the clear filtrate to dryness in a small porcelain capsule mounted on a water bath. There was practically no residuum, and not even a trace of lead was indicated by iodide of potassium; so that I may fairly assume that the fine silver from which these crystals were prepared was perfectly pure.

By way of accounting for the peculiar discoloured appearance of the crystals, which I have shown with some degree of probability to be due to a very superficial incrustation of blackened chloride, it has just now occurred to me that this sample of nitrate of silver may have been spread out to drain and dry in a slightly chlorinated atmosphere, such as would result from the simultaneous preparation of chloride of gold,

or the working of platinum—operations in which *aqua regia* is employed—in the same laboratory; and although such a film of chloride, at first white, might not be noticed in the ordinary course of manufacture, it would undoubtedly render the crystals liable to alteration by light.

I have only to add, that the sample given me by Mr. McLachlan was apparently neutral to litmus paper; but this mode of testing for free acid in silver-salts is not nearly so delicate as is commonly supposed.

Woolwich, May 25th, 1868.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XVIII.

"In such cases there will be found a better likeness, and a worse; and the latter is constantly to be chosen."—*Dryden*.

"The body of beauty is as essential as the soul of truth—truth without beauty cannot make art. \* \* \* Without beauty there is no art. Over both the choice of subjects and their execution, this canon is inflexible. No other consideration in the choice of a subject, and no other merit in its execution, can atone for the neglect of beauty. Mere accuracy of portraiture is draughtsmanship, not art. The artist is he who above all men has an eye for the beautiful, and can embody the beautiful in some art form."—*Tainsh*.

PORTRAITURE—continued.

As I am dealing with principles, I shall not, in these chapters on portraiture, give any illustrations of poses, which could be of very limited application, and would only induce in the student a habit of servile imitation, very detrimental to originality, and unworthy of him who would call himself an artist. An inferior photographer may find a few illustrations of different poses of some use to him, inasmuch as they may assist him in varying his *one* pose; instead of the one pose beyond which his feeble imagination will not allow him to venture, they may give him the use of three or four; but if he will take the trouble, or has sufficient ability, to master principles, he will find himself possessed of a continual fund of ideas ready for use, as is necessary in successful portraiture, at a moment's notice; if he have not the ability and patience to master the few principles on which his art is based, I hope he will excuse me if I hint that he had better try some other means of being of use to his fellow-creatures, for he would be only doing mischief to photography by continuing in the profession.

Besides being of very little use, there is also actual harm in a "set" of poses, the structure of which is not understood, as will be seen if a sitter is allowed to select the position in which he will be taken, and which has perhaps exactly suited some other person.

Sitters often want to be made to look like other people; or, rather, they think that if they sit in the same position and attempt the same expression, however unsuitable, they will look as well as some example they have seen. It constantly occurs that persons will come into the reception-room, and, selecting a portrait of another totally unlike in age, style, and appearance, will say: "There, take me like that." Peter Cunningham gives an anecdote that, possibly, may be out of place here, but is too good to omit. "When Bernard Lens was drawing a lady's picture in the dress of Mary Queen of Scots, the fastidious sitter observed: 'But, Mr. Lens, you have not made me like Mary Queen of Scots!' 'No, madam,' was the reply; 'if God Almighty had made your ladyship like her—I would.'" The same may be said of the *lenses* of the present day!

Other sitters endeavour to improve their faces by all manner of contortions: stare with their eyes to make them larger, and screw up their mouths to make them smaller. Opie was once troubled with such a sitter, and he quickly said to him (so Haydon tells us): "Sir, if you want your mouth left out, I will do it with pleasure." Instead of blunt wit of this kind, the photographer will find it answer better, and will involve less trouble, to make the sitter forget his mouth

altogether. This cannot be done if the sitter is constantly reminded of particular features. Many photographers keep a cheval glass in their studios to enable their sitters to look at themselves while the exposure is proceeding. There are rare cases where the practice may be beneficial, but on the majority it has a very bad effect. I have tried it in my own practice, and found it was a great temptation to the sitter to make the most ridiculous contortions of the face, in the hope of calling up a satisfactory expression. King Lear's wise fool was, perhaps, not far wrong when he said "there was never yet fair woman but she made mouths in a glass."

A good deal depends on the temper of the sitter at the time of sitting. If he come in a great hurry, and feel bored by the operation, good results cannot be expected. Engagements should be made that sitters should not be kept waiting. This is not so difficult to manage as may appear. Be punctual, and exact punctuality. Do not accept pictures to do in half an hour that should have more than double that time allotted to them. It is impossible to make a hungry man look happy. It may be said of a man whom the photographer has kept away from his dinner, as Menenius Agrippa said of Coriolanus:—

"He was not taken well: he had not dined;  
The veins unfilled, our blood is cold, and then  
We pout upon the morning, are unapt."

It almost constantly happens that the photographer sees his sitter for the first time as he enters the studio. Thus he has no opportunity of studying the characteristic attitudes or expression, or the best general arrangement or effect. This difficulty is almost insurmountable, but can be most nearly overcome by an intimate acquaintance with the rules of art, which will enable the artist to think quickly and make all his arrangements without hesitation, thus allowing him more time to study character. The figure should not be posed until everything is ready, and then the final arrangements should not take a minute. This can only be done when the operator quite knows his business, and has thoroughly made up his mind what he is going to do. He should be able to see the finished result in his mind's eye from the beginning. There is nothing so irritating to a sitter as being kept waiting after being posed; he begins to feel he is in a ridiculous position, when it should be the object of the photographer to prevent him thinking that he is in a position at all. A well-posed figure may be easily upset by a bungling use of the head-rest. (Let us lay it down as an axiom that this instrument is indispensable, even for short exposures, say of five or six seconds.) The rest should be understood, in ordinary cases, to be a delicate support, not a rigid fixture against which the figure is to lean. There is another rule that photographers should regard as axiomatic: *the rest should be moved to the head, not the head to the rest*: first the pose, then the rest; not first the rest, and then the pose. In my own practice, I prefer a very light, simple rest, of the old American pattern, without any complications; one so light that I can carry it about after the sitter without trouble.

It must be borne in mind that, in a good photographic portrait, as in a painted one, it is expected will be produced—

"Not the form alone  
And semblance, but, however faintly shown,  
The mind's impression, too, on every face."

Here the educated photographer has a great advantage over those who are less fortunate. He will endeavour to so entertain his sitter that he will feel more at ease than if he were taken into a strange room, fixed inconspicuously in a chair, and photographed. It will be found that not only the expression will be improved, but that pictorial effect, as regards arrangement of lines, will also be much improved by the increased ease the sitter feels as he becomes more familiar with the studio and the student. I have known many persons who, after months of persuasion, have consented to have their portraits taken, and who come in fear and trembling, but who, by judicious treatment, have eventually so posi-

tively enjoyed the operation, that it has become almost a passion.

It is more than probable that this objection to "sit" has been engendered by the brusque manners and rough, uncourteous, and concealed behaviour of photographers themselves. A certain amount of self-confidence, if there is any basis for it, reacts favourably on the sitter, but it should not be carried too far, or some sensitive people may consider it amounted to rudeness.

A good deal depends on such an apparent trifle as the manner of taking off the cap of the lens and exposing the plate; and there is as much difference in the method of performing this simple operation as there is difference of opinion amongst photographers on any other circumstance connected with their art. One will shout: "The exposure's agoing to begin!" in such an angry and threatening tone that you feel inclined to call the police; while another will so smother you with the suavity of his manner that you feel ashamed of troubling him. The first rarely succeeds in anything but disgusting his customers; the other oppresses them by over-politeness. It is evident that some course between these two is the correct one. The photographer must have a strong will to enable him to carry out his idea as to arrangement, and sufficient subtlety to do so, and, at the same time, please his subject. His motto must be, *suaviter in modo, fortiter in re.*"

It may be asked: What has all this to do with "Pictorial Effect in Photography"? Simply this: It is the province of the artist to secure the most characteristic, the most truthful, and the most pleasing aspect of every subject; and that, without regard to the matters to which I have been directing attention, character, truth, and beauty will alike be wanting in photographic portraits, whether the originals be common-place or distinguished.

## GRADATED BACKGROUNDS FOR HEADS, ETC.

BY R. GILLO.

THE effect of gradation on a background in producing relief in a portrait often seems to be overlooked by photographers. Ruskin says: "No colour exists in nature, under ordinary circumstances, without gradation," and enforces again and again that an ungradated touch is bad at any time. Any one, on looking over a collection of photographs, vignette heads, medallions, &c., cannot fail to notice the even and unbroken tint of the backgrounds generally. Look at a portrait by a first-rate artist, a miniature, or any finished work of art, and you will find the background a study of itself, and that on account of the gradation it contains.

The following plan will, in great measure, supply what is wanted, without extra time or trouble:—A square background (about four feet is a convenient size), on a frame with a cross-piece at the back, in the centre of which is a hole to allow the horizontal rod of rest to pass. It will be seen that when the rest is placed against the head of the sitter the face appears in the centre of the square. There will be found no difficulty in painting this small background with a gradation from dark on one edge to light at the other. Lampblack and whitening, with a little size, answers capitally.

When you have arranged the sitter, you can turn this round any way you please: light at the top, shading into dark below, or *vice versa*, or a diagonal gradation to suit circumstances and your own feeling. It is astonishing the different effects produced by turning this background round. Sometimes the effect may be improved by shielding part of the light from the background with a blind or curtain. From the fact of this background being so close to the head of the sitter, you often get a boldly cast shadow from the head or shoulders, which is very effective.

## PHOTOGRAPHIC PRINTING IN SILVER, THEORETICAL AND PRACTICAL.

BY W. T. BOVEY.

### HANDLING SENSITIVE PAPER—FILLING FRAMES, ETC.

THE chemical influences which work out a photographic facsimile of objects are so delicately arranged, so exquisitely sensitive to disturbing agencies, and the turning points that create an issue of weal or woe are so tenderly balanced, that a philosophic regard for minor details becomes an imperative necessity if the operator would steer clear of the difficulties that so frequently make shipwreck of his hopes and productions. Doubtless many of my readers who have hitherto failed to recognize the importance of minor considerations will feel inclined to scoff at the idea of any value being attached to so insignificant an operation as handling paper and "filling in frames." Whether inclined to scoffing or scepticism, believe me, dear reader, when I say that I would prefer entrusting the work of printing to inexperienced hands than allow the paper to be creased, thumb-marked, and stained by the careless fingers of an ignorant assistant, whose sins of commission and omission are too frequently visited on the devoted head of the paper-albuminizer or dealer, whose daily routine is made a worry and bore by the complainings of thoughtlessness and the denunciations that proceed from ignorance.

And here let me observe, I have not the slightest ambition to become a sensational agent, nor do I wish to wound the self-esteem of photographers; but I am backed so strongly by evidence indisputable I hold in my possession that I have no hesitation in asking every photographer to pay heed to the instructions I from this point proceed to give, for they need it sadly. And I beg every reader to throw his prejudices in favour of this or that method overboard if the results such methods yield are wedded to uncertainty. I fully purpose placing in the hands of my readers a sure and certain remedy for all toning difficulties, a remedy based on strictly scientific grounds. And I must here apologize for the liberties I feel bound to take in showing that, however strong the remarks and ridicule levied on the self-devoted, and, I believe, entirely disinterested Mr. McLachlan, on account of the round-about path he takes to obtain certain results, precisely the same adverse arguments apply to all the fashionable toning methods, where the fanciful bases either perform their work tardily, or bother the action of the gold in such a way that it takes a fit of sulks, and won't tone at all.

When sketching out the design of the present series of papers on printing matters, I purposed taking each operation in regular course, and to deal with all matters pertaining to silver printing exhaustively; but I am tempted to deviate from my original plan by the numberless applications I am receiving from all parts for aid in ridding the applicants of their toning difficulties; and as the season is advancing I am desirous of assisting my readers in the most effective manner; consequently I shall run through the preliminary instructions as briefly as possible, and at as early a date as circumstances will admit.

I shall first deal fully with the toning bath, and afterwards retrace my steps to describe the various dodges connected with the printing which are resorted to by printers who are desirous of getting something more than the negative alone is capable of yielding.

I now return to the high road, and proceed to deal with the handling of photographic paper. Summarizing the remarks I have to offer, and, for simplicity sake, dividing them into three parts, my first is a caution.

1st. Never bring two albuminized surfaces into immediate contact, either previous to, or subsequent to, sensitizing. Neglect of this rule occasions abrasions, streaks, subdued lustre, and divers other imperfections, which the injured prints alone are capable of rendering intelligible.

2nd. Avoid any contact of fingers with the surface of the sensitive paper. However clean the fingers may have

been made with soap and water, there is always a saline dampness exuding from the skin which will produce markings on the paper that by no means improves the beauty of the picture aimed after.

3rd. By every precautionary mean take heed that the paper at its back be not defiled. Nothing so forcibly shows up a slovenly workman as display of hideous, yellowish, greenish and mud-coloured stains on the backs of the prints he produces. I would as readily condemn a print stained at its back as one spoiled on account of any unconcealable defect.

When cutting up paper I prefer using scissors, placing the paper before me, sensitive surface upwards. If carte size pieces are needed I cut the paper into two halves, again divide into quarter sheets, and once more subdivide into quarter-size pieces. A sheet of paper thus treated should yield thirty-two carte prints. For pictures of larger dimensions the requisite mode of procedure will be readily suggested to those who make up their minds to go in for perfection. It will be observed that I do not fold the paper at all, and it is surprising how accurate the eye becomes after a brief allowance of practice.

Moving on another stage, I ask care and attention in the "filling in of frames." Don't be over "cheese-paring;" cut the paper large enough, for it is wise at all times to allow a margin beyond the extremities of the negative for handling purposes. When fingering the paper the fingers should, as much as possible, be applied to its edges; never must they be permitted to touch the surface on which any portion of the picture is to appear.

The remarks contained in the above threefold division deserve the careful attention of those who are desirous of obtaining clear and delicate prints. The reward I offer to all who will digest and practise the hints embodied in those paragraphs are unsullied prints, on surfaces as brilliant as the albumen surfaces they received from their photographic paper dealers.

The subject of printing now demands attention, and I ask my reader to recall to memory the sun *versus* shade printing controversy which, a few months since, engaged the pens of Mr. Cherrill and myself. Since that time I have paid special attention to the subject, and the results of my numberless experiments have more than ever convinced me that sun printing (save under rare exceptions) is altogether a mistake, oft-times the unsuspected cause of failures and unsatisfactory results. If the several gradations of a negative that range, without perceptible divisions, from opacity to transparency, maintained a proportional power to resist light under all circumstances, sun printing would, under such conditions, be perfectly admissible; but on reflection it must be admitted that such is not the case. Direct sunlight finds ready entrance where diffused light would be for a longer time excluded; hence it follows the weaker light effects a considerable reduction in the deeper shadows ere the higher lights become at all changed. A second and no less forcible protest against sun printing presents itself. When an excited albumen surface is exposed to diffused light, the most sensitive salt first succeeding that salt being the chloride of silver, the print for a considerable time is seen to assume a violet hue. If the light is very weak the picture finishes up without reduction, to any extent, of the organic salt; but in ordinary diffused light, with the now usually weak salted paper, the albuminate of silver goes to make up to a considerable extent the last printed half of the picture. Thus we have the softness of the chloride picture with the vigour and persistency which the albuminate of silver imparts, and together, perfection is to a considerable extent worked out. But alter the conditions; instead of printing in diffused light do so in the direct solar rays: what is the result? The albuminate of silver is reduced at once; a superficial film of the reduced organic salt is made to form the picture; the dense portions of the negative are penetrated long before the shadows have attained the requisite depth, and you have a poor, flat print, which, in some instances, appears as mealy before toning as one that had been

exposed to the most virulent attack of chlorine. Reason why: If the surface of a negative is closely examined, it will in most instances be perceived that the deposit by re-development is not perfectly even, that some portions are more transparent than others; the defect described is not seen when the print is executed in diffused light, but sunlight penetrates direct, everywhere, and registers everything. My advice, therefore, must be, print in diffused light, except you have a specimen of the ancient "soot-and-whitewash negative to deal with; then by all means print by the direct solar rays. The quicker the printing qualities of a negative, the deeper the gloom in which the printing should be conducted. I frequently allow a whole day for printing a copy from a negative which, in sunlight, would yield hundreds of copies in the same time. But quality makes ample amends for loss of quantity. As I am soon to enter on toning matters, if you make up your minds to try my new-fashioned method, do not print much deeper than needed in the finished picture, and place it in your portfolio, where it must remain until my next, which, on account of the many demands I have received, will soon put in an appearance. And until details are given, pray accuse me not of egotism.

## COLLODION-CUIR AND THE CARBON PROCESS.

BY M. DESPAQUIS.

At the April meeting of the French Photographic Society, the author demonstrated the practical working of the process he employs to obtain photographs in pigments by means of collodion mixed with castor oil, a compound denominated *collodion-cuir*. The film of collodion on which the pictures are produced may either be rendered dull and semi-opaque, like ground glass, or may be left in its original transparent condition, the prints in the latter case having the appearance of glass photographs. Throughout the process ordinary spring water may be used, and the gelatine employed, so long as it is soluble, need not be of the finest quality; it is as well sometimes to add a few drops of ammonia to the gelatine solution, to prevent the formation of air-bubbles when the material is being poured upon the glass or paper surface. The best colouring matter that can be used in the process is indian ink of the finest quality which has been carefully filtered; for portraiture no other pigment is admissible. Lamp-black and other similar materials, although very finely ground, always produce a disagreeable effect in the delicate half-tones of a portrait, where the minute grains or particles of the pigment are visible. For landscape photography, however, lamp-black may be used with advantage; it is more intense in colour, and likewise more moderate in cost, for while 100 grammes of it may be obtained for half-a-crown, the same amount of colouring would scarcely be produced by a litre of indian ink, costing from twelve to sixteen shillings. To improve the tone of the prints, various colours may be added to the blacks employed, such as archil red, Prussian blue, purple, &c.; indigo is also one of the finest colours that may be used, as it is soluble, and produces no grain. Unfortunately, mixtures containing indigo preserve their sensitiveness for a very short time only, and it is necessary, therefore, to employ the same within twenty-four hours of its preparation. In fact, whenever any other pigments but indian ink, or a carbon black of some kind, are employed, the sensitive mixture does not retain its qualities unimpaired for more than a week, fortnight, or at most a month; whereas compounds made up with indian ink and bichromate of ammonia preserve their sensitiveness for twelve months or more. If bichromate of potash is added, the mixture soon loses its sensitiveness, and becomes useless after a period of two days.

The formulæ used are as follows:—

Gelatine ...	...	10 to 12 grammes
Indian ink ...	...	20 "
(Or of lamp-black a sufficient quantity.)		
Water ...	...	80 "
Colours according to circumstances.		

This mixture is dissolved in a porcelain dish on a hot-water bath, and then is added:—

Bichromate of ammonia... 1½ grammes

The whole is agitated for several minutes, in order to bring about perfect dissolution and mixture of the bichromate.

A glass plate, such as is used for obtaining gelatine moulds, is rubbed over lightly with a little ox-gall: it is then coated with the sensitive mixture by passing it over a very fine wire sieve covered with a piece of fine cambric, the superfluous material being poured off and the plate allowed to dry horizontally. Five or six hours are required to dry the film when placed in a room heated to 20 degrees Cent. When dry, the plate is coated in the ordinary manner with thin normal collodion, and, five or ten minutes afterwards, when this has set perfectly hard, a second coating of thick collodion, made up according to the following formula, is placed upon it:—

Ether ... ..	100 grammes
Alcohol... ..	100 "
Gun-cotton ... ..	2 to 6 "
Castor oil ... ..	4 "

The castor oil is an indispensable constituent of this collodion, for upon it depends the whole value of the process. It imparts suppleness and strength to the collodion, and prevents the latter from becoming shrivelled. From some cause or other, for which no chemical reason can be assigned, it is found that if the castor oil penetrates into the sensitive material, the employment of repeated applications of boiling water is necessary for washing and developing the picture. It is on this account that a thin film of collodion mixed with castor oil is first applied as a preservative to the sensitive material.

To avoid the employment of two films of collodion, the coating of thick castor oil collodion may first be applied and allowed to dry, and then the sensitive mixture superposed: in this case no fear need be entertained of the castor oil doing any harm, but great care must be taken to employ glass plates of the most even and uniform description, placed upon a perfectly level surface, so that the film of collodion is of the same thickness throughout. An irregular coating of collodion will militate against the perfect removal of the film, which refuses to leave the plate in those parts where the material has been insufficiently applied.

Either of these methods may be followed, according to the description of pictures that are desired. The first is applicable to the production of prints required on a thin film destined to be mounted upon cardboard or upon glass, or of dull unglazed pictures, in which case the film of collodion is dissolved away, in order to remove the brilliant surface. This is best done by mounting the print, when it is thoroughly dry, upon cardboard or glass, and dipping it into a solution containing alcohol and ether in equal proportions. The pellicle of collodion is dissolved, and the print remains adherent to the cardboard or glass: the operation must, however, be closely watched, in order that the print is removed as soon as the collodion disappears, as a prolonged sojourn of the photographic image in the alcohol and ether has the effect of detaching the picture from its support. The ether and alcohol in which the collodion has been re-dissolved may be subsequently used for the manufacture of collodion by adding thereto a certain quantity of gun-cotton.

The second mode of operating is useful for obtaining prints upon a thick film of collodion, which are to be used unmounted without any support, and for preparing fabric for photographic purposes. The fabric is prepared as follows:—A piece of fine linen or cotton cambric is moistened with alcohol, stretched upon a glass plate, and pressed by means of a roller, to expel the air-bubbles. When it has been well pressed against the glass, it is covered with a film of castor oil collodion, and allowed to dry. The sensitive carbon mixture is next applied, and, when this is per-

fectly desiccated, the whole is removed from the glass plate.\* This prepared fabric is very suitable for photo-paintings and for enlargements; for the latter purpose photographers will find it especially applicable, as being very economical in its employment, and successful and permanent in its results.

It has been stated that the carbon process is less costly than the ordinary silver process. This statement is easily proved by giving the cost price of the sheets of *collodion-cuir* and prepared fabric as manufactured and sold at the author's establishment. A sheet of prepared carbon paper ready for manipulation in the pressure frame or upon the screen for enlargements, which is sold for rather more than three shillings, costs from one shilling to fifteen pence to prepare, according to the thickness of the collodion film.

But to proceed with the process. As soon as the sensitive film has been prepared, as has been described, upon a thin transparent pellicle, the sheet is placed under the negative, taking care that the collodionized surface is put in contact with the cliché. After a sufficient exposure, which varies according to the intensity of the light, but which is always much less than that required in the ordinary silver process, the print is placed in a bath of warm water in a dark room, and afterwards dried and mounted.

One of the principal features of the process is the possibility of imparting to the *collodion-cuir*, if necessary, the dull opaque appearance of ground glass, by means of which the necessity of backing is dispensed with in stereoscopic slides and pictures of that description. The specimens exhibited by the author sufficiently showed the value of this modification. The unglazed surface of the film allows of painting and retouching of every description, and no glass mounting being required for transparent photographs, their weight and expense are much diminished.

The author accompanied his remarks by a practical demonstration of the process. He applied the sensitive material to the surface of a plate; detached another film prepared some time beforehand, and developed in warm water three prints, of which two were stereoscopic on dull collodion, and the third a large transparency. The experiments were exceedingly successful, and were watched with great interest.

## ON THE PRESERVATION OF COLLODIONIZED PLATES IN A MOIST CONDITION.

BY GENERAL MONGIN.†

At the special request of a member of the Society, I have much pleasure in communicating the details of a method, recently employed by myself, of working with wet plates which had been preserved and exposed to the vicissitudes of travelling in a grooved box constructed for the purpose. The process (if process it can be called) is based upon the fact that if a plate coated with collodion in a certain manner, which I will hereafter indicate, be carefully washed after its exit from the sensitizing bath, and afterwards placed in a bath of pure water sheltered from the light, the collodion will remain perfectly adherent to the glass, provided the water surrounding it is not violently disturbed; moreover, the prepared plates lose but very little of their sensitiveness in this condition. In making this statement I must frankly admit that I cannot speak for certainty of a longer period than ten days, as I have myself never kept plates for a longer time; the only thing to be observed in working the process is to add to the developer a few drops of nitrate of silver solution to replace that removed in the operation of washing.

### The Collodion and Silver Bath.

First of all it is necessary for me to state that when speaking of the employment of water, I always mean rain-water;

\* We are at a loss to understand how the linen prepared in this manner is to be printed, as the treatment with alcohol would scarcely render the fabric transparent.—ED. P. N.

† Read before the French Photographic Society.

not but what ordinary water would no doubt give similar results to those I have obtained, only I have never experimented with it. Next with regard to collodion. The material I use is that iodized and bromized with cadmium salts only, and sensitized in a bath prepared with re-crystallized nitrate of silver, and not containing even a trace of any other metallic salts than those of silver and cadmium; that is to say, the bath should be one that has never been employed for sensitizing collodion of any other description than the one I have indicated, for otherwise it would most likely contain small quantities of nitrate of potash, ammonia, &c., derived from other collodions. If this matter is not strictly cared for the process will be unattended by success, as the plates will become fogged at the moment of development, or be otherwise rendered unserviceable.

#### *Cleaning and Coating the Plates.*

The plates are cleaned and coated with collodion in the ordinary manner, but care should be taken in this, as in all other processes, to collodionize the plates in a room of the same temperature as that in which they were cleaned, otherwise a deposition of moisture, imperceptible to the eye, may be formed, which prevents the adherence of the film.

#### *Washing the Sensitized Plates.*

The plates are sensitized in the regular way, and, on leaving the bath, carefully washed. This is done by holding the plate at one of the corners, and allowing a small jet of water from a wash-bottle to play over the back and front of it; it is then passed carefully into two or three baths of pure water in succession, remaining a few minutes in each, and finally placed in the grooves of the water-box. This box should previously have been put into its bucket, or outside covering, which is filled with water to within an inch or two of the top. To introduce the plate into the box, the collodion face should be turned towards the bevelled part of the groove, and so manipulated with the hand that the surface of collodion does not become injured at the edges; the same precaution is necessary in withdrawing the plates from the box.

The water baths will serve for the preparation of twelve or fifteen plates before they require to be renewed.

#### *Carriage of the Plates.*

The plates are now ready for use, and, when the lid of the water-box has been closed, and the cover of the bucket containing it adjusted, they may be transported without the least inconvenience. The fluctuation of the water in the bucket, caused by movement during transit, is broken against the sides of the box, and is not transmitted, therefore, to the interior, and the plates are thus kept immersed in a liquid in a state of perfect repose. I have contemplated the feasibility of replacing the water in the bucket by an accelerative bath, either of nitrate of silver or tannin, or some such substance, but as my process is merely for landscape work, there would be no advantage in a proceeding of that description; besides, the employment of tannin, or of any material susceptible of fermentation, would bring about mildew, and possibly give rise to other evils.

#### *Exposure.*

In operating, I first fix my camera in the proper position, and then focus my picture. When this has been done I place myself in the dark, and withdraw one of the plates from the box. Everybody has his own peculiar style of dark tent; mine is simply a bag of dark stuff rather more than a yard in diameter, which I pull over my head, kneeling down in such a manner that the sides touch the ground in every part. By the aid of a light furnished with a yellow shade I am then able to perform my operations as well as in a laboratory. The exposure required for plates of this description is about two or three times that necessary for ordinary wet plates; four times the ordinary exposure may even be given, as the plates, being free from nitrate of silver, rarely evince symptoms of over-exposure. After withdraw-

ing the plate from the camera it should be returned to the box with the same precaution as before, the development being effected on the return home, either on the same evening or on the morrow.

#### *Development.*

The operation of development requires the most careful attention, a strict adherence to the following rules being necessary to prevent the formation of stains and markings, which are otherwise often obtainable in this method of working. I prepare, first of all, two solutions compounded as follows:—

No. 1.—Nitrate of silver	...	...	4 grammes
Citric acid	...	...	4
Water	...	...	100 cub. cents.

This solution will keep good for an indefinite period. A white crystalline deposit will be formed at the end of two or three days, but this may be allowed to remain at the bottom of the bottle, as it exerts no influence upon the liquid.

No. 2.—Pyrogallie acid	...	...	15 grammes
Alcohol	...	...	100 cub. cents.

The acid is dissolved in the alcohol, and the solution filtered. This liquid may also be kept for a considerable period.

#### *Pyrogallie Acid Bath.*

This is very easily prepared from No. 2 solution. Ten cub. cents. of the latter, and a like quantity of acetic acid, are added to 200 or 250 cub. cents. of water, and the whole well shaken. It will keep in good condition for a fortnight or three weeks.

The operation of developing is conducted in the following manner:—Two small glass vessels are taken, and into one of them (which we will designate No. 1) are poured a few drops of the No. 1 solution. The other vessel (No. 2) is then filled with liquid from the pyrogallie acid bath, a proportion of the latter being afterwards transferred to No. 1 vessel. The negative is carefully withdrawn from the box,\* and covered with the pyrogallie acid solution contained in No. 2 vessel; this operation is indispensable to the production of clear negatives. Subsequently the liquid in No. 1 vessel is applied, and the development proceeded with in the ordinary manner.

The image is sometimes three or four minutes before it becomes visible, but when once apparent it develops with great regularity. When the operation has been carried sufficiently far, the plate is carefully washed by means of a wash-bottle, and fixed with cyanide of potassium. The subsequent manipulations require no special description, and are carried out in the ordinary manner.

#### REMARKS UPON THE WET COLLODION PROCESS.

BY MR. MCLACHLAN.†

THERE is now the silver bath, upon the proper preparation of which everything depends; it is, in fact, the foundation of the whole process, to prepare which, obtain, if possible, a rather dirty-bluish-looking crystal, transparent, and quite neutral; dissolved in distilled water, it deposits whatever is mechanically held in the crystals, and is afterwards quite clear in solution. I believe it to be the most neutral of any, and the only kind free from nitrite or acid; this silver is best for any bath, especially after a day's sunning in concentrated solution; there is no other which gives the same firm pictures for such a long time.

This silver can be obtained from Johnson and Son. To prepare the bath, take 1 oz. of the silver described to 1 oz. distilled water, place whatever quantity you prepare in the open light—the most actinic part of the year is the best, say from May to the end of July; this length of time is quite long enough, even with Manchester light. This silver, by lengthened exposure to light, has the power of dissolving and keeping in solution a great quantity of oxide of silver; from some experiments I am now making I think the stopper should be very loose in the bottle.

\* The hands should be perfectly clean when manipulating with the plates in the box.

† Continued from p. 247.

It is very likely the change might be quicker brought about if the silver was dissolved in a greater quantity of water. After sunning, filter; then take a solution of caustic potass, strength 1 grain to 1 oz. water; add one drop of this to every ounce of silver in strong solution; more potass than this will take away, to a certain extent, that perfect modeling that is peculiar to this bath, and no other; allow the potass to remain in the concentrated solution from one to three days, of course not in the light. Now, for every ounce of silver take two or three drops of the strong solution in a glass measure, in another measure dissolve 2 grains iodide of potassium in a few drops of water; add to measure No. 1, stir and wash well; add this iodide of silver, which will have a slightly green appearance, to strong solution (this is 2 grains to every ounce silver); let this rest about an hour, then add distilled water, to make up to 35 grains to ounce; this addition of water will not precipitate any iodide, that is if the silver in the first instance has been sunned enough; if not there will be more or less precipitate, according to the effect the light has had upon the silver: this never happens when the silver is sunned three months, but will often in a shorter time. When it does, sun again for a day or two, and filter. Remember, the bath is not in a proper condition unless it keeps quite clear when the water is added. After a few days in the fully sunned bath, the great excess of iodide will be suddenly precipitated, still leaving the solution clear; filter this out, and never after does this bath want anything doing to it, whatever the quantity may be, and however long in use; much water could now be added to it without causing the slightest precipitate. A bath that keeps clear has the power of dissolving and keeping in solution a much greater quantity of oxide of silver than the one that the precipitate is from. It is this quality that gives it its value, and is the foundation of the whole process; without it you cannot neutralize your collodion; for with a bath that goes milky you are liable to get the plates fogged; indeed you most certainly will, after a few trials. The other takes away the possibility of this, because of its power instantly to dissolve any alkalinity. This is its great virtue, and keeps everything right; the quality of the picture is maintained for a very long time, quite out of all proportion to any other bath that can possibly be made. Want of quality will at last arise from this power becoming partly exhausted, but it is never wholly so. In this state the iron should give an excess of half-tone; the drop of weak potass is added to the strong solution for two reasons—first, to neutralize any free acid that might not have been detected in the silver; secondly, to give it a faintly alkaline reaction, so as to cause the collodion to harmonize with it when rectified with the potass. If transparencies are wanted, sun until you get the density wanted. They will be absolutely perfect in half-tone and clearness. After once obtaining silver in the proper condition, a drachm, or even one drop of it, can be tested with a weak standard solution of potash; the amount dissolved will be a guide for preparing it in the same state at any other time, although three months makes a bath that will allow any number of plates to be taken in it without breaking down in any way, nothing exhausting it but the silver becoming so low as not to cover the plate. It may be used every day, never gets in the least greasy when the collodion is properly tempered to it; in fact, you can never injure it by the ether and alcohol from the plates. A few days' very actinic light will give you a very good bath, but not to be compared to the first. Every kind of silver that I have obtained, however pure so far as appearance and guarantee is concerned, is acted upon by light at any time of the year, to a certain extent. I am quite sure that the condition of the silver is everything; for instance, if you take the same neutral silver-salt, dissolve 6 oz. in 6 oz. distilled water, and drop into it one drop of weak potass solution, you take from it, to a great extent, the power of exchanging in light; every drop added makes it less changeable. Pictures taken with this silver want firmness; the bath breaks down immediately. If nitric acid is added, even the thousandth part of a drop, there will be greasiness in development; the more acid, the worse the bath becomes, for no developer will lie even on the plate. After the acid, the pictures, as long as you can get any, will be very soft; before the addition of acid, and according to the amount of potash, they would want half-tone, though they will be quite clear.

Now take another silver that has an opaque look, and that you suspect to incline to alkalinity; drop into the 6-ounce silver as before (say) two drops weak nitric acid of the strength of 1 drachm to 6 ounces of water; place this in the light; but

first test if it is neutral; and although it appears so to test-paper after sunning, test again, and you will find an acid reaction, the light in some way developing the acid, or, at any rate, causing it to indicate its presence, while before it was disguised. A bath made from silver in this state would give streaky pictures, and would not be acted upon so quickly by the light; by this you will see the silver should be quite neutral without any addition to make it so, unless pure oxide of silver would answer to neutralize any acidity; this I have not tried. What causes greasiness in a bath is not the accumulation of alcohol and ether, for a new bath will often be found in this state, and ought to be sufficient to prove this. The true cause is a certain amount of acid—alkaline base and alcohol—forming a kind of fusel oil, so that you will see to work this bath it is essential that no free acid shall be allowed to be in it, more especially that kind of acid which arises from pyroxyline, which is made by an excess of sulphuric acid. It is this peculiar acid which causes streaks in the direction of the dip, brain markings, &c.; spots arise, but not always, from the solvents being too strong. This kind of collodion is the best, nevertheless, for the present method of working. Most defects are easily remedied by the weak potash solution. I like the collodion, in the first instance, to be pretty deep in colour, not old. I use Mawson's. When very bad, the best way is to make the collodion slightly alkaline; take 2 drachms, or thereabouts, of another old collodion free from these imperfections, and add 6 oz. of the alkaline kind; this is almost certain to put things right. Hardness and other imperfections cannot now be entered into; any neutral collodion that gives good pictures will do for my bath. I cannot give a better practical illustration of the cause of greasiness in the ordinary nitrate bath than the experiment with the iron solution; for the alcohol and water never become homogeneous in the iron until the alcohol is made slightly alkaline.

It is advisable when the nitrate bath has been long in work, and the picture is inclining to be hard, to expose well, redevelop, but very little, with the iron in the dark room, finish with pyro in the light—2 grains to 15 drops glacial acid; this gives more brilliancy under such circumstances. Baths that are old have another peculiarity. Suppose you were to apply a developer at 70 deg. temperature, you would get hardly any picture, and a fogged plate; the amount of alkaline base in the bath seems to decompose the developer; fix with cyanide or hypo; wash very well. There are more negatives spoiled through careless washing than is supposed.

I believe the action on silver might be much hastened by placing it in shallow dishes or cells, and concentrating light upon it by reflectors or lenses. I have an idea that it might be charged at once with perfectly pure oxygen or ozone, for I believe it is oxygen changed by light, and absorbed by the silver, that is the cause of its peculiar condition. Silver in this state answers much better for the printing-bath, keeping clear much longer, and giving more brilliant prints; and as it has the power of holding oxide of silver in solution, all acidity can be effectually destroyed, which leads me to hope much from it as a means of preventing prints from fading, especially if they were allowed to remain a short time in a very weak solution of caustic potass dissolved in alcohol.

If a definite crystal of silver was chosen, it would act as an actinometer for measuring the amount of actinism in light of different colours. Very long exposure would be necessary in deep yellow, red, or blue dishes; the amount of actinism all over the world might be registered: as a certain exposure to light will only dissolve a certain quantity of potash, a scale could easily be graduated to indicate the differences between one quarter of the year and another. My theory of the latent image is, that the iodide is oxidized; I could bring many proofs to support this.

Remarks upon what is to be most attended to in working this process.—Be sure the collodion is neutral, for as long as you keep out acidity the bath will never get greasy, nor even want filtering, unless from pieces of collodion falling into it. Never try a new collodion in this bath, use an old one for this purpose, and never add any silver to it unless it is of the same kind. For baths partially sunned, take a 6-ounce bottle, place in it about 3 drachms old collodion free from imperfections, fill up with the neutralized or slightly-alkaline collodion; this should leave it about a sherry-colour. A bath used with collodion in this state will want sunning often, and filtering often, from the acidity of the collodion causing a precipitate of iodide of silver. This happens more to a sunned bath than any other. What-

ever you do, keep out nitric acid, or you will certainly have plates that the developer will not lay upon. There are other peculiarities belonging to a partially sunned bath that would take too long to describe.

To reintensify, take 7 grains iron, 14 grains citric acid, to 1 oz. water; make several Winchester quarts of this, as the longer it is kept the better it gets, and is not in good condition for at least two months. To each Winchester add 3 drachms glacial acid; weaker iron makes the picture whiter in the face, stronger, greyer, and develops more. Here again the different kinds of iron give different results. The iron that remains clear a long time when dissolved gives the strongest picture, that which dissolves the most milky gives the most half-tone suitable for a very hard collodion.

There is a pyroxyline that will act the same part in the collodion that the sunned bath does in dissolving oxide of silver. I expect soon to accomplish this by exposing certain kinds to light in different ways. I had prepared everything for these experiments last year, but was so exhausted by continual experimental testing of what I had accomplished, that I was afraid to begin a series of experiments, that would require an almost endless proving, between bath, collodion, and developer. To prove with certainty a success, even if obtained, when I accomplish this my original idea, then it will be impossible to fail but by gross carelessness. Until this is done, the process will be imperfect, as I consider doctored collodion and all others only temporary experiments. With a collodion made from such gun cotton and my bath, you will not be able to obtain any iodide of silver but the proper kind. At present this is not so. The rapidity will be something extraordinary, as I know from the few successes I have obtained. To accomplish this has been the object of all my aims, and I have failed; but it has been to me the hidden treasure, and has given me an experience that could not possibly be obtained otherwise. From these experiments I have learned that bromides are injurious in making a perfect collodion, and that they are not necessarily more sensitive to coloured light than the iodides; in fact, they are highly injurious for perfect working.

Understand distinctly that I am only giving the natural action of each chemical; for it must not be expected that an iron, the character of which is to give soft pictures, will do this when the collodion has not the quality of giving half-tone; but it will favour it all that is possible. If the collodion is tame, the iron that dissolves and keeps clear, and gives a vigorous picture, can only help it; but it will never do the work of the collodion; what is wanted is harmony; and if this is not attained, no chemicals, however perfect, are of any avail in giving constant success. Success depends much more upon the condition or state of chemicals than their perfect purity. I know of no chemicals, however pure, that can be obtained with any certainty twice alike; their conditions are different; and unless this is taken into account, there cannot be certainty of results. I have nine different bottles of silver in the light. There are three distinct kinds, three bottles for each; one of each kind with saturated solution, another with twice the amount of water, the third with three times as much. I mean to put out more silver differently prepared, so as to make sure of the best method of preparing it.

This paper will not allow me to say enough of collodion to be of much value. I have not gone deeply into any part of the process, as I think the information wanted can be best brought out in discussion. The majority of facts here stated were known to me many years ago; my difficulty was to harmonize them.

Well knowing the odium that must fall upon me should I fail to accomplish all I say, I have put the whole to the test in daily practice for two and a half years, and I again assert that I am not only willing, but most anxious, to be put to the proof, as no argument will ever decide anything. This I expect will be done by the London Photographic Society. This is not the time to state how much I have sacrificed to obtain this knowledge, nor the motives that bear me up against an opposition that I felt certain I should have to encounter. I trust it will be admitted that I have so far performed all that I promised; and I have not accomplished this much without an expense that should at least place me above suspicion. I ought to know my business; for I believe there are few, if any, in Europe who have had the same amount of experimental practice; and for any one to assert that the common process is at all like mine, or could be made with any amount of skill to give a continued certainty and quality that I state mine will, is a great mistake.

## Proceedings of Societies.

### LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Association was held on Tuesday evening, the 26th inst., at the Free Public Library, William Brown Street, the President, Rev. G. J. BANNER, in the chair.

The minutes of the previous meeting having been read and confirmed,

Mr. FORREST laid on the table a number of pictures taken lately at Bettws-y-Coed, upon plates prepared by the Liverpool Dry-Plate Company, and stated that out of the whole number he had exposed he had not had a single failure. The development was effected by means of a weak solution of ammonia applied to the plate for a longer time than usual.

An animated discussion arose as to the relative advantages of weak and strong ammonia for developing, Mr. Mawdsley advocating a rather strong solution, and other members upholding the weak.

Mr. HUGHES said he had exposed a plate at Eaton Hall, the image upon which was perfectly visible before development.

Mr. MAWDSLEY said that it was a very frequent occurrence with over-exposed plates. He said he had noticed it in a marked degree upon a plate he had exposed for an interior when the window was well out, before developing.

Mr. GREEN remarked that since collodio-bromide had come into use very little was heard of comets.

Mr. MAWDSLEY said he had never, with collodio-bromide, met with a single instance of the old tannin spot, round, and transparent, with a black nucleus.

Mr. FORREST exhibited a piece of glass which had been exposed to light for over three years in the window of a church, part of it covered with paint, and pointed out the marked change which had taken place in the colour of the exposed part, it having acquired a decided pink tone. After explaining the cause of the change of colour, he touched upon the importance of having photographic lenses, especially those exposed to a concentrated light in enlarging, free from any cause of change of colour.

Mr. HUGHES said he had a pair of portrait lenses by Ross, one of which had been much used for enlarging, but no change had taken place in its colour, as it worked as rapidly as the other, which had never served that purpose.

Mr. WHARMBY said the change of colour in photographic lenses was generally attributed to the Canada balsam used in mounting them.

The PRESIDENT said he had great pleasure in announcing that Mr. Green had offered two more of his large photographs to the Society to be disposed of as follows:—One to be presented to Mr. Sayce in recognition of his efforts in perfecting the collodio-bromide process; the other to be given as a prize for the best collection of twelve stereo pictures, to be exhibited at the July meeting.

The cordial thanks of the meeting having been tendered to Mr. Green,

Mr. HUGHES made some remarks upon "Enlarging." He said he had brought all his apparatus with him for the purpose of practically illustrating the enlargement of microscopic objects, but owing to his inability to procure a dark room he was unable to do so. He, however, exhibited his apparatus, and explained the method of applying it, calling particular attention to the fact that the focussing was done upon the surface of a piece of white cardboard instead of through ground glass.

A discussion arose upon the subject of ground glass, &c., for focussing, and Mr. FORREST promised to show at the next meeting a specimen of a new sort of dull glass, which he thought was just the thing required for fine focussing.

A vote of thanks having been passed to Mr. Hughes, the second excursion was discussed, and it was decided to go to Llangollen on the 22nd of June, the President kindly inviting the members to dine with him upon that occasion.

## Correspondence.

## SEL CLEMENT.

DEAR SIR,—It is a very easy matter (but deserving protest which I offer), to attribute to an adversary absurd allegations. Where did the "Analyst," in your pages, find that I pretended to classify hydrochloric or nitric acid in the organic chemistry, because they contain hydrogen or nitrogen? That suggestion can be, without difficulty, returned against himself. Is carbonic acid or oxide of carbon classified amongst organic bodies, because containing carbon—*matter sine qua non* (as he said) in every organic substance?

Carbon is not the exclusive matter constituting those kinds of bodies; hydrogen or nitrogen (as I say), often both (oxygen, of course, frequently), are necessary, in simultaneous presence with the carbon, for building every organic matter. All chemists and all authors are unanimous in that doctrine. Also I said, and again repeat, the apparatus was not properly arranged for demonstrating the presence of organic principles.

Because the "Analyst" obtained a precipitate of carbonate of lime with a piece of sugar, and did not succeed the same with the Clement Salt, he concludes to a deficiency of carbon! I there stop him. He supposes, then, the analysis of nitrates (containing some other reagents) must be conducted by the same way as the analysis of a piece of sugar. I must exclaim there, as he does: "Impossible!"

Did the learned gentleman not know that alcohol, ether, spirit of wood, acetic acid, &c., will go through his apparatus without being decomposed and without precipitating lime water? Nevertheless, the above-mentioned matters are certainly organic, and doubtless very rich in carbon. Meanwhile, starch, gums, resins, sugar especially, will be suddenly, on the contrary, decomposed, and give the characteristic precipitate in lime water, but characteristic only with those kinds of substances.

Now, being complaisant as possible, I will admit the heat was sufficiently strong in the combustion tube to decompose the Clement Salt in its immediate principles. Then I must repeat what I have stated in my last letter:—

"The nitrous red fumes have probably altered the little quantity of carbonic acid present in a nascent state, because the free oxygen taken partially for the oxidation of the carbon had found sufficient quantity of hydrogen to produce water." In the present case, where is the supposed oxidizing atmosphere? What will disturb, also, the reconstitution of the hyponitrous acid in nitric acid, taking one equivalent of oxygen from the nascent carbonic acid, and showing consequently oxide of carbon? Every day, and in every furnace or closed apparatus, we notice that phenomenon; viz., production of oxide of carbon at the expense of the carbonic acid by deficiency of oxygen. And what will be the matter with the nitrogen, laying aside that included in the nitrates, if some proportion of the Clement Salt? It will certainly be acid of oxygen.

In my special case I am compelled to declare the apparatus was not well adapted for a public analysis, the tendency of which was evidently, if not willingly, to pull down my recent industry, and which was presented as a challenge to the manufacturer of the Sel Clement. For such serious matters something more correct, something fulfilling better the purpose, must be presented, I think, to the scientific readers. Whatever remains of the chemical lesson given by the "Analyst" to the maker of Sel Clement, only his final assertion: "The nitrate of magnesia and a great amount of water are the essential compounds of Sel Clement." "It is virtually conceded," he said. Where has the "Analyst" read such a concession? I wrote in my last letter that part of the magnesia was very exaggerated in the newspapers. I can easily offer the proof of it, sending to him a salt producing exactly the same effects as the Clement Salt, and containing only 2 per cent. of nitrate of magnesia. With regard to the water, the Sel Clement contains strictly its water of constitution, and the proof of it, easy to verify, is its quick decomposition, drying it more on the fire.

Dear sir, some other matters, till now not discovered, are present in the Clement Salt. Those matters—organic, of course—losing reductive power with the silver salt when dissolved in certain reagents—although in a very minute proportion—are not the less important in the mentioned product.

In the same number of your estimable Journal in which I found the letter of the "Analyst," you have a striking example

of such phenomena. The first paragraph of "Talk in the Studio," entitled "Sugar in the Printing Bath," records a curious fact of an organic substance losing its reductive power, although in contact with nitrate of silver, in despite of scientific assertions. Adding some alcohol—organic and carbonic matter—the same phenomena persist.

Let me conclude in few words. The public certainly will be indifferent to a more prolonged doctrinal discussion, which I have not sought, and which obliged me to be disagreeable to the "Analyst," defending my right and my industry. Amidst all that noise and such contradictions, the direct and personal experiment of the photographers will be the only right and true criterion of the economical and technical properties of the Clement Salt. To the photographers I commit my product, if, as I hope, its French origin shall not be a stigma of reprobation amongst the employers of Rivo's albuminized paper. Chemistry is, like all sciences, a cosmopolitan one, without native soil.

THE MAKER OF THE SEL CLEMENT.

Paris, 13th May, 1868.

## INJURY TO NEGATIVES BY VARNISHING.

DEAR SIR,—There is one little piece of manipulation which may possibly be of service to some beginners in photography. Some year or two since, when varnishing my negatives, I was very frequently troubled with the varnish causing the dense parts of the negative to become extremely coarse and granular. Under a microscope, the appearance was as if the density was broken up and gathered together in granules, large and small. The consequent picture was very coarse indeed, and thoroughly unsatisfactory. Various samples of varnish brought the same disaster, and I was compelled to take to an aqueous solution of gum arabic to get the film to give me a passable positive. I at the time intensified with pyro, citric acid, and silver, preceded by the solution of iodine and iodide of potassium.

I am quite satisfied that using too much silver is one cause of this coarse deposit; but I have reason to believe there are others, as it has occurred when no excess of silver was used.

This continued for some time, and I could get no cure for the evil, when one day I attempted to intensify further a negative rather weak, with a varnish which contained a small portion of tincture of iodine, recommended by Mr. Jabez Hughes. Much to my surprise and delight, on the application of this, the negative resumed its normal state; the coarseness disappeared; and since then I have never failed in curing this evil by a similar application. The negative will, of course, be slightly further intensified by the treatment, which may, or may not, be a benefit; but I was glad to get rid of the coarse deposit at all cost.

Any one troubled with the annoyance, may safely try this remedy; it will not harm his negative much, if it should not cure.

As I have very often indeed been greatly benefitted by sundry hints in the pages of the News, I owe it to mention this, as I do not remember having seen it stated anywhere.—I remain yours, &c.,

KENT.

May 19th, 1868.

## Talk in the Studio.

ACTINISM versus ILLUMINATION.—A curious illustration of the distinction between the actinic and the luminous quality of light recently brought under our attention by Mr. Rejlander. A few days ago he was producing a portrait in the open air, a little after seven in the evening. The setting sun, low on the horizon, illuminated all objects on which it shone with a yellow glow; whilst the opposite arch of the sky was bright clear and blue. On examining the sun-illuminated image on the ground glass, Mr. Rejlander was struck with the fact that the side which was practically in shadow was much more actinic in colour, and expressed a conviction that the side of the face on which the sun shone would, in the picture, be the darkest side, and the opposite and apparently shaded side the lightest. Singularly enough, such was the result, and a print of a very fine portrait, now before us, illustrates the odd phenomenon of sunlight being represented by shadow, and reflected light producing the actual lights of the picture. We have seen clever paintings of candle-light effects, in which one half of a face is brilliantly lighted by a candle or lamp, the other relieved from

perfect blackness by the bluish grey light of the moon, or of twilight through a window. Such pictures would in photographic reproduction probably yield a result as we have mentioned; but it is very rare that a scene in nature would be so represented.

**SALE OF POISONS.**—A Bill has recently been laid before the House of Lords by Lord Granville which may possibly affect all dealers in photographic chemicals. It proposes to enact that after the 31st of December, 1868, no persons shall keep open shop for retailing, dispensing, or compounding poisons, or use the title "chymist" or "druggist," unless he is a pharmaceutical chymist, or was before that date in business as a chymist and druggist keeping open shop for compounding prescriptions, or has for two years before the passing of this Act been apprenticed to a chymist and druggist, or at the time of passing this Act, being of full age, has been actually engaged in compounding prescriptions as an assistant. An annual register of qualified persons is to be issued. Poisons are to be distinctly labelled. The Bill, as at present proposed, is not to extend to wholesale houses, or to sales for use in photography, or to patent medicine vendors, or to qualified medical practitioners or veterinary surgeons. Chymists and druggists are not to be liable to serve on juries. The following are to be declared poisons:—Arsenic and its preparations, oxalic acid, prussic acid, chloroform, cyanides of potassium and mercury, strychnine, and all poisonous vegetable alkaloids and their salts, aconite and its preparations, emetic tartar, corrosive sublimate, belladonna and its preparations, essential oil of almonds, unless deprived of its prussic acid, cantharides, and savin and its oil. Those interested should keep an eye on the matter to see that clauses are not introduced, in the passage of the Bill, which may curtail the proper trade facilities in vending various chemicals.

**INFLUENCE OF THE SHAPE OF THE APERTURE IN STOPS.**—Mr. Rejlander has recently brought under our attention a very curious illustration of the influence of the shape of the aperture in the stop employed with a lens. The picture is a pretty open air group, with trees in the background. Photographers will have noticed that the light passing through the apertures of foliage which is out of focus assumes the form of numerous white discs. In the case in question a square aperture was used instead of the circular hole commonly employed, and here the light spaces between the foliage which is out of focus consist of so many square white patches instead of the usual white discs.

**ROYAL SOCIETY OF MEDICAL AND NATURAL SCIENCES OF BRUSSELS.**—The chemical prize of this Society has just been awarded to an Englishman, Dr. T. L. Phipson, F.C.S., of London, for a paper "On the Application of certain Optical Properties of Bodies to Chemical Analysis." Dr. Phipson's name is known to our readers as a frequent contributor on the chemistry of photography.

**RE DISDERI AND COMPANY.**—An application was made a few days ago, before Vice-Chancellor Sir R. Malins, for the appointment of a provisional liquidator under the 80th section of the Companies' Act and the general orders. Mr. Disderi, having establishments in Paris and Spain for the carrying on a superior photographic process, had endeavoured to form a company in this country, but without success. The seven shareholders and directors had paid nothing, and creditors were suing Mr. Disderi. Under these circumstances he had presented a petition himself, and now asked *ex parte* for the appointment of Mr. George Augustus Cape, the well-known accountant, to be appointed liquidator until the hearing of the petition. The Vice-Chancellor made the order.

**INDECENT PHOTOGRAPHS.**—On Tuesday, at Bow Street, John Dukes was charged with selling indecent photographs. The prosecution was conducted by Mr. Sleight, the barrister, instructed by Messrs. Pritchard and Coletto, solicitors to the Society for the Suppression of Vice. The "cartes" had been purchased by Willis, an agent of the society. The defendant said they were artist's photographs, and not indecent. Mr. Flowers said they were not so bad as many which, unfortunately, it had been the duty of the magistrates at this Court to deal with; still they were decidedly indecent, and it would be for a jury to say whether they believed that such productions could have been intended for the use of artists or for any innocent purpose whatever. He should commit the prisoner for trial. Sophia Dukes, wife of the last prisoner, was committed on

similar evidence for selling photographs decidedly more offensively indecent than those purchased from her husband. Mr. Abrams, who defended her, said she was acting under the direction of her husband, and on Mr. Sleight expressing his dissent, Mr. Abrams said the learned counsel would have taken that view if he had been acting for the defence. Both prisoners were bailed in two sureties of £20 each.

**COPYRIGHT IN PHOTOGRAPHS.**—*Strahan v. Graham*—Vice Chancellor's Courts, May 30.—In this case, the details of which will be within the memory of our readers, Mr. Strahan, the publisher of *Good Words*, purchased from Mr. Graham the right to engrave certain photographs of the Holy Land, to illustrate articles in *Good Words*. Mr. Strahan also published the engravings in a volume called "Eastward" in a separate form, and an injunction was obtained to restrain him. This order was appealed against, but confirmed on appeal. It appeared that 1,300 copies of the work had been sold, and it was referred to Chambers to ascertain the amount of damage sustained. The Chief Justice was of opinion that 2½ guineas was a fair sum to be allowed for each photograph. One party appealed against this view, and the other side moved to have the photographs delivered up. The Vice-Chancellor said the question ought never to have been raised, and dismissed both applications with costs.

**ELASTIC AND SWEET GLUE**, which does not spoil, is obtained as follows:—Good common glue is dissolved in water, on the water bath, and the water evaporated down to a mass of thick consistence, to which a quantity of glycerine, equal in weight with the glue, is added, after which the heating is continued until all the water has been driven off, when the mass is poured out into moulds, or on a marble slab. This mixture answers for stamps, printer's rolls, galvanoplastic copies, &c. The Sweet Glue, for ready use by moistening with the tongue, is made in the same way, substituting, however, the same quantity of powdered sugar for the glycerine.—*Druggists' Circular*.

**PHOTOGRAPHING THE INTERIOR OF A TUNNEL.**—Mr. Evans has presented to the New York Institute of Engineers a photograph of the high level tunnel of the Central Pacific Railroad. The east end of the tunnel being sometimes illuminated at sunrise, a large mirror was employed to reflect the sun's rays equally over the whole of the interior while the picture was being photographed. The plate having been exposed about fifteen minutes, a print was taken showing every detail, even to the timbering of the drifted headings, with great distinctness and accuracy.—*Scientific American*.

**SUICIDE WITH CYANIDE.**—A few days ago an inquest was held on the body of William Augustus Barnes. The deceased had been engaged at Drury Lane Theatre as pantaloons in a pantomime last Christmas, since which time he had taken to photography. A *post-mortem* examination of the body showed that death resulted from taking cyanide of potassium.

**ORNAMENTING WINDOWS IN STUDIOS.**—A correspondent of the *Scientific American* describes how he treated the window of his dark room, which communicated with his studio. He says: "Thinking I would make it ornamental, I procured a pint of stalo alo, four ounces of Epsom salts, and a small vial of magenta-coloured liquid. I then took out the window, and in its stead placed a large single pane. After mixing a saturate solution of the ale and salts, and adding the colour, I filtered the solution, then cleaned the glass with alcohol and cotton chemically clean, placed it on a levelling stand, and made a small ledge with putty around the edge, then poured on the solution enough to cover the plate evenly in all parts. In a few hours the crystals began to form around the edge, and in forty-eight hours it was all covered with the most beautiful crystals, of large size and of a rich purple colour. When it was perfectly dry I placed it in the window, where it remained all summer, and was the wonder and admiration of the curious. But when winter came, and the stove was put up close to it, it soon began to lose colour, and the crystals gradually dropped off."

**A WONDERFUL PHOTOGRAPHIC SECRET.**—A singular advertisement recently appeared in the *Times*, to which we give a gratuitous publicity in the circles where it may be interesting. We quote it verbatim: "The secret of different modifications of a photographic collodion wool, produced exceedingly cheap, by a new and easy proceeding, is to be sold, for a sum of £3,000. Certificate from the Russian Technical Society, and from the Photograph of the Imperial Court of St. Petersburg, as well

as specimens that will distinctly show the manner of proceeding, will be immediately forwarded upon the receipt of 3 rbls. Apply to the inventor (in the German language), by letter, post paid, addressed C., to the Central Office of Advertisements of Al. Wileken, in St. Petersburg, Wassili Ostroff, 5 line."

**PHOTOGRAPHY THE BEST DETECTIVE.**—The Viennese *Neue Freie Presse* relates the following respecting the capture of an Englishman, named Grey, who by means of forged cheques on the Union Bank of London swindled the house of Rosenbaum of a large amount of money. Through accident the said banker, Mr. Rosenbaum, became possessed of a photograph of the fugitive, and gave the same to the police inspector, Breitenfeld, at Vienna, who remitted it to Mr. Pollaky, an Austrian resident in London, who caused the necessary inquiries to be made in London, as it was supposed Grey made direct for England with his booty. Last week it happened, however, that Mr. Pollaky, on his way to Vienna, passed through Hamburg, and there visited the theatre, and during the *entre'acte* passed his time by inspecting the audience, when, to his great surprise and no less satisfaction, he discovered in one of the visitors the most striking resemblance to the photo sent to him some months ago from Vienna. Of course this man was at once closely watched, and a telegram despatched to Vienna; upon which the firm despatched their cashier, who recognised the swindler, although a great change in his appearance had taken place since his *debut* at Vienna. A large sum of money has been recovered, and Grey has since pleaded guilty to the charge, and has been sent to Vienna to be dealt with there according to the Austrian laws. Strange to say, this man, who assumed the nationality of an Englishman, is no Englishman after all, but a Frenchman by birth, and speaks English very imperfectly. About £7,000, with drafts to the amount of 30,000f., have been found on his arrest.

**MR. WARREN DE LA RUE'S PHOTOGRAPHS OF THE MOON.**—Our excellent contemporary the *Engineer*, of last week, has a most admirable and complete account of Mr. Warren de la Rue's photographic operations at Cranford Observatory, with capital and extensive illustrations. We shall have something more to say on the subject in our next; but we should counsel all our readers having any interest in this branch of our art to get last week's *Engineer* for preservation.

## To Correspondents.

**F. B.**—Hitherto no licence has been required by amateurs for working with Swan's carbon process, and, so far as we know, none will be required in future; but as the patent is passing into fresh hands, and its commercial application will receive energetic attention, we cannot with certainty detail the future arrangements. We believe that a common screw-press may be made available for effecting the transfer.

**AMATEUR.**—A weak solution of sulphide of potassium may be employed to intensify a negative after it has been suffered to dry; care must be taken, however, to moisten the film thoroughly first, otherwise there will be danger of uneven action of the intensifier. For the purpose you require, we should be disposed to try pyrogallie acid with a very slight trace of nitrate solution added.

**HENRY WILLIAMS.**—The flatness and want of modelling and texture in the card sent, and which constitute the chief difference between it and the productions of your Regent Street namesake, are mainly due to over-development or over-intensification. You have also a little too much top-light. The print sent would have been much better for deeper printing; but when a negative has had detail and texture buried in an excess of deposit, it is difficult, by any mode of printing, to secure the delicate soft texture of flesh in the print.

**C. A. M. W.**—It is difficult for us to form an opinion without seeing the negative, as to whether it will yield more brilliant prints than that you enclose; but we should think it very probable that it will. Pictorially, the negative is capital; the grouping and light and shade are very good; but the print certainly lacks vigour. Try a sample of Rive paper, use a 50-grain bath, print somewhat deeply, and tone with the lime bath. It is very probable that this mode of working will give you a print with more vigour and contrast. 2. A varnish made by dissolving shellac in wood naphtha or in methylated spirit will answer well for varnishing the perforated oak false bottom to your washing machine, and it will be all the

better for such treatment. It is difficult to estimate the length of time that will be required to wash prints thoroughly in such a machine. We should think that if the machine is suffered to fill and empty itself ten or twelve times, the prints would be well washed, especially if they receive a thorough washing for a quarter of an hour with rapid changes of water before placing in the machine; but we should prefer using some of the most delicate known tests for the presence of hypo to little of the water draining from a print supposed to be well washed. 3. The continuous dribbling of the syphon is probably due to insufficient pressure of water in the supply-pipes. Let the water enter with greater force, and also flatten the bend of the syphon. 4. The silver bath with sugar, recommended by Mr. Bovey, answers admirably for amateur purposes. The sulphocyanide bath gives excellent results of a special kind. You will best ascertain if they please you by trying. 5. The yellow varnish for dark-room windows was described in the *News* for 1864 and the *Year-Book* for 1865. It consists of equal parts of raw sienna and orange chrome No. 3, as sold in tubes by colourmen, diluted to a consistency for use with japanners' gold size and turpentine, with a little "patent driers" added.

**ARTHUR STRIDE.**—The yellowness and spots in the prints forwarded are probably due to imperfect fixation, although such a result might, in some cases, arise from leaving the print saturated with hypo. It is probable, however, that the prints were immersed in an old and exhausted hypo bath, and are imperfectly fixed. The prints enclosed in your letter seem to be perfectly fixed. 2. The lens in an English portrait combination are generally so fixed that you cannot very well place them wrong. In French lenses, which are not burnished into the cells, it is, however, possible to arrange them improperly. The front part of the combination is placed with the convex side outwards; in the back combination the bi-convex is placed in the cell first, the ring is placed in next, and then the meniscus, concave side towards the bi-convex lens. 3. We cannot recommend any very simple work on photographic chemistry. You will best find what you require by reading the various articles in our pages.

**W. J. A. G.**—For landscape work, such as the Scottish Highlands, decidedly No. 3; for architecture, No. 2. A plate of about  $6\frac{1}{2}$  by  $4\frac{1}{2}$  or 7 by 5 we should recommend.

**J. C. S.**—A monohydrated acid is the strongest form of the acid, and contains only one atom of water. Pure nitric acid, for instance, is a solid crystalline body; but the most concentrated available acid is the monohydrated, which has a specific gravity of about 1.500.

**AN ASPIRING ONE.**—The chief photographic fault in No. 1 is that the negative has been slightly under-exposed, and the print a little over-printed. In No. 2 the negative has been slightly over-intensified, which makes the face a little chalky. The light is too directly in front of the sitter to give relief; to secure the best effect of relief and modelling, you require a high side-light as the dominant light, with a little diffused light or reflected light to prevent hardness and blackness in the shadows. Your carpet is too decided in pattern, and gives a somewhat spotty effect. We shall have pleasure in helping you at any time.

**S. ARTIDGE.**—You have succeeded very well considering the difficulty of the task; but perfect success in such an undertaking, with such limited facilities, could scarcely have been expected.

**Wm. BARTHOLOMEW.**—We fear that much of the chaos to which you refer will remain after the most careful explanation. We do not know whether the magnesia toning bath is commonly used or not, but shall print your brief remarks thereon. Thanks.

**MR. W. H. WARNER**, of Ross, has favoured us with an example of a tinted mounting-board in which the anti-chlor is said to be quite neutralized. We shall test it carefully, and again refer to the subject.

**IGNORAMUS.**—We do not recommend making any portion of the northern roof opaque; but it might be well for summer use, at least, to make such portion of it as may permit the entrance of direct sunlight semi-opaque, by stippling with white paint or covering with tissue paper. The proposed projecting board would keep out direct sunlight in sunny weather, but would obstruct much light in dull weather. For the roof light, a series of blinds; for the side-light, curtains. 2. For intensifying before fixing, when necessary, iron and citric acid, with a little nitrate solution, is most convenient, and gives excellent results. Thanks in advance for the projected account of operations.

**ERRATUM.**—Through an inadvertence, the diagram in Winstanley's article on Artificial Light in our last was placed upside down.

**DINSDALE AND CO.**, and several Correspondents, in our next.

All Communications for the Editor to be addressed to 15, Gough Square, Fleet Street, London, E.C.

\* All photographs forwarded to the Publisher for registration receive attention at once; but the pressure on our space sometimes compels us to defer the acknowledgment in this column. It should be borne in mind, therefore, that non-acknowledgment at once does not necessarily imply non-receipt or non-registration.

### BROMIDES IN A COLLODION CONTAINING A POTASSIUM SALT.

ALL who have experimented in the manufacture of collodion are familiar with the difficulty of introducing any moderately large proportion of bromide into collodion in the presence of iodide of potassium. Bromide of potassium is so well known to be comparatively insoluble that, as a rule, no attempt is made to use it in collodion. Bromide of cadmium, being very soluble, is most frequently used; but a difficulty has generally been experienced, especially if the solvents employed were highly rectified, in using at the same time an iodide with a potassium base. A double decomposition has been found to take place, in which bromide of potassium has been formed and precipitated in the collodion.

Nevertheless, the use of a portion of iodide of potassium in conjunction with iodide and bromide of cadmium is often desirable. The potassium salt possesses advantages over other alkaline bases which make it a favourite with many photographers. Its presence in a collodion frequently secures intensity, brilliancy, and freedom from fog in degree greater than many of the iodides. The product of its decomposition in the silver bath—nitrate of potash—assists, by its deliquescent character, in the retention of moisture on the plate during long exposures, and checks the tendency to matt silver stains. The difficulty of using it with a full proportion of bromide has therefore often been a subject of regret with photographers.

Mr. Russell Manners Gordon informs us that as the result of some carefully conducted experiments he is able to introduce as much as two grains per ounce of bromide of cadmium into a collodion containing iodide of potassium without causing a precipitate. The proportion which can be added in the usual mode of mixing rarely exceeds half a grain per ounce. To secure the power we have just indicated a certain order of mixing must be carefully observed, the potassium salt being dissolved in water and the bromides in alcohol of 805 sp. gr. It will readily be seen that in adopting a method of this kind rigid accuracy is required to secure the exact condition in which, without adding too much water to the collodion, a sufficiently aqueous condition is maintained to keep the salts in solution. If the alcohol employed in collodion be much weaker than 820° the collodion will risk showing signs of reticulation; but if alcohol of this strength be employed in a direct manner for dissolving the salts, the bromide of potassium formed will generally be precipitated.

The first consideration, then, is to ascertain that the minimum quantity of water in which the potassium can be dissolved, and which, when mixed with the alcohol containing

cadmium salts, will keep the whole in solution, does not reduce the alcohol below the proper standard for making collodion without reticulation. Mr. Gordon has carefully worked out the conditions necessary. Commencing with alcohol commonly called absolute, but containing really a little over three per cent. of water, it will be found that the addition of water changes the specific gravity in the following ratio:—

To 1 ounce of alcohol	...	...	805 sp. gr.
5 minims of water added give	...	...	810 "
10 " " " " " "	...	...	817 "
20 " " " " " "	...	...	822 "

With these facts before him, which have been carefully verified by the aid of the specific gravity bottle, Mr. Gordon proceeds as follows:—

First prepare the normal collodion after the following formula:—

Ether, 725°	...	...	4 drachms
Alcohol, 805°	...	...	2 "
Soluble cotton	...	...	6 grains

Then proceed to prepare the iodizer, as follows:—

#### No. 1.

Iodide of cadmium	...	...	8 grains
Alcohol, 805°	...	...	6 drachms

#### No. 2.

Iodide of potassium	...	...	8 grains
Water	...	...	20 minims

Dissolve, and add to No. 1.

#### No. 3.

Bromide of cadmium	...	...	8 grains
Alcohol, 805°	...	...	2 drachms

Dissolve and add to the above, then filter and keep for use. Then add one part of this mixture to three parts of the normal collodion.

Each ounce of the prepared collodion will then contain—

Ether	...	...	...	$\frac{1}{2}$ ounce
Alcohol, 805°	...	...	...	2 drachms
Alcohol, 822°	...	...	...	2 "
Soluble cotton	...	...	...	6 grains
Iodide of cadmium	...	...	...	2 "
Iodide of potassium	...	...	...	2 "
Bromide of cadmium	...	...	...	2 "

"This," Mr. Gordon adds, "I find as good a collodion for the wet process as any I ever used."

"I do not like it for dry plates, as I prefer 3 grains of bromide for this purpose, and the potassium salt will not admit of so large a quantity."

## PICTORIAL EFFECTS IN PORTRAITURE.

WE have recently received from Messrs. Robinson and Cherrill\* some very admirable examples of cabinet portraiture, in which it is attempted to secure something beyond mere portraiture, each subject being treated as a picture possessing charms independent of the question of likeness. In relation to picture-making, the superiority in size of the cabinet to the card portrait becomes an important element of success or failure. It is an advantage and an element of success if the photographer be master of the art department of his work; it is an element of failure if he lack the power of composition or securing pictorial effect; and this is probably one reason for the tardy adoption of cabinet portraiture: it undoubtedly taxes the artistic capacity of the portraitist to a greater degree than does the card portrait.

The idea embodied in the charming portraits introduced by Mr. Edge has doubtless suggested the mode of treatment adopted in these pictures; but as the size is larger, a more ambitious treatment becomes necessary. In Mr. Edge's cards the picture consists chiefly of foreground and distance, without appreciable middle distance, and the limited dimensions of the picture seem sufficiently filled, and scarcely suggest a want. In the larger cabinet size this treatment is not permissible: every plane must be properly made out, or the picture is imperfect. The subjects consist, for the most part, of pretty children, some in rustic costume, playing amid trailing wild flowers, grass, and ferns; in some cases a fine landscape from a second negative furnishes the background; in other cases a skilfully painted scenic background is employed, which is so contrived as to admirably blend the natural effects in the foreground with the painted effects on the screen. In some other of the specimens a winning little child is dressed in somewhat quaint-looking, old-fashioned costume, forcibly reminding us of some of the favourite pictures of Sir Joshua Reynolds, whose style is somewhat followed in the treatment of the pictures, which have dark backgrounds, with a few dimly made out accessories, employed for the effect of light and shadow, rather than the sharp rendering of their forms as objects of importance. In all cases the pictorial effect is admirable, and many of the pictures altogether charming.

We have also before us some very admirable examples of cabinet portraiture by Mr. Inglis, of Montreal, especially distinguished by their pictorial treatment and for the skill with which a natural foreground is supplemented by a scenic background. In some of these the effects of snow and ice, which we have before described in connection with Mr. Notman's pictures, are admirably rendered, and produce a good effect of harmony with the Canadian winter costumes of the models. In others a good effect is produced by a rocky foreground with well painted sea and sky for distance. In others, again, we have children playing in a garden scene, with capital natural accessories, and well-painted landscape beyond. Fine judgment is required in this blending of the natural with the artificial, in order to secure keeping and harmony, and Mr. Inglis has in all cases succeeded admirably. The portraiture and the technical photography are throughout of high excellence.

A series of card portraits of children with which Mr. Inglis has favoured us are amongst the most marvellous things we have seen in child portraiture. The models chiefly consist of two little ones, of apparently about two years old and four years old respectively. They furnish about a couple of dozen different subjects, in which almost every phase of expression possible to childhood is embodied. There are various phases of mirth and laughter, various forms of grief and crying; surprise, defiance, mischief, study, pensive contemplation; action of various kinds, and repose in various forms, all very capitally rendered, and telling their own tale. Mr. Inglis appears to have succeeded in acquiring the true art of taking young children—working rapidly, keeping the sitters interested, and avoiding coercion or fatigue.

## ECHOES OF THE MONTH.

BY AN OLD PHOTOGRAPHER.

ENGLISH LENSES—MR. McLACHLAN'S COMMUNICATION—MR. WOODBURY'S PROCESS—THE CARBON PROCESS—M. SALOMON'S UNMOUNTED PRINTS—DRYING NEGATIVES BY HEAT—TRANSFORMATION OF SILVER INTO OTHER METALS—SOCIETIES.

I WAS strikingly reminded of the wholesome old proverb, *Ne sutor ultra crepidam*, by a recent article in your generally excellent contemporary the *Mechanics' Magazine*, in which the writer is excited to virtuous indignation by a contemplation of the high prices charged by English opticians for photographic lenses, whilst, according to this writer, equally good lenses can be purchased in Paris for half the money. It seems, too, that photographic journals have sadly neglected their duty in not informing photographers of these facts, and calling their attention to the superior cheapness of the continental productions. There is something very amusing in the profound ignorance of the writer, who fancies he is communicating a new thing to photographers in stating that French lenses are cheap, or rather low-priced. Perhaps there is scarcely a studio in the kingdom in which there is not, or has not been at some time, a cheap French lens, which in some exceptional cases may be a good one, but which, in the majority of cases, is so far otherwise, that when the photographer can possibly afford it he will pay three times the price of the French lens for a first-class English instrument. If the writer had been informed upon his subject he would have known that not only are photographers generally tolerably familiar with the qualities of French lenses, but that French and other continental photographers know something of English lenses, and, notwithstanding their greater price, use them. If he had visited the studios of Bingham, Reutlinger, Ferrier, Disderi, Angerer, and many others whose works are known throughout the world, he would have seen that they employed English lenses; and he ought further to have known that his statement that at the late International Exhibition a "foreigner carried off the first prize for photographic lenses, leaving the best English opticians out in the cold," was simply not true. There were only four silver medals awarded to opticians, and these were for English, French, Prussian, and Austrian lenses; and, further, the two principal English opticians each received gold medals. The scientific blunders in the article, I presume, you will deal with in good time.\*

The conviction I stated in my last *Echoes*, that Mr. McLachlan underrated the intelligence and capability of photographers generally, was, I think, more than justified by that gentleman in his recent communications to the Photographic Society, and I was glad to hear Mr. Fry, with considerable point and force, endorse my remarks. It required all one's respect for Mr. McLachlan's honesty and earnestness, and gratitude for his evident good intention, to keep anything like patience with the strange farrago of unscientific terminology. I felt strongly inclined to quote Sir Walter Scott's *Antiquary*, where he exclaims to Sir Arthur Wardour: "Take a glass of wine, and wash down that bead-roll of unbaptized jargon that would choke a dog." If I understand the practical advice given to photographers, it is to this effect: "You have already sunned your baths a little; you will find it advantageous to sun them much more. You have been in the habit of using nitric acid; henceforth avoid it. You have preferred ripe reddish collodion; in future use a colourless neutral sample. You have hitherto found that an iron developer worked cleanest when a portion of it had become oxydized; I recommend you to produce the same result in what I conceive to be a better manner." *Voilà tout!* Much of the advice is doubtless good, but I cannot see why it should have been heralded as a great secret.

\* The charming pictures by Messrs. Robinson and Cherrill are published by Marion and Co.

\* The article in question was so curiously full of obvious error that it is not likely to mislead many. The pressure on our space of more interesting matter leaves us no room for dealing with an unimportant matter.—Ed.

Few inventions have been the victim of so many commercial misfortunes as Mr. Woodbury's photo-relief printing process, all of which tend to retard its fair chance of commercial application. After more preliminary troubles than most novelties encountered, a company was formed for working it in Manchester; but, beyond causing considerable delay, nothing was effected. The commercial utilization of the process did not seem to be advanced at all. Next, we hear that the patent has been purchased by a company in London, Disderi and Co., Limited, and active preparations are made for the working of the process. Fine examples of the work begins to be seen in retail establishments, and a full tide of prosperity seems to be promised, when suddenly Mr. Disderi is reported as "wanting," and shortly his solicitor applies to the Court of Chancery for a liquidator, and states that no money at all has been contributed by the shareholders and directors. *On dit*, that not less than £40,000 has been supplied by a French capitalist to the company in London to initiate and carry on its business, but that no satisfactory answer can be given as to where the money has gone. To those having a purely scientific interest in the progress of this mode of printing, these things are somewhat distressing, because they delay the establishment of a good process, which, in spite of the commercial difficulties, has steadily progressed in the excellence and certainty of its results.

The commercial application of the carbon printing process has not been so rapid as might have been desired; but it has had no such drawbacks as those I have just mentioned, and in the hands of the new company, which will, I understand, direct its fortunes for the future, will, I believe, be worked with great energy. Perhaps its success in the hands of Mr. Braun, of Dornach, is unparalleled in the history of our art. It seems only the other day since it was initiated by Mr. Swan, in Dornach, and now they are turning out fifteen hundred prints daily by the process; and the spirited proprietor, who has invested over £16,000 in the work, is, I hope and believe, making a rapid fortune by it. The purpose of the Autotype Company, to inaugurate a new system of reproduction by the aid of this process, promises well for art education in a form hitherto sadly neglected.

The unmounted Saloman prints will, I presume, remove the remaining doubts of sceptics. For my own part, although fully satisfied that the photography was of rare excellence, I must confess that a sight of a score of such examples of magnificent photography in the rough state has surprised me, and I am almost disposed to concur with the dictum of an artistic friend, that any touching upon such prints was almost desecration. I may here repeat one curious remark I have heard, to the effect that if any "dodge" had been practised, it consisted in giving a few touches, to suggest that a far greater amount of artistic skill had been applied in finishing than the prints had either received or required.

Have any of your readers ever noticed a fact recently mentioned by an American correspondent in your pages, namely, that a negative dried by the fire was generally more brilliant than one left to dry spontaneously. I have never seen it mentioned before, but I remember to have been occasionally struck by the fact in my own practice. It is surely something worth further examination.

One of the most interesting papers I have read for a long time is that recently contributed by Herr Grune to your pages, on the transformation of the image obtained in silver to some other metal by a process of substitution. It appears to me to point out a comparatively unworked field for photographic experiment. With the exception of the well-known method of converting the image in a salt of mercury, but little has been done in that direction. Research in this direction furnishes a new field, I fancy, for experimentalists in photographic engraving.

The meetings of societies during the month have in many cases been interesting. The length of Mr. McLachlan's

communication at the Parent Society left little time for discussion; but the remarks made were interesting, and to that purpose. Mr. Spiller's comments on the statements put forth furnished an admirable example of quiet force strikingly in contrast with Mr. McLachlan's excited exuberance. The example of Mr. Robinson's promised presentation print, a charming composition, entitled "Watching the Lark," excited much interest. At the North London, Mr. Boekett's paper on the condition acquired by chemicals after long disuse, was interesting, and might in a fuller meeting have excited more copious discussion. At the South the material was more meagre than usual, or the members were less disposed for discussion. Some capital engravings were exhibited by Mr. Henderson, and some fine studies by Mr. Rejlander, as well as a large number of M. Salomon's unmounted prints, which excited equal surprise and gratification by the photographic perfectness of the pictures.

At the Oldham Society, which maintains its activity, Mr. Beverley read a good paper on "Dry Plate Photography," in which he expressed his preference for Mr. England's process. At the Edinburgh Society Mr. Muir gave some photographic experiences in Sweden. A discussion followed on the fading away of the image on dry plates when kept long before development. At the Liverpool Society an interesting discussion took place on the collodio-bromide plates of the Liverpool Dry Plate Company, some fine negatives, obtained by development with a weak solution of ammonia, being shown in illustration of the value of this mode of operating.

#### SKETCHES OF TRAVEL FROM A SUN-PAINTER'S PORTFOLIO.

BY STEPHEN THOMPSON.

"What we write  
Should be the reflex of the thing we know.  
How can he limn the glories of the morn  
Whose eyes have never looked upon Aurora's face?"

Prof. Aytoun.

##### No. 1.—A WEEK ON THE ISLAND OF IONA.

THERE is a little island lying off the bleak and stormy coast of Argyshire to which, in bygone days, a peculiar odour of sanctity was attached, and a belief in special privileges to be conferred at the end of the world on those buried thereon. There together sleep the mighty of a long past age—a long line of Scotch, Irish, and Norwegian kings; a race of "Lords of the Isles," and powerful chieftains from far and near. After many a stormy and turbulent life, Norseman and Scot alike came there to repose in quiet proximity. On dark winter nights, when the storm-driven waves of the Atlantic lash the wild rocks on the seaward side of the island, and the blue hills of Morven to the north, wreathed in mysterious mist, are full of all that which inspired the song of Ossian, the ear of fancy may hear borne on the wings of the wind the wail of sorrow for "the dark-haired Orla, destroyer of Lernes, chief of Oithona," or the bards raise the song of praise for the yellow-haired son of blue-eyed Mora,—

"Whose dark ghost gleams on the red stream of tempests?—Lovely was thou, but not harmless was thy sword! It hangs in thy cave: the ghosts of Lochlin shriek around its steel. Hear thy praises! Thy name shakes on the echoes of Morven! Then raise thy fair locks, spread them on the arch of the rainbow, and smile through the tears of the storm."

A low rocky isle set in the Northern Sea, is the island of Iona, one

"Where more of winters than of summers be,"

but though destitute of tree or shrub, there are patches of verdure here and there, upon which the black Highland sheep graze and are content. The cottages in which the islanders dwell are of the rudest description:—roofs of thatch, secured with lacing of hempen rope where the Swiss chalet would have had rude planks of dark brown timber secured with large stones at regular intervals. Under one of these roofs I was fortunate in possessing half a bed-room shared with an engineer engaged in superintending the construction of another lighthouse near the far-famed Skerryvore, built by

Stephenson. Many rough days and tough yarns had we at night over difficulties experienced in effecting a landing, he on his rock, and I on mine at Staffa!

But there is no place sacred from the ubiquitous camera, and Wilson's admirable views have made the island familiar to many of those who will never tread its shores. The remains of the world-famed cathedral and monastic establishment are situate on the more sheltered side of the isle, looking towards the Ross of Mull. This earliest of Christian temples, this link of links between past and present, is invested with associations of undying interest. The story of St. Columba is a peculiarly fascinating one, and reads like an epic: his noble self-denial, his lofty piety and indomitable courage, his formidable contests with Druid priests and a barbarous people, until Christianity spread over all Scotland; how he lived and laboured on, and how, when life's long day was spent, laid himself down in his cell by the sounding sea, and at evening time there was light!

It presents no peculiar difficulties to the photographer, save those of forethought in connection with the safe transit of fragile apparatus and chemicals over seven or eight hundred miles of land and sea, and the landing and re-shipping the same in small open boats at sea on an iron-bound coast. The finely-balanced nervous temperament of the Duke of Wellington, we are told, consisted in a due mixture of the apprehensive and the resolute—a constant apprehension and expectation of contingencies, and a perpetual preparation against them. When once questioned on the subject, he stated that he never thought of what he should do if victory were his, but a great deal about what he should do in case of defeat. Similar qualities should be those of a landscape photographer. The journey occupies three or four days from London; from Glasgow two days. Leaving the Bromielaw at 7 a.m., by Messrs. Hutchison's magnificent steamship *Iona*, built on the American principle, you reach Oban the same night by way of Ardrishaig and the Crinan Canal. In the season, another boat leaves Oban twice or three times a week for Iona and Staffa. As the wind and weather in these Western islands is often of such a nature as to ensure a long detention, it is as well to prepare beforehand. Those mindful of their creature comforts may be reminded that there are such people as Crosse and Blackwell, and such things as potted meats and other et ceteras. Good eggs and butter may generally be obtained, but anything further must not be reckoned upon. Even fish, except a species of weak, watery flounder, is not to be had. Their boats are not seaworthy enough for good fishing. Spirits of any kind is interdicted upon the island by the Duke of Argyle, to whom it belongs. No whisky toddy (!) unless you have a flask of your own. I, who write, have often subsisted for days and weeks upon little more than oatmeal cake and butter, in remote parts of the Highlands; but there are times when one is overtaken by an inexpressible longing for the flesh-pots of Egypt.

There is one great comfort in photographing cathedrals: being always built from east to west, and generally cruciform, you know beforehand at what time your subjects will be duly lighted for your purpose. The east end must be looked after pretty early; the south porch during the day; the north porch at almost any time, as the sun will never be on it; and your *chef-d'œuvre*, the west front, later in the day; or, best of all, if the porches are not very deep, just as the sun is stealing round and casting flickering shadows athwart its best points. If the foundations of the hills were laid from east to west, and the rivers all flowed in one direction, what a deal of prospecting it would save us. Now an artist (!) has to spend a day in prospecting, or run the hazard of perhaps hiring an expensive hack-carriage, to find himself, on arriving, just an hour too late. As there is one hour when a subject is at its best, the odds are exactly eleven to one against him. Indeed, even as the first Napoleon said battles were lost or won by a critical quarter of an hour, so even of the hour at which a subject is due, there is one quarter of

an hour at which it is emphatically best. If any one doubts this, let him take two or three negatives fifteen minutes apart, and he will not have any difficulty in afterwards indicating the best one. The wind is always troublesome here; but, from the bare and sterile character of the place, there is no difficulty with the foliage, because there is none; and a big stone, as heavy as possible, laid on the camera will always keep it rigid. There are but two good views to be had of the Cathedral—one from the S.E. and one from the S.W., beside some details. A view of "Dun-Y"—mentioned in Scott's "Lord of the Isles"—may be taken; but *le jeu ne vaut pas le chandelle*.

Here, on the skirts of civilization, papers and letters reach you at long intervals. It seems a place "half without and half within" the busy world. The "Post Office" is a rude hut, with mud for the floor, and the arrival of Her Majesty's mail *viâ* "Mull's dark sound," per marrowbone-stage, is duly celebrated on those nights by a tallow candle stuck in the neck of a bottle, a great sorting of half-a-dozen letters, and much excitement.

If you get some rainy days, it is well if you have books with you, for there is little else to kill the time. It is always better to carry one or two standard books of a calibre that will bear reading again and again. Lighter books, once read, are "sucked oranges," and perhaps, notwithstanding, being too expensive to toss aside, become an annoying encumbrance all the remainder of your journey. If you are familiar with that inimitable biography, "Boswell's Life of Johnson," you may go and stand where the worthy Doctor stood with his attendant's shadow Boswell, while "doing the Hebrides," and once again hear him utter, in ponderous sentences, full of the true Johnsonian ring, with outstretched hand, and cane firmly planted the while, that remarkable passage containing one word for Iona and two for the mental superiority of himself and his friends: "We are now treading that illustrious island which was once the luminary of the Caledonian regions, whence savage clans and roving barbarians derived the benefits of knowledge and the blessings of religion. To abstract the mind from all local emotion would be impossible, and would be foolish if it were possible. Whatever withdraws us from the power of our senses, whatever makes the past, the distant, or the future predominate over the present, advances us in the dignity of thinking beings. Far from me and from my friends be such frigid philosophy as may conduct us, indifferent and unmoved, over any ground that has been dignified by wisdom, bravery, or virtue. That man has little to be envied whose patriotism would not gain force upon the plain of Marathon, or whose piety would not grow warmer among the ruins of Iona."

But few of the beautiful crosses which marked where slept mighty sea-king or bold chieftain are left. Upwards of 300 of them were thrown into the sea by order of a stupid *Synod* of Argyle in the sixteenth century. There are, however, three still standing: Maclean's Cross, by the pathway, and two within the Cathedral precincts. Others now sleep within the lonely walls which encircle this and St. Oran's Chapel; and graves of more recent interest may there be found side by side.

One dark December day—the last of the old year—disabled, dismayed, unmanageable, scarce knowing where she was (for the Skerryvore light had been sighted by her fine Scot-American captain too late to save, had the ship been still under control), the *Guy Mannering*, a big New Yorker, cotton laden, came headlong on the pitiless rocks facing the wild Atlantic. On the cliff top the islanders gathered in a group, having hurriedly left the afternoon service at the little kirk by the shore (it was Sabbath day) on learning there was a big ship "coming in." Little aid could they render, but gazed in powerless horror, while some of them endeavoured to indicate the best place—if there could be any best—to be dashed upon, or where, at least, most lives could be saved. Alas! all control was gone, and bold hearts and skilful seamanship could avail nothing. Gathered

in another group, on the fore-castle of the doomed ship, stood officers, crew, and passengers, awaiting in silent terror their inevitable fate. A brief interval, and on she came. One crash—a rebound—another, and the *Guy Mannering* was rent into a thousand pieces. Where a huge ship appeared a moment before, the seething waves were dotted with planks, broken spars, bales of cotton, and drowning seamen. Darkness soon veils the rest, and when morn glimmers on the shore the sleepers are many. The breeze of ocean lifts their locks, but they do not awake. The people gather them together under a sail on the hillside. After a few days, in the feeble sunlight of an early January afternoon, with bare head and measured step, these islesmen bore them in long procession across the island to the lonely Cathedral ruins, where the last rite man paid to man was paid. So they buried them, these simple Islanders, and the dust of these nineteenth century seamen—Yankee, Irish-American, and negro—mingles with that of kings and chiefs who lived before the Norman Conqueror, 800 years ago.

#### "LUX GRAPHICUS" ON THE WING.

THE LATE LORD BROUGHAM—NEW FIELDS FOR PHOTOGRAPHY—NATURAL OBJECTS COLOURED—THE MONOCHROME AND AUTOTYPE—MR. MCLACHLAN AGAIN.

DEATH has just swept away one of the most gigantic intellects of the nineteenth century. For me to state what the late Lord Brougham was, or attempt to enumerate his vast attainments, or measure the strength of his colossal mind, would be a piece of intolerable presumption; but I think I may safely say that he was an enthusiastic admirer of photography. Years ago, in the midst of his parliamentary and other pressing duties, whenever he could find time to enjoy the quiet of Brougham Hall, near Penrith, his giant mind was not above indulging in the delightful relaxation it afforded; and many a pleasant hour he used to spend chatting with Mr. Jacob Thompson, an artist of great ability, and also a very early amateur photographer, on the wonderful results obtained by the new art. The late Lord Brougham began his literary career by publishing a treatise on Light, before photography was known or thought to be practicable; in after life he interested himself in its marvellous productions; and his last literary labour was also about light. Not only did the great statesman "know a little of everything," he did a little in everything. The deceased lord took a lively interest in the progress of photography during his lifetime, from its earliest introduction to within a short period of his death; and it would have been a graceful and fitting compliment to the memory of the great man of law, politics, literature, and science, if the English newspapers had embellished their memoirs of the late Lord Brougham with a photographic portrait of his lordship. Such a thing is quite practicable, and has been done successfully by our more enterprising confrères in Canada and the United States. The *Montreal Weekly Herald* of April the 18th illustrates its memoir of the late Mr. T. d'Arcy McGeoe with a very excellent carte-de-visite portrait of the lamented and unfortunate Canadian Minister, mounted on the upper corner of the front page, surrounded with a deep black border. What an appropriate accompaniment such a presentation would have been to the able articles and memoirs which appeared in the daily press on Monday, May 11th, 1868! How much more interesting and valuable those clever biographical sketches of great men, as they pass away to their rest, which appear in the *Daily Telegraph* and other daily and weekly papers, would appear if illustrated with a photograph from life! That it can be done the *Montreal Weekly Herald* has recently and satisfactorily shown; and surely there is enterprise, spirit, and wealth enough among the British newspaper proprietors to follow the very laudable example of our transatlantic cousins. Negatives of great men are always attainable, and there need be no commercial difficulty between the photographer and newspaper proprietor on the score of supply. A multiplication of negatives or Woodbury's process, would afford all the necessary facilities for producing the prints in large numbers.

Many new fields for the good of photography are opening up. Pathological works have been photographically illustrated with some amount of success. But far pleasanter fields are open to enterprising photographers in the faithful representa-

tion of natural objects, such as flowers, fruits, ferns, grasses, shrubs, trees, shells, seaweeds, birds, butterflies, moths, and every variety of animal life, from the lowest orders to the highest. I believe the time is not far distant when the best works on all the physical sciences will be illustrated by coloured photographs. Those very beautiful German photographs of flowers recently introduced show most conclusively of what photography is capable as a help to a study of the natural sciences. The flowers are not only photographed from nature, but exquisitely coloured after the same fountain of truth; and the sense of reality, roundness, and relief which they convey is truly wonderful. Hitherto the colouring of natural objects photographed from nature has been a very difficult thing to accomplish; but now it is done, and with a marvellous success.

The monochromatic process is also making great strides in advance. Those very beautiful transparencies, cabinet size, of the Queen and Royal Family are now to be seen in most of the photographic picture shop-windows in town and country. Those transparencies are the productions of the Disderi Company, by Woodbury's photo-relief process, and the results now obtained are really beautiful, both in effect and colour, and sold at a very low price. But the *chef-d'œuvre* of all monochromatic effects has just been achieved by the triple labours of Mr. Macnee, the artist, and Mr. Annan, the photographer, of Glasgow, and Mr. J. W. Swan, of Newcastle. The subject in question is a work of art in every respect. The original is a full-length portrait of Lord Belhaven, painted by Daniel Macnee, and now in the Royal Academy Exhibition. A photograph taken from the painting by Mr. Annan was worked up in monochrome by the eminent artist, from which another negative was taken by the same skilful photographer, and placed in the hands of Mr. J. W. Swan, to be printed in carbon, which the latter gentleman has done in the most admirable manner. Altogether, the result is the most satisfactory reproduction by photography that has ever been placed before the public, and is less like a photograph and more like a fine mezzotint engraving than anything I ever saw. Mr. Annan is now publishing the work on his own responsibility, and a specimen of it can be seen at the offices of "The Autotype Printing and Publishing Company," 5, Haymarket, London. Mr. Hill, of Edinburgh, is also about to publish, in carbon, a photograph of that beautifully painted picture entitled "A Fairy Raid," which was exhibited last year in the rooms of the Royal Academy by Sir Noel Paton. As in the former case, Mr. Annan copied the painting, Sir Noel worked on a print in monochrome, which was again photographed by Mr. Annan, and the negative passed to Mr. J. W. Swan to be printed in carbon. I understand that Prynter's celebrated picture of "Israel in Egypt" is about to be published, in a similar manner, by the Autotype Company. It is therefore quite evident that photography is becoming, in reality, more and more "a foe to graphic art," and eclipsing the lights and deepening the shadows of the *unlucky* engraver.

Mr. McLachlan has again spoken without giving any very materially new facts, or throwing much more light on his mysterious mode of working. The great point is, to throw light on the concentrated solution of nitrate of silver; and until that has been done it will be impossible for any one to say from experience and practice that there is nothing in the principle. Mr. McLachlan attributes a chemical property to the action of light on the bath that has never been thought of before, and he seems to believe it so sincerely himself, and expresses his convictions so earnestly, that I think photographers are somewhat bound to wait patiently till time and light will enable them to comply with all the conditions he lays down, and make a series of careful experiments, before they can say whether they are under obligations to him or not. At any rate, natural justice suggests that they should not render a foregone verdict.—Yours very truly,

May 17, 1868.

LUX GRAPHICUS.

#### A NEW MODE OF DRYING PLATES.

BY M. CAREY LEA.\*

I SHALL endeavour, in what I am about to say, to show the vital importance of perfect drying for dry plates, the imperfection of the methods commonly employed, and then shall describe a new method exclusively employed by me for nearly a year with most satisfactory results.

\* Philadelphia Photographer.

First, then, I believe that the importance of perfect drying is as yet being only begun to be understood by some of the most experienced dry-plate workers. To this source I am disposed to ascribe the uncertainty commonly attributed to dry-plate work, which uncertainty quite disappears when a perfect method of drying is used. I can say that having dried hundreds of plates by my own method I have never seen one turn out insensitve.

M. de Constant, an experienced dry-plate worker, writes me that he has succeeded in tracing up cases of at first most puzzling non-success to a deposition of dew upon plates transferred from a colder to a warmer and damper atmosphere. This is the same thing in another form. A dry plate must be dry. And when a photographer takes with him a dozen imperfectly dried plates, and finds spots, stains, and irregular development, he should have known that he was preparing for himself nothing but disappointment. Dry plate work, properly conducted, is singularly free from stains of all sorts.

Again, the ordinary methods of drying lead directly to imperfect results, unless, perhaps, where the operator places his plates in an oven, and so applies a steady, dry heat. Few persons, however, have conveniences of that sort, and most photographers will very decidedly prefer to dry their plates in the dark room. This leads directly to placing the plates in a dark closet to dry, a method of the most imperfect character, and liable to several grave objections. First, the whole air of the closet becomes damp by the evaporation, which is consequently checked. The last portions of dampness are those most difficult to expel, and it is just when the plates have reached that stage that the atmosphere becomes most incapable of finishing its work; in fact, the tendency in such a case is to establish a sort of equilibrium of moisture, the plates reaching the same stage of half dryness as the air, and then ceasing further to dry. It is not surface dryness that is wanted, but through and through dessication. Another defect of closet drying is, that the plates are rested on blotting-paper, which keeps up moisture at one end and tends to irregular drying, which is always accompanied by irregular sensibility, leading to unsatisfactory results; and if the closet be left a little open to change the air, we then run the risk of dust settling on the moist surface.

In a close box some of these evils are avoided, but no satisfactory drying can possibly be effected unless there is present a substance that energetically absorbs moisture. So far chloride of calcium is the only substance that has been used; very few, however, have been willing to use it. It rapidly liquefies, and then must either be rejected as worthless, or else must be evaporated down to dryness, and then be fused in the fire. There is yet another objection to this method, that if a particle of dust of the chloride should get on a plate it would adhere, liquefy, and cause a ruinous stain.

I avoid these difficulties, one and all, by the use of sulphuric acid. However inappropriate this substance might at first seem, it works so well as to leave nothing to be desired. Sulphuric acid has long been used in analytical chemistry for dessicating, and it may most advantageously be introduced into photography.

The mode of employment consists simply in placing it in a pan or basin in the drying-box. The plates to be dried either have a corner set in one of a series of tumblers ranged round the sides, or else are set in a frame which is placed in the drying-box.

Now, one great advantage of this method is that its cost is absolutely nothing. Sulphuric acid is so cheap, that even if, after it had performed its office, it was rendered worthless, the cost would not be great. But there is not even this drawback. A considerable quantity of sulphuric acid is wanted in the photographic laboratory for cleaning plates, so that the method here proposed for drying works in most conveniently with the method of cleaning with bichromate of potash and sulphuric acid which I introduced some years ago. The sulphuric acid, after it has absorbed so much

moisture in the drying-box as to be no longer useful, is as good as ever for cleaning with.

As the acid augments continually in bulk, by reason of the water which it absorbs, the photographer will do well to bear this in mind in the selection of a vessel to contain it. Ordinary photographic porcelain pans are not very suitable, even the deep ones, on account of the danger of spilling when they are lifted out. Basins about three inches deep are better. Good porcelain will stand sulphuric acid indefinitely; bad will not. Glass is excellent; common glass finger-bowls will do very well; several should be placed in the box with half a pound to one pound of sulphuric acid in each. After the acid has swelled to double its original bulk it should be replaced with fresh.

Although I had used this method for a long time, and with regular and unvaried satisfaction, I did not care to publish it without making a careful comparative test. Some might imagine that plates which had been in presence of so powerful an acid might, though very well dried, exhibit less sensitiveness than plates managed in the usual manner. To be able to reply positively to any such objection, the following comparison was made:—

Two plates were prepared under circumstances absolutely identical. One was dried by the new method; the other was set in a dark closet, resting against a large bottle of very hot water; after drying, both received an equal exposure, and were developed side by side in pairs. The plate dried over sulphuric acid proved the more sensitive of the two.

It seems of interest to make the remark here, that imperfect drying always diminishes the sensitiveness. For example, the lower end of a plate is always the last to dry. If a plate be exposed before the lower end is dry, that part will be found to give a thinner image than the rest.

My own experience points to twenty-four hours as being the proper time in the drying-box. At least I find that if plates be prepared at night, and be used the next morning, there is danger of finding the lower corners insensitve from incomplete dessication. Of course, when plates are dried by heat, the time may be greatly shortened, but I have never liked this mode. When a plate is dried horizontally, spots tend to dry more slowly than the rest, and these cannot fail to show themselves in the development. If the plates be reared up, resting partly on a hot tin and partly on their own edges, these edges need blotting-paper under them, and this must tend to irregular action and cloudiness. Plates dried as here recommended, in a box with sulphuric acid, are very free from all faults that can be ascribed to irregular drying.

## PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN  
COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.

### CHAPTER XIX.

"Peculiar toil on single forms bestow,

Then let expression lend its finished glow."—*Du Fresnoy.*

"We must not omit to speak of the hand as an instrument of expression. Formal dissertations have been written on this; but were we constrained to such authorities, we might take the great painters in evidence, since by the position of the hands, in conformity with the figure, they have expressed every sentiment. Who, for example, can deny the eloquence of the hands in the Magdalen of Guido; their expression in the cartoons of Raphael; or in the Last Supper, by Leonardo da Vinci? We see there expressed all that Quintilian says the head is capable of expressing. 'For other parts of the body,' says he, 'assist the speaker; but these, I may say speak themselves. By them we ask, we promise, we invoke, we dismiss, we threaten, we intreat, we deprecate, we express fear, joy, grief, our doubts, our assent, our penitence; we show moderation, profusion; we mark number and time.'"—*Sir Charles Bell.*

### PORTRAITURE—continued.

PORTRAITURE may consist in the representation of a single figure, or of a group of persons. We will first consider the composition of a portrait picture in which one person only is represented.

Long experience will show that the two sides of every face differ. This is very evident in many faces, and in all, how-

ever regular the eyes may seem, or however straight the nose may appear, close observation will discover that one side is better than the other. It is this side that should be taken. Even in a full, or nearly full, face this variation should always be noticed and taken advantage of. These deviations from exact correspondence of the sides of the face have not been considered blemishes by great painters, who invariably noticed and recorded them. It is notably so in the portraits by Reynolds. It may be seen in the print from the *Ugolino*, where it increases the look of fixed despair, and in the front face of Garrick, in which the difference of the eyes strikingly assists the archness of the expression.

In photographic portraiture the face should be turned away from the light. If the face is turned to the light, however delicate the half-tones may be, the line of the nose will be partly lost in equal light on the cheek behind it. Painters occasionally represent faces in this position as regards the light, but then they have the advantage of colour to produce relief. The only exception to this rule—that the face should be turned from the light—is in the case of a profile, or the profile showing a glimpse of the off eye when the nose comes clear against the background. For these reasons—that is, because it is necessary to choose which side of the face is to be represented, and because the face must be turned from the light—it is well to have a studio so constructed that the light can be obtained from the right or the left; in a ridge-roof studio, with one side glass and the other opaque, both ends should be available for use. It is also well to have it sufficiently wide to enable the operator to work diagonally, and thus get a modification of the shadows without the use of reflectors.

Having decided the side to be taken, which also determines the general direction of the light, the next consideration is that of attitude. As regards the position of the head, Burnett observes: "Every one who takes the trouble to reflect must perceive that all faces contain two points of view, where the character is more or less developed—a profile, and what is termed a front view; and that the seat of a strong likeness lies sometimes in one greater than in the other. They must also perceive that what is called a three-quarter view of the head gives the artist an opportunity of representing both; independent of which advantage, it has a greater variety in the forms, and gives an opportunity for introducing a greater breadth of light and shade, and also of showing the ear, which is often a beautiful feature." A full face is seldom so agreeable in photography as one slightly turned away.

In selecting and arranging an attitude, the application of the general principles I have dwelt on in previous chapters will be of more value than any recipe that could be given; in fact, as I have said before, any specific directions or plans of portraits—thus will we arrange a man, thus will we arrange a woman, or thus will we arrange a child—would interfere with individual characteristics, and do more harm than good. But a few general remarks may be useful.

A single figure should be complete in itself; it should not appear as though it had been cut out of a group, and it should be incapable of having another figure added to it without injury. The head being the chief object, every line should be composed in relation to it, and the student will find the rules of pyramidal composition invaluable to him here. He must consider contrast of lines and balance, variety, repose, and, above all, unity and simplicity. All the rules for the composition of a group—such as the "Blind Fiddler"—hold good for the single figure, bearing in mind that the head is the principal object, to which everything is to be subordinate, which is to receive the sharpest focus, the highest light, and the chief attention; after which the hands will claim consideration. The hands will be found very useful in repeating, in a minor and subordinate degree, the mass of light presented by the face. They have the advantage, in one respect, of not being of so much importance as the face; they may be displayed (always without affectation) if they are fine in form, or they may be hidden if

necessary. Just as, in the "Blind Fiddler," no head is exactly under another, so ought not the hand to be exactly under the head. A great deal of character can be given to the hand if properly treated. Sir Walter Scott, writing to Wilkie of a picture he had seen at Windsor, says, "There was a picture of the Pope, which struck me very much. I fancied if I had seen only the hand I could have guessed it not only to be the hand of a gentleman and a person of high rank, but of a man who had never been employed in war, or in the sports by which the better classes generally harden and roughen their hands in youth. It was and could be only the hand of an old priest, which had no ruder employment than bestowing benedictions."

The action of the figure should be that which is most common to the individual—such a position as shows it to the best advantage. No violent action should be allowed; no appearance of strain. Some photographers seem to think that grace consists of twists, and make spirals of their figures, especially ladies, by causing them to turn their heads over their shoulders and try to look down their backs out of the corners of their eyes. The absurdity and affectation of this position is caused by exaggeration. A position approaching to it, but without the strain, is exceedingly graceful if the figure should be sufficiently easy and pliant to allow of this pose. It cannot be too strongly impressed on the student that the possibilities of the figure must be considered before the attitude is chosen; every figure will not allow of every attitude, any more than a decrepid old man of eighty or ninety could perform the feats of skilful acrobats. Some figures are graceful in one position, while they would be awkward in another, probably still more graceful in a figure it suited. However graceful a figure may appear which has cost some effort in the sitter to attain, it does not compensate for the unaffected air and repose derived from the head and body placed in one direction, as we see in the grand portraits of old men by Titian, Vandyke, and Raphael.

It must not be supposed from this last remark that I advocate that every figure should be presented with the head and body exactly in one direction, although it is very suitable for some persons; but it will be found that a very slight difference of direction between the head and the figure—as in the illustration—will be sufficient to give animation without disturbing repose.

The student will do well to observe attitudes assumed in every-day life, and adapt them to his art. When he sees a beautiful attitude, let him speculate upon the cause of its being beautiful, and he will find that it depends on its consistency with the rules of composition; and although these

rules will not supply him with imagination sufficient to enable him to perpetually invent new arrangements, he will find they aid him very materially in giving expression to his inventions, and will prevent him being extravagant or exaggerated in his arrangements of the form. He should also store his mind with incidents suitable to his sitters, and he may then, perhaps, be able to give less occupation to the eternal book we see in the hands of photographées almost as often as a roll of paper is represented in the statues of statesmen.

Remarks on the treatment of the single figure should also contain something on the subject of vignettes, a style of portrait usually confined to the head and shoulders, a kind of picture so simple as apparently to require very little consideration, but I have seen them done so badly that a few words may be of service.

A vignette head should never convey the impression that the sitter was lounging in a chair or leaning on a table; the reason being, that as the chair or table is not visible, the figure would appear out of shape and deformed. As a general rule, the shoulders should appear level, as though the subject was standing. A little variation between the direction of the head and shoulders will always give variety and animation. The lighting should be more delicate than that suitable for other portraits, and the background should always be light. If the white margin to the vignette be very slightly tinted in the light after printing, the delicate effect will be increased; but, when this is attempted, it is usually overdone, and then the effect becomes heady, and worse than if the white paper had been left pure.

In conclusion, make it a constant practice, before removing the cap from the lens, to first give a rapid glance at the sitter to see whether the outline of the figure composes well, that the light and shade is massive and round, and that there appears some indication of the expression you desire on the face of the sitter. If there is a lack of either of these qualities, do not waste your plate until you have got them before your lens.

#### SOLAR PRINTING ON CANVAS.

MR. ISAAC RENX, of Philadelphia, has recently secured a patent for a process for coating or sensitizing the surface of canvas for printing enlargements upon, by means of the solar camera, by the use of which he claims to get perfect results easily, and without injury to the canvas. He proceeds as follows:—"Take of—

Pure zinc-white	...	...	1 ounce
Albumen of fresh eggs	...	...	1½ ounces
Salt, or chloride of ammonium	...	...	20 grains
Solution of ammonio-nitrate of silver, containing 30 grains of nitrate of silver to each drachm	...	...	4 drachms

"Dissolve the salt in the albumen, then grind fine on a painter's slab the zinc-white in a portion of the albumen, then add the remainder, and mix it uniformly; place the pigment mixture in a Wedgwood mortar, and proceed to the dark-room; then add the silver solution, which will immediately coagulate the albumen; take the pestle and triturate the coagulum until it becomes smooth and pulpy. It is then ready for use. Now take a flat camel's-hair brush about two inches wide, and paint evenly over the canvas or other material with this combination, and it is ready for use when dry; or, if it is desired to print with the solar camera, it is quite as good wet. If a very intense print is required, the coating may, when dry, be subjected to the vapour of ammonia, which will still add to the sensitiveness of the coating.

"This combination is very sensitive to light, and hence due caution must be observed in regard to it, so as not to injure the whites of the picture. It has also the quality of taking very kindly to all kinds of surfaces, oily or not, and may be therefore very easily laid quite free from bubbles or other defects. I have had quite as good results by first

applying the non-coagulated coating, allowing it to dry, then flowing the silver solution over the coating; but this method is not so economical or convenient as the process first described.

The method of preparing the ammonio-nitrate of silver solution is as follows:—Take of—

Nitrate of silver	...	...	1 ounce
Water	...	...	1 "
Pure nitric acid	...	...	2 drachms

Ammonia sufficient quantity.

"Dissolve the silver in the water; remove a small portion, say 1 drachm. To the larger portion add carefully sufficient ammonia to precipitate the silver and re-dissolve the precipitate, guarding against any excess of ammonia. Then add the remaining drachm of the silver solution to insure a decided excess of silver. Lastly, add the two drachms of nitric acid, and the solution is ready for use at any time.

"After the printing process has been carried as far as may be desired, it remains only to fix the impression, which may be done in the usual way, namely, the rinsing away of the free nitrate of silver, and then pouring over the picture a solution of hyposulphite of soda for a few minutes, afterwards removing the hyposulphite of soda by washing the print under a gentle stream."

#### ON A NEW AND SIMPLE METHOD OF RECOVERING METALLIC GOLD AND SILVER FROM RESIDUES.

BY VICTOR G. BLOEDE, CHEMIST.\*

MERCURY has the property of rapidly combining with, or dissolving, as it were, metallic gold and silver, and, in fact, most other metals, forming with them a liquid or pasty mass (according to the amount of foreign metal) which is technically termed an amalgam or "butter." A few drops of mercury poured upon a gold dollar or silver five-cent. piece very quickly dissolves either. When the mercury has taken up a considerable amount of the precious metal from the powdered ore, it is drawn off into bags or large pieces of fine tough buckskin, and then subjected to pressure either between the hands or under a screw. The pure mercury, owing to its extreme permeability, rapidly oozes through the fine pores of the leather, finally leaving in the bag a compact, brittle mass consisting of the precious metals, with a per centage of mercury in combination. To obtain from this crude mass the gold or silver in its pure reguline state the amalgam is placed upon an iron vessel, or, better yet, in an iron retort, and subjected to a low red heat on an ordinary coal fire. The mercury, owing to its extreme volatility, very rapidly evaporates, and, in the course of a few minutes, leaves the precious metals in a state of purity. If the process is carefully managed, as we shall presently describe, there is, however, no danger to be apprehended.

#### To Reduce Old Baths and Nitrate of Silver Solutions.

Filter the solution of silver proposed to be operated upon until it is clear, and place the filtrate into a clean white bottle of suitable capacity. To each pint of the liquid add 4 ounces or more of mercury, and allow the mixture to remain at perfect rest for a few days. In a very few hours a beautiful sparkling corrosion will be found forming upon the surface of the mercury. This shining deposit consists of perfectly pure metallic silver, and has been called *Arbor Diana*, or "tree of life." It is formed upon the surface of the mercury by what is known in chemistry as double elective affinity, and for each atom of the silver so deposited, a corresponding amount of mercury is acted upon by the nitric acid of the silver, and passes into solution as nitrate of mercury. The deposition continues until all the silver has been thrown down, when we find over it a strong solution of the nitrate of mercury, which may be obtained in the

\* Condensed from *The Philadelphia Photographer*.

solid crystalline form by evaporation. In a few days the deposition will be completed, which can be readily seen if the tree ceases to grow; and when the experimenter has become tired of the motto, "A thing of beauty is a joy for ever," &c., and has sufficiently feasted his eyes upon the magnificent sparkling foliage and mossy bark of his shivering tree, he may proceed to draw out its material value. Shake the bottle thoroughly, so that the branches and coruscations of the tree are detached and broken, and brought in thorough contact with the mercury, where the spangles of silver are quickly dissolved. The watery part of the mixture can now be drawn or decanted off from the mercury, and the latter placed in a bag, or, better yet, a large piece of fine tough buckskin, and pressed with force between the hands. When no more mercury can be squeezed through, the bag may be opened and the lump of brittle amalgam removed, and preserved in a well cleaned and stoppered bottle until more has accumulated, or it may be immediately treated as I shall presently direct. In case all the mercury should disappear at the end of the process, a little more may be added to the watery solution to ascertain whether it still contains silver.

#### MR. WARREN DE LA RUE'S PHOTOGRAPHS OF THE MOON.

THE *Engineer* devotes a long article to the description of Mr. Warren de la Rue's observatory at Cranford, and the photographic appliances employed in securing lunar photographs. After describing the apparatus, which consists of a reflecting telescope with a mirror 13 inches in diameter, and of 120 inches focus, and clock-work movement to follow the moon carefully during the necessary exposure, the photographic arrangements are detailed. We annex some extracts from those portions most interesting to our readers.

"When the moon or a planet is to be photographed with the apparatus already described, the operations begin by selecting a glass plate for the picture. Mr. De la Rue uses the flatted crown plate,\* the best glass obtainable for photography, and after receiving a parcel, he rejects all those which contain specks or air-bubbles, so that one-third of the supply is usually at once cast aside. The glass is cut into circular discs 2½ inches in diameter, because the shape of the holder is round, in order not to stop off more of the central part of the aperture than is necessary. Shortly before use the edge of the glass is roughed with a piece of sandstone, such as is used by gardeners to sharpen their scythes. After washing away the grit carefully, the surface of the plate has to be made chemically clean—as good a method as any being to rub it well with prepared whiting and a strong solution of cyanide of potassium mixed up to the consistence of cream, then rinsing it with clean water, and drying and polishing it with a clean cloth.

"The cleaned plate is next coated with collodion, and the choice of a suitable collodion is a matter of some importance. Mr. De la Rue uses good commercial samples of plain collodion, iodized with iodide of cadmium only, and no bromide. The sample of plain collodion chosen should be more limpid than usual, for iodide of cadmium tends to make it gelatinous; it should also give an even film upon the glass, free from structural markings. The sample of pyroxyline from which it is made should be one which does not give a tough, strong film, but a film readily permeated by liquids. An iodide of cadmium collodion, when made from a pyroxyline which gives the highest sensitiveness, is very liable to spots and markings; and pure chemicals, absence of dust, and cleanly manipulations are necessary to get uniformly good results. Mr. De la Rue is very careful to have no traces of sediment in the collodion itself, for he says: 'Collodion should not be sensitized until after it has stood for at least a week after it has been purchased, and it must then be carefully poured into the mixing vessel without disturbing the sediment which is always present. It must be agitated occasionally for some hours after mixing with the sensitizer before it is set aside to rest and deposit the new sediment which forms. After standing

for a month or two it should be carefully decanted for use to the extent of three-fourths into a perfectly clean glass bottle. The plate, having been coated with collodion, is dipped into a bath containing 30 grains of pure fused nitrate of silver to each ounce of distilled water. This bath is perfectly neutral if the nitrate of silver has been carefully fused at the lowest temperature requisite for its fusion.

"The best way of effecting the fusion is to put about 60 grains of crystallized nitrate of silver into a small porcelain dish, heated by an air-flame gas jet, and as soon as the mass has melted pour it into about a quart evaporating basin, previously heated a little over 212° Fahr. (100° Cent.) By a rapid whirl of the basin the fused mass forms a thin ribbon easily broken with a glass rod. When broken it is transformed into a counterpoised stoppered bottle, and weighed at once for use. In preparing the baths the nitrate of silver, 600 grains, is dissolved in 2 ounces of distilled water, and to this a solution of 5 grains of iodide of potassium in about a drachm of water is added. The precipitate at first formed is soon redissolved. Eighteen fluid ounces of distilled water are added, little by little, and the whole agitated. A precipitate of iodide of silver separates, and it is allowed to deposit in the dark for twenty-four hours. The clear liquid is then passed through a filter previously washed with a little nitrate of silver solution. A bath thus prepared is at once in working order. When it becomes less sensitive, as it will do after a time by the accumulation of alcohol and ether and their derivatives, it cannot be restored by doctoring, so that when failures occur it is best to discard the old bath and to have recourse to a new one. Mr. De la Rue usually prepares about a gallon at one time, so as always to have a store at hand, for it may be kept for any length of time.

"The plate having been sensitized, is at once exposed. When pictures of the moon are to be taken the time of exposure varies considerably. When it is full moon and the atmosphere is clear, the pictures may sometimes be taken instantaneously, and in this phase an exposure of from one to two seconds is usually the utmost that is necessary. The moon, as a crescent, would require ten to twenty seconds' exposure under similar circumstances, in order to obtain a picture of the parts visible near the dark limb, and in order to get these dimly-illuminated portions in most perfection the brighter limb of the moon must be somewhat over-exposed. An almost imperceptible mist in the atmosphere will sometimes double the time of exposure. During this operation a clock beating seconds distinctly should be in the room, that the operator may be able to measure the time of exposure with accuracy. The planet Jupiter, when in opposition, is photographed in about five seconds; Saturn in from twenty to thirty seconds. The plate-holder, for exposing the plate to the luminous image, is made entirely of metal, and the circular plate, when placed in it, rests at portions of its edge upon three silver supports. This is a much better plan than letting the wet plate rest upon wood, because in the latter case impurities from the wood often find their way across the solution on the plate, and in the development stains and faults result. The plate-holder is well dried with a cloth before the next picture is placed in it. Above all things, in taking astronomical photographs, it is necessary that the sensitized plate should be placed exactly in the focus of the telescope. The focussing is first done approximately upon ground glass, but finally upon a silvered collodion film placed in the plate holder itself. The latter film is made by sensitizing a plate in the usual way, briefly exposing it to diffused light, then throwing down a light deposit of silver with the developer, washing, fixing, and drying. A few scratches are then made upon the film, which is placed in the holder, the image of the moon is allowed to fall upon it, and the focussing is done from behind, the operator making the picture come to focus on the film, while he makes the adjustments with the aid of a lens sliding in a tube, and in the first instance focussed on the scratches.

"After the plate has been exposed in the camera it has to be developed. Iron developers are of little use when the collodion, as in this case, contains no bromide salt, and Mr. De la Rue rejects them altogether, because he finds that pictures produced with them always show granulation, whilst negatives developed with pyrogallie acid will bear examination under the microscope. To get rapidly it is necessary to employ a weak retarding acid, and to use as little of it as possible. Mr. De la Rue makes his developer of pyrogallie acid 3 grains, glacial acetic acid 1 fluid drachm, distilled water 3 fluid ounces. In very cold weather the above quantity of acetic acid is reduced.

\* Formerly he used the extra-white patent plate, but this glass is so hygroscopic that many pictures have been lost by its absorbing moisture and destroying the collodion film; hence the use of this kind of glass has been discontinued.

After the picture has been developed it is never intensified, as in ordinary photographic operations, because some loss of detail in the image is always the result of such treatment, and thin negatives are best to produce enlargements. Lastly, the picture is fixed with hyposulphite of soda, and very thoroughly washed afterwards, for although a very faint trace of this salt left in the film might be harmless for some years, it would eventually cause the destruction of the picture. After the washing, the finished picture is put aside to dry.

"The picture of the moon thus obtained is only about 1 inch or 1 2-10 inch in diameter, according to the distance of the satellite from the earth. The greater the focal length of the telescope the larger would be the direct pictures of the moon obtained, so that with Lord Rosse's telescope it would be possible, by means of good clockwork and high class photographic ability, to get magnificent pictures of the moon between 6 inches and 7 inches in diameter. The great Melbourne telescope is provided with photographic apparatus, and will give pictures of between 3 inches to 4 inches diameter. Mr. Le Suen, who will have the direction of this instrument in Melbourne, has worked at Cranford, so as to familiarize himself with astronomical photography. Such pictures, if obtained, would be of scientific value. Mr. Warren de la Rue finds that parts of the moon which are equally bright to the eye do not reflect the chemical rays equally, for there is considerable difference in the intensity of these parts in the photograph. Jupiter and Saturn, as taken at Cranford, are small specks upon the photographic plate, and require a magnifying glass to show details. Saturn's rings, and the belts of Jupiter, are then distinguishable in the pictures.

"When an astronomical picture has been obtained and finished, it becomes necessary to render it permanent and safe from liability to injury. This is done by cementing a second sheet of glass in optical contact with the picture by means of Canada balsam, so that the film is protected like a fly in amber. A brass plate, about 18 inches long by 9 inches wide, is supported upon four legs, each about 8 inches in length. Lengthways, underneath the middle of the plate, is a gas-pipe with a row of holes along the top, giving a line of little jets heating the plate above. Levelling screws on the legs, and a circular spirit level laid for the purpose upon the plate, enable the latter to be adjusted in a truly horizontal position. The plate of glass is then laid picture side uppermost upon the brass plate, by which it is heated. A small circle, 2 inches in diameter, of plain, clean, patent plate glass, having also been warmed upon the brass plate, is then laid over the centre of the picture, but not so as to touch it, for a slip of thin paper has its end laid under the edge of one side of the upper glass. A few drops of Canada balsam are then allowed to drop upon the lower glass at the point where it is touched by the upper one. The balsam is rendered more fluid by the heat, and slowly travels on its way between the plates of glass, being drawn on by the force of capillary attraction. Slowly does it travel between the plates, and when it has gone a little more than half its journey across, the slip of paper is removed, and the balsam at last fills up the infinitesimal space between the upper and lower plate. This operation requires patience, as it takes about a quarter of an hour before it is complete, and when any feeding with balsam is necessary it should be added to that side where the upper glass touches the lower one. At the close more Canada balsam is applied round the edge of the upper plate, and the cemented picture is left for a little time upon the brass plate that much of the volatile essential oil contained in the balsam may be driven off by heat.

"The very perfect little photographs of the moon, having been taken as thus described, enlarged copies have been made of them upon circles varying from 18 inches to 38 inches in diameter, the latter being about the scale of Beer and Madler's large map. The photographic picture is necessarily the more accurate of the two, from the truthfulness of photography, and from the fact that draughtsmen cannot draw the moon in a short time, so that some portions of their pictures must be taken when the moon has turned itself a little out of its former position with regard to the earth. The copying camera, used to obtain the enlarged pictures, is of the usual construction. It is pointed to the north pole, a shutter opening in the roof of the camera-house for that object, for the sake of the steady light emanating from that part of the heavens, which light is allowed first to pass through a tube, that the rays may be parallel when they fall upon and illuminate the small, transparent photograph of the moon, lying at the bottom of the tube. Inside the

camera, a little below the illuminated negative, is the copying-lens, which throws an enlarged image of the little photograph upon a large sensitized plate at the bottom of the camera. The lens and small negative may be very accurately adjusted with respect to each other, a small microscope being brought into play in the operation. Generally, positives on the scale of 9 inches to the moon's diameter are taken in this way, and the pictures so obtained used for the secondary enlargements. In this copying process, as might be expected, there is some loss, details being visible in the little negative which are not fully rendered in the enlarged copy. Mr. Dallmeyer, the optician, has recently made a lens, which he says he thinks will render every detail without loss, and when it is received it will be rigidly tested."

## Proceedings of Societies.

### AMERICAN INSTITUTE.

At the May meeting of the Photographic Section of the American Institute, Mr. JOSEPH DIXON in the chair, after some general proceedings,

Mr. E. G. SQUIER detailed some experiences of photography in Central and South America. He expressed his conviction at the outset, that the traveller in the present day could not do his work properly without the assistance of photography. Travellers' tales became travellers' truths when the camera and lens were brought to their illustration and vindication.

He then proceeded to state that having accepted a mission to the Government of Peru, he resolved to take with him a photographer and photographic outfit. Soon after he had arrived in the country of his travels his photographer died, and he says:

"I found myself next day not only alone in the great American Thibet, but encumbered with a bulky apparatus and a large amount of material. To utilize them, I found no instruction except such as is contained in that lively and lucid book, 'Hardwich's Manual of Photographic Chemistry,' including [and here is where the laugh comes in] the 'Practice of the Collodion Process.' If you discover any silver streak in my beard, or other evidences of premature old age, you will now know to what to ascribe them. The last syllable of Mr. Hardwich's name is a pleonasm. Now I do not doubt that

is an exact formula, but it is not altogether a pleasing one to encounter when one is all alone among the Andes, with these mule loads of bottles and other things, which he must try to utilize, or surrender the object of all his labour and outlay.

"How I made baths and collodion in low thatched Indian huts, staining my fingers and spoiling my clothes; how my ether went off with a bang, on the shallow pretext of being too closely approached by the dimmest of all dim tallow dips; how my *Arriero* nearly died from taking a surreptitious swig of Atwood's 95° alcohol, and afterwards nearly murdered me by bringing glacial acetic acid when I asked for vinegar; how—But, gentlemen, if you want to know how, forget all you ever knew about photography, and go up among the Andes when the thermometer is 'steady' at zero, with three mule loads of chemicals and instruments, and 'Hardwich's Manual and Practice.'

"But badiage apart: How photography may be best utilized for the purposes of the traveller, it seems to me, is a problem worthy of engaging the attention of the practical professors of the art. Unfortunately, however, there are few of these professors who know all the difficulties which beset the traveller, especially in remote savage or half-civilized countries, where, perhaps, neither house nor hut is to be encountered for days and weeks, where the weather is forbidding and freezing, the earth over-shadowed by forests or overflowed by water, or else desolate and dry, and where, always, above all things else, transportation is expensive, difficult, or impossible to be had, and where the baggage of the traveller requires to be reduced to a minimum.

"The traveller does not expect to take fine pictures, to be exhibited as among the highest achievements of photographic art; but he wants to obtain fair results cheaply and rapidly; and to do this he must have his apparatus compact, dispense with tents, be able to get along for a reasonable time at least without water, and with the least possible amount of that heavy and fragile material called glass. He must also be able to do his whole work without assistants, who are seldom to be had, or, when had, are sometimes worse than none at all.

"But above all," continued Mr. Squier, "he wants a manual simple in language, clear in direction, brief as a primer, which shall tell him what to do, and not why anything is to be done. Many travellers have a certain knowledge of chemistry, and most a fair knowledge of things in general; but they seldom have the time or inclination to perfect themselves in photographic chemistry. They want the instruments and the materials, and plain instructions for their use."

Mr. Squier then proceeded to discuss the varying forms of equipment for the traveller, finally giving the preference to something of the character of a manipulating camera like that of Titus Albites, and promised, at an early date, to show one he had contrived. At the conclusion of Mr. Squier's communication the proceedings terminated.

#### THE PHILADELPHIA PHOTOGRAPHIC SOCIETY.

The monthly meeting of the Photographic Society of Philadelphia was held Wednesday evening, May 6th, 1868, the President, Mr. FREDERIC GRAFF, in the chair.

The minutes of the last meeting were read and approved.

Mr. BROWNE suggested that an appropriation be made from the funds of the Society, to aid the committee appointed at the National Convention of Photographers, held in New York April 7th and 8th, 1868, in their efforts to defeat the extension of the Bromido Patent. The sum of \$20 was appropriated for that purpose.

A paper was read, describing the work of the new Steinheil lens for landscape purposes, by Messrs. DAVIDS and BROWNE, and Mr. Davids made a few remarks about the new wide-angle Dallmeyer rectilinear lens.

Mr. TILGHMAN called the attention of the Society to a new process for intensifying negatives, advocated by Mr. G. Wharton Simpson, by the use of a solution of permanganate of potash. After fixing the negative, wash and place the plate in a solution of permanganate of potash, ten grains to the ounce of water, and allow it to remain for about ten minutes. Mr. Tilghman exhibited a negative, one-half of which had been strengthened in this manner, also a print from the same. The colour of the negative which had been acted on by the potash salt was changed to a yellowish red, almost impenetrable to actinic rays. Mr. Tilghman expressed himself as much pleased with the result, considering the idea of great value to photographers.

After the exhibition of some apparatus the proceedings terminated.

### Correspondence.

#### THE ACTION OF HYPOCHLOROUS ACID IN THE NITRATE BATH.

DEAR SIR,—My attention has been called to a passage in a letter from Mr. Carey Lea to a contemporary which runs as follows:—

"The suggestion made by Mr. Spiller, that the increased sensibility may be due to the formation of hypochlorous acid, seems to be quite incapable of support. For, firstly, it could not even continue to be present. It is an unstable substance, and the solution, if left for several months, as expressly directed by Mr. McLachlan, would not contain an atom of it—it would all have passed into the condition of chloric acid. But even putting aside this chemical difficulty, there is the photo-chemical objection, that neither chloric nor hypochlorous acid could aid in exalting the sensitiveness of the plates. Thus this view can neither be sustained on chemical or photo-chemical grounds."

I am disposed to think that the discussion on Mr. McLachlan's communication is now nearly over, and that photographers will scarcely need to revert to the general question; but in the passage in question Mr. Lea so strangely misapprehends the question at issue, and so completely misrepresents what I have said, that I must ask you to insert a word or two of correction.

The question of increased sensitiveness is for the first time introduced by Mr. Lea. I have never said that the presence of hypochlorous acid would induce increased sensitiveness. I said, on the contrary, that, being a powerful oxidizing agent, it would, if present, prevent fog, and, as all photographers know, bodies which would operate to prevent fog would tend to check rather than increase sensitiveness. I never said that hypochlorous acid was a stable body and would remain in the solution. I suggested that in the decomposition of chloride of silver, hypochlorous acid would be generated, and that its

oxidizing action would aid in removing impurities present in the nitrate, and might so effect in the end that Mr. McLachlan said was produced by the action of light on an impure sample of nitrate of silver, the description of which suggested the presence of chloride. Subsequent examination of a sample handed to me by Mr. McLachlan has confirmed my first conjecture as to the presence of a chloride.—Very truly yours,  
Woolwich, June 1st, 1868. JOHN SPILLER.

#### REMOVING THE COLLODION FILM USED IN TRANSFERRING ENAMELS.

DEAR SIR,—In last week's NEWS I notice that you refer to the difficulty experienced in getting rid of the film of collodion which has been used as a support in transferring the pictures in Joubert's and other enamel processes, as such a film resists the action of the ordinary solvents of collodion.

This difficulty, however, may be entirely obviated by submitting the plate of enamel or porcelain on which the picture, embedded in the collodion film, is mounted, to a gentle heat at first, then slowly raising the temperature, and, when at the proper point, the film, it will be observed, has been consumed. The only care necessary for the success of the operation is that the picture be carefully mounted, with no air-bubbles underneath it, and that the rise in the temperature should be very gradual.—I am, dear sir, yours truly, W. T. WATSON.

### Talk in the Studio.

PERMANGANATE FOR RECTIFYING THE NITRATE BATH.—The various reports which have reached us of continued experience with nitrate baths treated with permanganate of potash are decidedly favourable to its use, although in some cases the plates are said to be less sensitive. Mr. Bartholomew writes:—"I some few weeks ago made a bath with rain water treated with Condy's fluid; it worked pretty well, but certainly slower than my usual ones, and on leaving a plate in all night (inadvertently) I had a fine crop of acicular crystals on it. I then made it alkaline, and sunned it for a day, and added about 5 grains chloride barium, filtered, and it works much quicker now, and perfectly free from fog, although I have put no acid in. Next bath I make with distilled water I shall try the chloride barium in place of nitric acid, after Mr. Spiller's experiment."

MAGNESIA TONING BATH.—Mr. Bartholomew also says:—"Do you hear of many that adopt the toning bath made with magnesia? I find it far easier and more certain than any other. I dissolve the gold in aqua regia, and neutralize with common magnesia carb., and it seems always alike, and keeps well."

STOPPING-OUT SKIES, ETC.—A correspondent says:—"Some time since a gentleman advocated smoking the backs of negatives, to obviate imperfections, &c. I find it is the easiest way of blocking-out a negative that I know of. One can follow the outline with a pointed and stiff brush to perfection."

A BANKRUPT PIRATE.—At the Court of Bankruptcy, before Mr. Deputy Hazlitt, William Banks Prince, a printseller, carrying on business at 307, High Holborn, made application for release out of custody. Mr. G. Lewis, Jun., opposed on behalf of Mr. Graves, the well-known printseller and publisher in Pall Mall. He said that the debtor was convicted on the 16th of May, and sentenced to pay nineteen penalties of £5 each for infringing the copyrights of various photographs, engravings, and prints, the property of Mr. Graves, including the copyright of the engraving called the "Railway Station." In default of payment the magistrate directed the debtor to be imprisoned for the period of fourteen days for each offence, and a warrant for his commitment was accordingly issued. Immediately upon judgment being given in the summons in the first case the debtor executed a deed providing for payment to his creditors of 2s. in the pound by instalments. In opposition to the application Mr. Lewis contended that the Court ought not to interfere—certainly not until time had been given for the examination of the debtor, and the creditors said to assent to the deed, which, it was believed, had been concocted for no other purpose than to defeat Mr. Graves. His Honour held that he ought not to delay the release for an indefinite period, pending an inquiry into the deed, and he should grant the application. Mr. Lewis asked that the order might be stayed forty-eight hours, to enable him to appeal, and the Court granted the application.

## To Correspondents.

**DINSDALE AND CO.**—We have received a letter from these correspondents in reply to the recent note of Mr. Griggs on the subject of photo-lithography; but as it is exclusively devoted to the consideration of matters of a personal character, uninteresting to the public, and is discursive in tone, we cannot give it insertion in our columns. In substance, the object of the letter is to deny the truth of a statement, in Mr. Griggs' note, that he had taught Mr. Dinsdale photo-lithography. Whether he did so or not is unimportant to the public. To this denial various allegations of the incompetency of Mr. Griggs are added, which allegations, from the successful public exhibition of his powers, we are indisposed to accept as true, and should therefore act unfairly in publishing the statements. That our correspondents offered to undertake commercially the photo-lithography upon which Mr. Griggs was engaged at the Indian Museum, and that their offer was not accepted, is scarcely a matter of public interest. The letter concludes as follows:—"We hope, Mr. Editor, you will permit us to be present at the printing of the proposed 'silver surface stone,' when we shall be happy to supply your readers gratis with the results so illustrated after the first hundred pulls." Messrs. Dinsdale and Co., in a former letter, intimated that it was impossible to produce a drawing in chalk upon a stone upon which a silver photographic image had been produced. They now suggest that the thing is possible, but that it will not yield more than 100 impressions. This is a question which is more interesting than any personal discussion, and the practical decision of which we hope shortly to be able to announce.

**PHOTOGRAPHY.**—Mr. England's studio is in St. James's Square, Notting Hill. He does not, we believe, print for the trade.

**A LONDONER IN IRELAND.**—You are familiar, doubtless, with the various formulae for lime toning baths which we have given from time to time, and lime is the oxide of calcium. The calcio-chloride of gold is a double chloride of gold and calcium.

**W. J. A. G.**—If you require one lens for all purposes the triple is best, and it has really no fault; but if it be required for landscape only, in which straight lines are not important, a single combination will give a more brilliant image. We should prefer to have both, but if we had to select a lens for universal use, it would be the triple. Exaggerated perspective does not necessarily belong to wide-angle lenses, but is often incidental to their use. It is due to the use of lenses of extremely short focus. If, for instance, you use a wide-angle lens of 10 inches focus, and an ordinary landscape or portrait lens of 10 inches focus, and produce a picture of the same size with each, the quality of the perspective will be the same in both cases. We cannot give absolute advice as to the most suitable lens to get, unless we know what your friend has already, and the subjects to which his attention during his tour will be especially devoted. 3. Of the tents you mention we decidedly prefer No. 2, as combining the greatest number of advantages.

**J. R.**—As to the keeping of plates by Mr. England's process, much depends on the details of preparation and on the temperature. In hot weather Mr. England used more dilute albumen and more dilute silver solution. He has kept the plates a month or more; but, as a rule, they are better prepared and developed within a week if the weather be very hot. In cold weather they will keep much longer. The general experience seems to be that if they are long kept they require longer exposure.

**NZO.**—The method we have generally employed in stopping-out a sky when necessary is as follows:—After varnishing the negative, the lower part of the sky to the horizon is stopped-out with water colour, using lampblack generally: a band of about a quarter or half an inch of this is sufficient. The remainder of the sky is then stopped-out at the back, either by means of black varnish, or a mask of blackened silver paper. Sometimes we find that the whole stopping-out can be best effected by a mask of very thin excited albuminized paper, blackened by light. With skill the outline can be sufficiently carefully followed (the image having been first printed on the paper) to place this in contact with the face of the negative.

**A. PARRY.**—From the irregular shape of the dense spot in the middle of your negative it is not probable that it is flare, unless you were using an improvised and irregularly-shaped stop. It is probably the result of a drop of nitrate of silver having fallen on the face of the negative after the developing solution has been drained off. This would in many cases produce a dense spot. A dirty plate might cause a similar result. 2. The Amateur Photographic Association's address is at 12, York Place, Portman Square, W. Mr. Melhuish, the Secretary, will give you all particulars if you write to him at that address.

**R. B.**—The chief disadvantage of using only salts of cadmium in collodion is, that they have a tendency to produce a glutinous condition, which renders it difficult to obtain an even film. To obviate this a sample of cotton giving a thin limpid collodion should be employed, or else the collodion should be kept for many months, during which time it gradually becomes more limpid. 2. The quantity of cotton must depend upon its quality. With some samples the collodion is quite thick enough with 3 or 4 grains per

ounce; with others 5 or 6 grains, or more, will be required. We, as a rule, prefer a sample in which 5 or 6 grains give sufficient body. 3. The authority is not trustworthy.

**X. X.**—The time allowed for either the gallic acid or the gum solution to remain upon the plate before draining is not, we believe, important; about a minute or two in each case. Mr. Gordon's experience is that the film becomes loosened from the plate during the various processes of developing, fixing, and washing, remaining attached to the varnished edge; but not that it blisters. In his experience the finished negative shows no trace of the effect of the loosening, but that it dries evenly without either marks or wrinkles. 2. The extra amount of bromide is to be added directly to the collodion. We will consult Mr. Gordon as to the blistering, and let you know his opinion in our next.

**FRED YOUNG.**—See answer above. Mr. Gordon's opinion will, doubtless, help you, and we hope to give it in our next.

**M. D.**—The excessive washing of prints before toning often increases toning difficulties. We prefer a slight washing, but neither the use of a chloride nor a prolonged washing in common water. 2. Always wash the print between toning and fixing. It is a good plan to immerse the print in a solution of carbonate of ammonia before placing in the hypo bath. A long immersion in weak hypo is not desirable. Use a strong hypo bath; not less than one ounce in four of water. Wash the prints well in several rapid changes of water before placing them in the washing machine. 3. It is very much a matter of taste. We generally prefer a warm tone; a good black is suitable to some subjects; but a blue or inky black is, to our taste, always unpleasant.

**D. D. D.**—Our own experience with the collodio-bromide process is too limited to decide absolutely as to the cause of your difficulties. We have used collodio-bromide made by ourselves, and used without a few hours of mixing, and we have used it after having been made some days by Mr. Sayce, and, in each case, with success. Those who have had experience in the process lay some stress on the bromized collodion having been prepared some time before working. The use of hot water having proved useful in Mr. Sayce's practice, we should recommend you to adopt it, although it is possible to succeed without. 2. The tannin should be allowed to soak into the film for three or four minutes. 3. These plates may be employed for enlarging upon, but the time of exposure can only be learnt by experiment. 4. If you make your own collodion, dissolve the bromide first in the alcohol; if you buy your plain collodion, add the bromide to the proportion of alcohol which would be usually employed as the iodizing solution with the collodion in question.

**VIGNETTE.**—A very light grey painted in distemper or oil-flattening will give a good background for vignettes. Unbleached calico, without any paint, may be used, but the background must, in that case, be kept some distance behind the sitter. For a curtain, either damask, or moreen, or velvet, or repp, or tabaret, or any of the materials commonly used for curtains in dwelling houses, may be used. Maroon, or brown, or green, may be used with advantage.

**LITTLE STUDIO.**—The discolouration in the print forwarded is due to imperfect fixation. It has apparently been immersed in a weak or exhausted hypo bath. Use strong fresh hypo solution, and never use it a second day.

**MR. WARNER'S MOUNTING BOARD.**—We have examined the tinted mounting board, with a sample of which Mr. Warner favoured us. It is found, on testing, to contain a very minute trace of hypo; insufficient, probably, to cause any injurious action, the more so that it is only obtained after long soaking, and is probably due to the white paper which forms the inner portion of the board.

**J. H. R.**—It is probable that your sample of Castile soap has not been pure, but has contained alkali in excess. The precipitate you have obtained is not pure oleate of silver, but is probably a mixture of oleate of silver and oxide of silver. We find it partially soluble in alcohol, leaving a brown residue, which, on examination, will probably be found to be oxide of silver. The late moment at which your letter arrived does not permit full examination this week. For use with the collodio-bromide of silver you will probably find it less trouble to add a little alcoholic solution of soap to the collodion, or even to add a little pure soap in shavings. We have found that method answer with collodio-chloride of silver. 2. Probably the simplest and most convenient actinometer would consist in a piece of paper prepared with collodio-chloride of silver, and observing the time required to colour to a certain standard light tint.

**FOURTH VOL.**—We cannot tell you how far it is probable that you will find a market for a series of stereo negatives, nor their probable value; it is a question dependent upon so many circumstances. You can only learn by enquiry of probable buyers. Try the Stereoscopic Company. 2. The patchy effect of red and blue which you describe is due, of course, to irregular toning. This may arise from some imperfection in the paper; or from handling the prints before toning with soiled fingers; or from the prints sticking together in the toning bath. There is no remedy for such defects after they are produced. 3. "Nitrate of magnesium" is simply an incorrect mode of phrasing nitrate of magnesia. We have not tried Newton's printing bath. Several correspondents in our next.

## SIMPLIFIED MANIPULATIONS IN CARBON PRINTING.

THE growing appreciation of the beauty of carbon pictures as examples have become more familiar, and the inevitable conviction of their permanence, which forces itself on candid minds after the fullest examination of the subject, has had a tendency to induce many experimentalists to strive after some simplified method of manipulating, the double process of transfer necessary in Swan's process suggesting at the outset a complication of troubles from which the novice shrinks. That these transferring processes, or any other of the operations, really involve any serious difficulty is, as all who have practised the process a little know, altogether a mistake. When once everything is prepared, and the manipulations understood, the operations are easy, systematic, and certain. Nevertheless, each step towards simplicity will popularize the process, and if simplified methods are possible, it is important to give them the fullest consideration, bearing in mind always that the simplicity which sacrifices one iota of excellence is not worthy of cultivation.

Mr. Arthur Taylor, of Marseilles, recently called our attention to a method of working, which, although yielding less delicate and sharp results than Mr. Swan's, was, he found, valuable for the purpose for which he specially required it—the rendering of architectural subjects. The method he has employed is simply an adaptation of the old method of printing through the paper coated with bichromated gelatine and pigment. The chief difficulty in this method, as those who have worked in this direction know, is, that the paper, being yellow from contact with the bichromate, is so non-actinic that it is almost impossible to print through it; an exposure of some hours being frequently necessary. Mr. Taylor has found that if, after exciting the carbon tissue by immersion in a solution of bichromate of potash, it be transferred to a dish of clean water, the excess of bichromate which stains the paper yellow is readily dissolved out, without removing that which has been absorbed by the gelatine, and which it would require prolonged washing to remove. A piece of tissue treated in this way will print in sunlight, using a calotype negative, in five minutes, yielding a good print.

The other difficulty of this mode of working consists in the loss of a certain amount of sharpness and of delicacy, inevitable in printing through paper, the texture, of course, being necessarily rendered in the print. Mr. Taylor finds this difficulty minimized, and, for architectural purposes, sufficiently removed, by using for the basis of his carbon tissue a thin fine *Saxe* paper, which is comparatively free from structural markings or inequalities. It will be seen that for some purposes this mode of working can be made with scarcely any trouble, and that all transferring is unnecessary. A reversed negative will of course be required.

Regarding some other proposals for securing simplicity, we may quote the suggestions on the subject from the letter of our excellent friend and *collaborateur*, Dr. Vogel, in our *Philadelphia contemporary*. He says:—

A drawback to the carbon process, which new beginners particularly are apt to mention, is the necessity of two transferring processes. First, the picture is transferred to caoutchouc paper to be developed, and next, from the caoutchouc paper to white cardboard or paper.

The latter transfer is necessary, on account of the ugly yellow colour of the caoutchouc paper, and also because right and left in the picture would be reversed without it.

The reversion could be overcome by reversed negatives, but the yellow colour of the paper is very objectionable, and this has given rise to the employment of other materials, as resin, for instance, albumen, collodion, &c.

All these experiments started with the belief that an adhesive medium was absolutely necessary; and I myself was of the same opinion.

I demonstrated, however, on a former occasion, that for the transfer of the developed picture from the caoutchouc to the white paper no medium was necessary. Swan went to the useless trouble of covering the paper with gelatine.

This circumstance led me to suppose that for the transfer of the undeveloped pigment film, the adhesive substance might be dispensed with, and experiments in this direction have confirmed the correctness of my views.

Carbon tissue, of Beyrich's manufacture, was exposed under a negative, placed at once in the rolling-press with moist paper, left to dry for an hour, and then developed.

The picture showed perfect on being transferred to white paper, and developed easy, giving all the half-tones. Only at the edges the film showed some tendency to peel off, which, however, could be prevented by proper manipulation.

The whites were faultless. It was curious, however, that the trouble with all beginners, bubbles, made their appearance. This demonstrates, evidently, that the caoutchouc paper is not the cause of bubbles, as has often been stated, but that they are a peculiarity of the gelatine film which forms the picture.

In transferring to caoutchouc paper, they are avoided by long soaking in cold water, previous to development. If, in the new process, they can be disposed of in the same manner or not, I will have to determine by further experiments. The result you shall hear in due time.

The method of mounting the carbon tissue here described, without india-rubber, will, as Dr. Vogel states, require fully verifying in practice before determining its practical value. We have not tried the plan of mounting without any adhesive material, but in the early stages of the process we tried several substitutes for india-rubber, but without in any case sufficient success to induce us to continue the practice. Starch paste, gelatine, albumen, collodion, and solution of shellac were all tried in turn; but none were comparable to india-rubber. We believe that Mr. Swan went through a similar series of experiments with a similar result.

The question of effecting the final transfer without the use of gelatine, and without waiting until the developed print has dried, is interesting; but its success depends upon certain conditions, which should be well understood. In our earliest experiments we attempted this mode of transfer

with success. We found the material of which the developed image was formed, although insoluble, sufficiently gelatinous to adhere to a wetted sheet of paper pressed into gentle contact with it. On mentioning the matter to Mr. Swan he pointed out the difficulties and dangers of this mode of working. The first danger consisted in applying pressure, which might readily destroy the sharpness of the image in the soft and plastic state in which it remains whilst wet after development. Another and more serious difficulty consisted in the fact that a carbon print is really an image in relief, the whites and delicate half-tones forming hollows, and the deepest blacks high ridges. Mr. Swan found that in final mounting some material should be used which would fill up the fine interstices which frequently occurred between two deep ridges of gelatine and pigment, otherwise the contact in the final transfer would be imperfect. This difficulty he subsequently found is, however, got rid of to a great extent by using thin paper in the last transfer, which readily adapts itself to the inequalities of the image, and permits perfect contact. Dr. Vogel has also found that this mode of final transfer without gelatine is practicable and successful.

A mode of transferring without the aid of a press, which Mr. Swan has found successful, is described in his article in our last YEAR-BOOK, from which we may make some extracts here.

Of the various methods of effecting the transfer without the use of a press which I have tried, the following has given me the most satisfactory results:—

After the complete development of the prints, I immersed them in a warm solution of gelatine consisting of—

Gelatine	...	...	...	...	...	4 parts
Water	...	...	...	...	...	100 "

to which may be added (after the solution of gelatine has been effected) one part of a 10 per cent. solution of sulphate of chromic oxide.

In this solution I also immersed the sheets of paper to which the prints are to be transferred. I find it most convenient to have only two prints and two sheets of paper in the solution at once. I draw the prints repeatedly through the gelatine solution, with the view of displacing the water lying upon their surface, and I brush, with a broad camel-hair brush, that side of the paper which will be brought into contact with the print, so as to displace air, and cause the gelatine solution to penetrate the paper. I then draw the brushed surface of one of the sheets of paper into juxtaposition with one of the prints, and similarly the other print and other sheet. This is of course done while the prints and sheets are immersed; and in bringing them together, I take particular care that no air-bubbles are enclosed between. Before their removal from the solution I lay the prints back to back, with the sheets of paper covering them on the outside, and, thus arranged, I slowly raise the pack out of the solution, and suspend it to a line by means of American clothes-pins, and when the prints are partially dry I separate them. When the drying is complete, the caoutchouc paper may be removed as usual, or its removal may be deferred until the print has been mounted upon card.

The paper that I have found best for this process is *very thin*, similar to that used for letter-copying books, but finer in texture and stronger in fibre. It must not be strongly sized. Owing to the ready penetration of the gelatine solution into this kind of paper it will be more or less transparent when dry, and the print will not look well until mounted upon white card. It will not be necessary to treat with alum if the solution of chromic sulphate has been added to the gelatine solution.

One or two precautions must be observed in order to insure success:—

1. In drawing the prints and attached paper out of the solution of gelatine, it is necessary to avoid anything like wrinkling or bulging of the thin paper; this will be accomplished by drawing the prints out of the solution slowly.

2. The prints must not be hung up to dry singly, but in pairs, as described, otherwise the caoutchouc paper will dry more quickly than the thin paper, and, as a consequence of this, will contract, and in doing so will cause the thin paper to pucker.

3. The pairs of prints must be separated before they become so nearly dry as to adhere strongly together.

It is not imperative that the transferring by this method should be done immediately after the prints are developed. The transferring operation may, if more convenient, be deferred until after the prints have become dry.

I would not have it understood that I *prefer* this method of transferring to that in which the press is used, but (at least, until I have had a longer experience of it) I should only recommend this new method where the means are wanting of performing the old one perfectly.

## SOME HINTS ON BACKGROUNDS.

In describing the studio of M. Adam-Salomon, we pointed out that much of the fine effect of space and distance in his pictures was obtained by placing one portion of his background screen in shadow, whilst another portion was well lighted, and that a canopy over-head served to cut off top-light from the head of the sitter, and to keep the upper part of the background in shadow.

We recently saw an excellent arrangement for effecting the latter purpose in the studio of Messrs. Robinson and Cherrill at Tunbridge Wells. A canopy attached to the background, and projecting three or four feet, was worked with a cord and pulley with a counterpoise weight, so that the canopy could be placed at any angle, and so regulate the amount of light falling on the head of the sitter and the background screen. If the canopy were allowed to project from the screen at a right angle, it protected the head from a considerable amount of light, and kept the upper portion of the background in shadow. If the string were pulled, the projecting end of the canopy was raised, and more light was admitted, until, when necessary, the whole of the screen became lighted, and a flood of light reached the head of the sitter.

Mr. Robinson had just been using a capital material for painting backgrounds, which, in producing scenic effects, was very valuable, inasmuch as, although it dried perfectly flat like ordinary distemper, it permitted the same kind of working as oil paint, which, from its slow drying, allows the artist to work into the wet colour, producing soft effects difficult to attain in distemper. The vehicle used instead of size was thin flour paste, to one quart of which an ounce of glycerine was added. Those of our readers who produce their own backgrounds will find this vehicle valuable.

Dr. Vogel, speaking of backgrounds and accessories in our Philadelphia contemporary, says:—

The pictures of Adam-Salomon are, with us as with you, the photographic town-talk, and really every new picture of his teaches something new. It is surprising with what simple means the man produces such marvellous results.

Many of our photographers believe that much helps much: pillars, mantelpieces, pilasters, large bureaux, chairs, and tables, are carried together, and one is sometimes surprised how the person managed to find room between all these articles. To leave nothing empty, a screen painted with decorations and flourishes is placed as a background, and, in order to complete the whole, a chandelier, the arms of which look like two horns growing out of the head of the sitter, is suspended from the ceiling.

Of all these gimcracks, Salomon has nothing: a table, a chair, a pillar, perhaps—that is his whole stock of accessories; and what superb pictures he makes with these! I do not mean to condemn all accessories; on the contrary, I acknowledge that there are backgrounds which produce wonderful effects. If we examine the portraits of Reutlinger we will find that particularly those with landscape backgrounds have a wonderful plastic effect.

The rather darkly-painted backgrounds are only superficially executed—I might say, daubed sketches—without any of the details of a picture. At first sight we hardly know if trees or clouds are represented; this sounds paradoxical, but the main point is, the pictures have a good effect.

The figure has a fine plastic appearance, and the want of sharpness in the background is, strictly speaking, an advantage, as it increases the relief of the figure.

My friend, Grasshoff, who is a very skilful background painter, tells me the best colours for backgrounds are Cassel's brown, mixed with more or less washed chalk. All other colours are superfluous. Persons buying a background will often find that some parts take too well—i. e., become too light, others too dark. It is only necessary to rub over the places which become too light a little powdered gold ochre or umber, and to paint the dark spots with some precipitated chalk. Many faulty backgrounds have been doctored in this manner.

## SMALL NEGATIVES AND ENLARGED PRINTS.

On Tuesday evening Dr Mann brought before the Photographic Society the mode of working employed by Professor Piazzi Smyth in obtaining his photographs of the Pyramids. This, as some of our readers may know, consisted in the production of negatives about an inch square, with a view to subsequent enlargement. The camera was made

of tin, and was about 8 inches long, upwards of 6 inches, however, acting simply as a hood or screen from the sun. A double combination lens of nearly 2 inches focus was worked at different times with an aperture of one-fifth, one-tenth, and one-twentieth its focal length. As, under the circumstances under which Professor Smyth worked, focussing with such a lens would have been difficult, if not impossible, a measured scale, determined beforehand, was used for adjusting the focus.

The bath, which was the especial feature to which Dr. Mann called attention, was made of ebonite. It was 4 inches high, 2 inches wide, and five-eighths deep, and was so arranged that the plate should occupy a definite and fixed position, as the exposure took place whilst the plate was in this bath, having been, however, previously sensitized in another bath; the whole equipment, besides that already described—collodion, nitrate bath, developing bath, and fixing bath—all being contained in three or four pomade bottles.

The especial reasons for adopting this mode of working in Professor Smyth's case were several. He wished to secure the rapidity of the wet process without its usual impediments; and, working at a high temperature and amid clouds of dust, he felt it desirable to effect all the operations and produce a completed negative without exposing the sensitive wet film to the hot and dusty atmosphere.

With the care and precision employed by Professor Smyth, he obtained very good results. The photographs produced from the negatives are transparent collodion positives on glass, enlarged about three diameters, and possessed very respectable definition, confessedly less perfect, however, than that of pictures of similar size obtained direct. The question, how far negatives sufficiently defined to bear enlarging without appreciable loss can be produced by the use of apparatus sufficiently small and portable to be carried by the tourist without inconvenience, is an interesting one, especially to amateurs. With the professional landscape photographer, the production of negatives is the end and purpose of his journey, and to that end trouble is quite subsidiary; with the amateur, the production of negatives is often merely an incident of the journey, and it is desirable that it should not interfere with health or pleasure. The generally expressed opinion of practical photographers on Tuesday night seemed to be that the apparatus was a pretty plaything, and little more. This opinion has been frequently expressed of the apparatus for completing all the operations within the camera, introduced a few years ago in Paris. Nevertheless, we think it not impossible that such a mode of working may be adopted with results sufficiently satisfactory for most amateur purposes. The chief objection we see to the results exhibited on Tuesday night is their unnecessary smallness. Few photographers would be content that their largest finished pictures should not exceed three inches square, and yet the negatives one inch in diameter, and enlarged three diameters, had lost quite sufficient to be appreciably worse than pictures of the same size taken direct. In enlarging, every defect of structure in the original negative is amplified in equal ratio with the image, and this magnified structure gives a degree of coarseness to a small picture which would not be observed in a large picture. A negative of three inches diameter, for instance, enlarged three diameters, would give a fine picture, in which the physical defects of the negative, still being only three times magnified, appear insignificant when compared with the size of the picture. We strongly recommend photographers contemplating working in this direction to bear these facts in mind. Negatives of three inches diameter, taken with care, will yield prints of 10 by 8 inches, in which the loss of definition is no serious pictorial evil; but with negatives much less than this, all results we have seen are far from satisfactory, especially if prints on paper are required.

By far the best apparatus for producing wet plate negatives without a tent which has come under our notice is that invented by Mr. Barrett, and described in our pages a few years ago.

## PHOTOGRAPHIC NOVELTIES.

WHILST the pressure of commercial inactivity has been much felt by photographers, it becomes matter of some surprise that so few novelties are attempted in this country, few photographers giving attention to anything outside their own groove. So far as we can learn, the occasional novelties which are introduced from the Continent have a remunerative sale. Surely the hint is worth the attention of some of our readers. Dr. Vogel says:—

"In Germany, photographers have made, of late, quite a successful speculation in a series of original articles, which have found quite a large and rapid sale. To this class belong, particularly, the flower pictures. These are photographs taken from natural flowers coloured with Jacobsen's aniline colours, and either of card or cabinet size.

"Similar are the bird pictures, taken from stuffed birds. The Latin name is printed under these as well as under the flowers, which makes them well adapted to instruction in natural history.

"Still another class are workshop scenes. These represent workshops, with all the men in full activity. For this purpose a whole workshop is built up in the gallery. Stereoscopic pictures are generally taken from these groups.

"Loescher and Petsch are preparing an edition of similar stereoscopic pictures: the most of them represent pretty little girls in various occupations, as reading, gathering flowers, &c., &c. It is curious that none of these speculations are long-lived; for two or three years the pictures will sell well, until some poor photographer will flood the market with miserable, trashy imitations, which are sold for a trifle; for a while the low price will attract purchasers, but when they find that they have been cheated, their taste for the article will be gone."

## Foreign Miscellanea.

THE new sensitizing material known under the name of the *Sel Clement* still occupies the attention of photographers in Paris, and in the last number of the *Moniteur de la Photographie* appears a letter from M. J. Laurent, giving his experiences of its employment in large quantities. That gentleman states that in sensitizing 405 sheets of paper he employed 1104 grammes of material, equal to 2.72 grammes per sheet, the paper weighing 20 lb. per ream. The bath used was of 18 per cent. strength, and, therefore, very rich; if a 15 per cent. solution was used, which is amply strong enough, and the paper employed was that in general use by photographers, weighing but 16 lb. to the ream, the *Sel Clement* would be found to be an economical sensitizing agent, as not more than 2 grammes or 2.30 grammes would be expended per sheet. By having recourse to ammonia vapour the tone of the prints gain very considerably in brilliancy, and the printing is greatly accelerated. The sensitized paper is put into a dark box and exposed to the influence of a little ammonia contained in a saucer for a period of three or four minutes; the time and trouble expended in this operation are amply compensated by the rapidity with which the prints are produced and the increased beauty of the pictures.

At a recent meeting of the Marseilles Photographic Society, held on the 1st April last, M. Taylor communicated the results of a series of experiments he had made with a view of obtaining carbon pictures by direct printing. He had carefully studied the influence of a greater or less quantity of colouring matter introduced into the gelatine, and he had obtained the most surprising results by the addition of very minute quantities. By immersing the sensitized paper into a water bath for the period of about five minutes prior to its being printed an improvement in the results was secured, for it was found that the excess of bichromate of potash, which imparted a yellowish tint to the picture and militated against its softness and rapidity of production, was thus elimi-

nated. By this method of proceeding M. Taylor was able to obtain prints possessed of great delicacy. This preliminary soaking in water was objected to at the meeting by M. Vidal, who was of opinion that, although it might possibly be beneficial for thick papers, for a thinner material it was unnecessary and even injurious. He had essayed with sensitized tissue paper, and had found that the process of washing had rendered his material perfectly insensitive. In all these experiments the pictures were produced by direct printing; that is to say, by printing through the paper material.

M. OBERNETTER communicated to the Berlin Photographic Society an account of the success which has attended M. Beyer's (of Warschau) efforts to obtain photographs in colour by M. Niepce's process. M. Beyer used a coating of sulphate of quinine to endow his pictures with permanence, and M. Obernetter was sanguine of being able to render his own paper applicable to the production of these pictures. Dr. Zenker was of opinion that sulphate of quinine was incapable of efficiently protecting the colours, as it had the effect of stopping the ultra-violet rays only; but believed that the Obernetter paper might possibly be employed in the process; and Dr. Vogel reminded the Society that Mr. Simpson had been able to secure colours by his collodion-chloride process.

In the *Mittheilungen*, M. Kleffel publishes a paper on the recovery of silver and gold residues, in which he recommends the covering of operating tables and shelves upon which utensils containing silver solution rest, with filtering-paper, to absorb any spilled liquid, and the reduction of all residues direct into metal instead of first converting them into chloride.

## PHOTO-ZINCOGRAPHY IN PRACTICE.

BY J. WATERHOUSE, R.A.

### INTRODUCTORY REMARKS.

EVER since the introduction of photography there has been a desire to possess a ready means of superseding the draughtsman and engraver in producing copies of views and works of art, which may not only preserve the accuracy of the photograph, but may be capable of being printed in either of the usual modes, and thus possess the permanence of ordinary prints and engravings. Much has already been done, but we are still searching for a satisfactory method of producing photo-lithographic copies of views, &c., in half-tone. My own opinion is, that no satisfactory results can be obtained in this direction except only for copies of inscriptions and architectural subjects. As regards views, the standards of pictorial beauty in photographs and engravings or lithographs are perfectly different. The dark foregrounds, black masses of trees, and the white patches of water and sky so common in ordinary photographs, cannot be tolerated in the plain black-and-white of a photo-lithograph, in which the delicate half-tones which constitute the charm of the photograph are more or less destroyed. At the same time a photographic image may be produced in half-tone on the stone which can be touched-up by an artist, and satisfactory pictures produced. There is now the less need of any further steps in this direction, since by Mr. Woodbury's beautiful process prints possessing the most delicate half-tones, and identical in appearance with photographs, can be produced as fast as ordinary lithographs. In photo-lithography with half-tones the best results have been produced by MM. Marechal and Tessie du Mothay. Their process, however, can scarcely be called photo-lithography, and but few prints can be pulled. Messrs. Asser and Simonon and Toovey have also produced good results. Some prints I have seen produced by M. Lemerrier, of Paris, who was sometime proprietor of Poitevin's patents, were full of delicacy and softness, but they were copies of plaster casts. In England some excellent results in half-tone have been obtained by photo-zincography at the Ordnance Survey Office, Southampton. There is no great difficulty in the process, but success depends entirely on the quality of the negative and

the suitability of the subject. For those who are interested in this application of photo zincography I shall give a short description of the process as practised at Southampton.

It is now generally recognized that the most useful and successful application of the photo-engraving, photo-typic, photo-lithographic, and photo-zincographic processes is to the reproduction to any required scale of hand-drawings or engravings and other works of art in line. The field for their use is very large, but it is surprising that these processes have not been more extensively practised in England than has been the case.

Their use is almost restricted to a few Government establishments, where the saving of labour and expense has been found to be very great. At Southampton photo-zincography has been extensively used in the reproduction of the national records of England and Scotland, and the Domesday Book. At Woolwich great use is made of photo-lithography to reproduce drawings of artillery material, &c. At the India Museum photo-lithography has been most successfully applied to the reproduction in chromo-lithography of the beautiful tissues and shawl fabrics of the looms of Delhi and Cashmere, and also in copying Sanscrit manuscripts, &c. On the Continent these processes have been far more used than in England, and are practised commercially with the greatest success. Among the photo-lithographers may be mentioned MM. Marie and Lemerrier of Paris, Simonon and Toovey of Brussels, Korn of Berlin; while in France, Messrs. Amand Durand, Placet, Garnier and Salmon, and Baldus have carried the art of photo-engraving to high perfection. Some fine specimens of maps in photo-lithography have been published by the Belgian Government, and, I believe, the same process is extensively used by most of the Continental Governments.

Photo-zincography has also been adopted by the Survey department in India, and is now successfully used in the reproduction of maps for district officers, engineers, &c.

I do not intend to enter into any account of the history of photo-zincography, but simply to give the *practical* details of the process, so as to render it capable of being worked by amateurs. There is a general prejudice in favour of using a lithographic stone in place of zinc, but I think that zinc will be found most useful for amateurs. It is said that corrections cannot be made on the zinc—that it has an unpleasant colour. In practice, however, I have not found any difficulty that might not have occurred with stone. Zinc has the following advantages over stone:—

1. It is cheaper than stone.
2. It is harder and more compact in grain, and, consequently, more readily worked, and resists the etching and pressure better.
3. It is not broken by rough usage or heat, and is more portable and less fatiguing for the workman.
4. Zinc plates can be stowed away in about one-sixth of the space required for stones, and do not require so much care in preserving the drawings from damp and weather.

I believe the cause of the dislike to zinc printing is that the details of working it are not generally known, and I trust these papers may contribute to further knowledge of the subject. The process I shall describe is identical with that practised at the Ordnance Survey Office, Southampton, and of which an account was published some time ago by Sir Henry James. I have lately worked the process practically throughout, at Southampton, and have had some experience of its difficulties in India, which has led me to adopt a few modifications of the original process.

My object is to draw attention to a process which, to judge from the numerous enquiries addressed to the Editor of this journal, is regarded with some interest. I shall endeavour to be as full and clear as possible in my explanations, but if any of my readers require further information on any point I shall be glad to furnish it. If any of my readers have had experience of the process, and can suggest any improvements, I should be glad if they would communicate them. I shall commence by a few general remarks on

## THE PREPARATION OF DRAWINGS, ETC., FOR REPRODUCTION.

One of the most useful applications of photo-zuicography is the reproduction of maps and civil and military engineering drawings; but as the requirements of the process are but little known, these drawings are seldom drawn in a suitable manner for reproduction by photography, consequently the results are unsatisfactory, and the process is blamed undeservedly. If care is taken to select suitable subjects, and to secure a good negative, results can be obtained which may compare with engravings in sharpness and delicacy. Success mainly depends upon the negative, which must be perfectly sharp, free from distortion, and possess the greatest amount of contrast between the lines and the ground, the lines being as transparent as the bare glass, the ground almost opaque. Attention to the following points will greatly lessen the labour of the operator, and conduce to success:—

1. The drawing-paper should be as white, clean, and smooth as possible. If the originals are on rough paper they should be passed through a copper-plate press, and, if necessary, cleaned with rubber or bread.

2. The Indian ink with which the drawing is made should be freshly rubbed down, quite black, free from grit and glaze.

3. The lines should be firmly drawn, and *pale ink* must on no account be used. The marginal lines must be well filled in.

4. Washes of any colour, except very light blue, are inadmissible, but *outlines* may be put in with dark burnt sienna, crimson lake, dark green, and similar colours, which will reproduce black.

5. When the plans are intended for reduction, care must be taken to draw the lines of the proper thickness relatively to the scale of reduction; that is, supposing it is required to reduce a drawing to one-fourth the size, it will be necessary to draw every line of the original four times as large as will be required in the copy. This rule is often neglected, and the result is the loss of all the finer lines. The best results are obtained when the drawings are prepared on purpose for reduction, and without any regard to clumsiness of appearance.

6. When practicable, the drawing should be left on the drawing board, so that the paper may remain perfectly flat, or should be mounted in such a manner as to secure flatness. This cannot be done by pinning the drawing to a board; the alterations of temperature will affect the paper, and cause it to expand unequally, and produce ridges. I think it will be found better to fasten the drawing down with tapes, fastened with drawing pins outside the margins of the drawing, and passing tightly over it, so as not to check any lateral expansion.

It is generally better to copy by strong diffused light, as then there is less danger of reproducing the grain of the paper, the removal of which necessitates considerable reintensification to the certain detriment of the negative. Old discoloured manuscripts, &c., are better copied in sunlight, taking care that the sun shines directly on the subject.

(To be continued.)

## THE DIAMOND.

BY JAMES MARTIN.

As the diamond is now one of the most useful accessories in the photographer's catalogue of implements, it would, no doubt, be interesting to your readers to learn somewhat of its history and application to the arts. The diamond has, from the remotest antiquity, been prized as the most valuable—or, more properly, the most costly—substance in nature. The reason of the high esteem in which it was held by the ancients was its rarity and its extreme hardness for the art of cutting and polishing; this gem not having been then invented, its superior brilliancy and lustre would not have been appreciated. They also considered it an antidote to poison, and that it was able to cure insanity; therefore it

was called, by some, *anachitis*. Its supposed occult qualities and superstitious uses no doubt contributed greatly to the high esteem in which this substance was held as being the most valuable and beautiful of gems. It was endowed with these hidden virtues in the highest degree; hence it was held to be an infallible specific in many diseases, and, amongst other absurdities a test of conjugal fidelity, a reconciler of domestic strife, and an amulet of highest power against poisons, insanity, witchcraft, incantations, goblins, and evil spirits. The diamond is either colourless, or of a light yellow or smoke-grey, passing into bluish or pearl-grey or clear wine colour, on the one hand deepening into clove-brown, and on the other into yellowish-green. It also occurs of a deep, almost black-brown, Prussian blue, or rose red; and the colourless varieties are the most esteemed, and, next to these, the blue, red and black, the light-coloured the least. The diamond is found crystallized in the regular octohedron, which is its primitive form, composed of two four-sided pyramids opposed base to base, or in the cruciform octohedron. Sometimes each triangular face of the primitive octohedron is replaced by six secondary triangles, bounded by curvilinear lines, in which case the whole crystal has forty-eight faces, and is of a spheroidal figure. Other spheroidal varieties of this mineral are the dodecahedron, a solid of twenty-four faces, and a compressed spheroid resembling a very short hexahedral prism terminated by very short, curvilinear pyramids. The surface of the natural crystal, especially of the spheroidal, is somewhat dull and chatoyant; this appearance, which is generally represented as the effect of a thin crust, appears to be caused merely by the salient edges of the laminae of which the crystal consists. When its surfaces are reduced to perfect smoothness by grinding and polishing, the diamond is of extreme brilliancy, far surpassing every other substance in lustre and the lively play of prismatic colours which dart from it in lines of light whenever its position with regard to the eye undergoes the least variation. The fracture of the diamond is straight foliated; hence it may readily be cleft in the direction of its laminae by a dexterous artist. Some of the spheroidal varieties, however, are composed of curved plates; these are of intense hardness, and cannot be either split or highly polished; they are therefore used by the glaziers and engravers on gems, or are ground into a powder and employed in polishing other diamonds. The specific gravity varies from 3.518 to 3.550.

The diamond, even when rough, acquires by friction the vitreous or positive electricity; it becomes phosphorescent when exposed either to the entire rays of the sun, or to the blue rays alone when separated by the prism and concentrated on the diamond by means of a lens. The diamond when heated to the temperature of melting copper, and exposed to a current of air, is gradually but completely combustible. It is surrounded by a luminous arc during the process. It is wholly converted into carbonic acid, and, therefore, consists of pure carbon. The art of cutting and polishing the diamond was probably known to the artists of Hindostan, and at a very early date, but the only material used in the East for this purpose being wundum, and the apparatus being of extreme simplicity, the jewellers of those countries are incapable of bringing out the peculiar beauty of the diamond in a degree at all comparable to what is effected by European artists.

Formerly diamonds were set in jewellery precisely in the state in which they arrived from India, and hence the octahedrons were much more esteemed than the rest, both on account of the regularity of their figure and the superiority of their polish.

Diamonds are cut and polished by jewellers into brilliants and rose diamonds; the former being for the most part made out of the octohedral crystals, and the latter from the spheroidal varieties. In the formation of either brilliant or rose diamond, so much is cut away that the weight of the polished gem is not more than one half that of the rough crystal out of which it is formed; whence the value of a cut

diamond is esteemed equal to that of a similar rough crystal of twice the weight, exclusive of the cost of workmanship.

The weight, and consequently the value, of diamonds is estimated in carats, one of which is equal to four grains; and the difference between the price of one diamond and another, *ceteris paribus*, is as the squares of the respective weights. Thus the value of three diamonds of one, two, and three carats' weight is as one, four, nine. The average price of diamonds that are worth working is about two pounds sterling for the first carat, and consequently in wrought diamonds, exclusive of the cost of workmanship, the cost of the first carat is eight pounds. The largest known diamond was in the possession of the Great Mogul; it weighs upwards of 279 carats, and is in size and shape equal to about half a hen's egg. Diamonds were more rare, and of course dearer, than they have been since the discovery of the Brazilian mines.

The uses of the diamond are principally in ornamental jewellery. It is also employed by glaziers for cutting glass; by lapidaries, for cutting and engraving upon the hardest gems; and in the finer kinds of clockwork.

The mineralogical situation of the diamond is not very well ascertained. It occurs in India in detached crystals, in a kind of indurated vitreous gravel, not far from the surface of the ground; but whether or not this is its native bed is unknown. The diamond mines of India extend throughout the whole chain of the Ghauts, from Bengal to Cape Comorine. Many of them are totally abandoned, the chief that are now worked being situated between Golconda and Masulipatam.

### COMBINATION NEGATIVES.

BY J. B. MIDDLETON.

I THINK all persons who are interested in the development of photography as a fine art will admit the vast importance of the possibility of employing parts of two or more negatives in the production of one picture, for it affords the artist more ample scope for the exercise of his inventive faculties, and enables him to obtain results which would be impossible by other means. Hitherto, I believe, this has always been done in the printing process, whereby, in spite of the greatest care and skill, many proofs are spoiled by the unequal printing or imperfect joining of the parts. Thinking on this matter some time back, it occurred to me that it might be possible to obviate much of this difficulty by the production of what may be called a compound negative in the copying camera by means of converging lenses thus:—

The copying camera must be large, and have a front constructed to carry as many negatives as may be required (perhaps four would be the largest number that could be conveniently used), which should be placed as closely together as possible; of course all parts of the negatives which are not required in the picture must be carefully stopped out. The lenses inside the camera, of which there must be one for each negative, should be mounted in such a manner as to have free motion in all directions (similar to that of a ball and socket joint), and should be provided with screw or other mechanical adjustments, so that they could be readily arranged in any position. Then, by causing the lenses to converge in various degrees, the image of the required part of one negative could be brought to fall exactly on the part of the focussing screen occupied by the corresponding "blocked out" part of another, and a transparent positive could be taken (which, if required, could be improved by hand "touching"), and from that any number of compound negatives might be obtained in the ordinary way. By employing lenses of long focus the angle of convergence would be diminished, and the risk of distortion from using the lenses obliquely would be less.

I do not know whether this idea is new or not, but if there should be any novelty or practical value in it, the photographic world is perfectly at liberty to make the best of it.

### PICTORIAL EFFECT IN PHOTOGRAPHY; BEING LESSONS IN COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

#### CHAPTER XX

"Thus bad begins, and worse remain behind!"—SHAKESPEARE.  
"If there be no room, thrust away the meaner parts, and give praise that find room in the chiefest portion!"—LAURENCE.

#### PORTRAITURE—continued.

A GREAT deal of the effect of a portrait will depend on the position the figure occupies in the picture. A glance at the illustrations will show this.

As a general rule, if the head be not equidistant from the sides of the picture, there should be more space allowed before the face than behind, as in Fig. 1. The awkward effect of the reverse of this will be seen in Fig. 2.

Fig. 1.

Fig. 2.

A disregard of this rule has spoilt the effect of many otherwise good pictures. In some photographs we see the figure walking almost out of the picture, for the sake of showing the last coils of the long caudal—almost prehensile—appendages with which ladies sweep the dust, thus sacrificing the head for the tail.

The apparent height of the person represented depends almost entirely on the position of the figure on the plane of the picture. The taller the person, the nearer to the top

should the head be placed, and, if a full length, the legs should be shown. A short person should be brought lower in the picture. In Figs. 3 and 4 the contrast is shown.

Fig. 3.

Fig. 4.

It too often happens that the figure is made much too big for the picture. I have seen some cartes in which the head nearly touches the top of the picture and the toes the bottom, so that when it was inserted in an album some part must be covered, perhaps a foot cut off, or perhaps half the head. This is done, I suppose, under a mistaken notion of the photographer's that he is giving enough for the money, a principle to which I have no objection, but let the "enough" be in quality rather than in quantity, and he will be right. A carte-de-visite displaying proportion, taste, and a right feeling for art, is of much more value than a life-size picture that does not possess these desirable qualities, whether by painter or photographer.

There has been a notion prevalent that all figures must be taken to scale; thus, if a six feet figure be represented in a carte-de-visite as three inches long (about the right proportion), therefore a child three feet high must be represented as half that height, or one inch and a half. If it be necessary to make elevations of (say) a family, to send to friends at a distance to compare with others taken sometime before, to demonstrate the fact that the children are growing, then this method must be followed, but the photographer should never forget that it is his business to make pictures, and that a figure one and a half inches high will not fill a picture of the usual card size with anything like effect;

I therefore advise that a little licence should be taken in this particular, and that when a child is to be photographed all consideration of how much of the picture would be filled by a grown person, with the camera at a certain distance, be forgotten, and that nothing but the child, the object then before the photographer, should engage his thoughts.

The same disregard of proportion exists amongst landscape photographers; many would prefer to sacrifice effect rather than cut away a little of the foreground, and thus depart from their regulation size.

## INKLINGS FROM THE WORKERS IN PHOTOGRAPHY.

BY JOHN H. HALL-NEACE.

### *Uranian Salt for Positive Printing and Measuring the Actinic Force of Direct Sunlight.*

THE above was a communication accompanied by a print from Prof. Joy to the Photographic Section of the American Institute. The positive print was obtained by sensitizing the paper with the oxyfluoride of uranium, and potassium, and formic acid. The print was made by Dr. H. Carrington Bolton, who was the inventor of this method; the specimen was the first and only one taken by this process, and was very indistinct; it was brought forward at this early stage in order to fix the date of the invention.

The picture is composed of the green fluorides of uranium and potassium, and is permanent. Formic acid produces no precipitate in a solution of oxyfluoride of uranium and potassium; but if the acidified solution be placed in the direct rays of the sun, decomposition begins immediately, and a green precipitate of the fluoride of uranium and potassium falls; the precipitate is quite insoluble in water and dilute acids, and could be employed to measure the actinic force of the direct sunlight.

The sensitizing bath is prepared by adding a few drops of formic acid to a tolerably concentrated solution of oxyfluoride of uranium and potassium. The paper, while still wet, is placed upon the negative and exposed to the rays of the sun ten or fifteen minutes. The subject will be further investigated and reported upon.

Mr. Newton gave me his process for making the rival Salomon prints which caused such a sensation. Mr. Newton's pictures are pronounced the most beautiful ever made in this country; and as a great many inquiries have been made as to the manner of making the prints, I shall give it for the benefit of all who wish to advance in the art.

The silver bath is the one first introduced by Mr. Newton.

#### *Silver Bath.*

Nitrate of silver	...	...	25 grains
Nitrate of magnesium	...	...	25 "
Nitrate of potass	...	...	25 "
Acetate of lead	...	...	5 "
Water	...	...	1 ounce.

After the bath is mixed and filtered he floated the paper for only half a minute, then dried and toned it for twenty minutes with carbonate of ammonia.

#### *Toning Bath.*

He used several different carbonates, such as magnesium, lime, and baryta; but with his 25-grain bath it seems to make no material difference which is used. Of course he used sufficient chloride of gold of his own manufacture, and fixed with hyposulphite of soda, to which he added a few grains of chloride of ammonia; but Mr. Newton thinks photographers do not take time to make fine prints, and most all over-tone these by destroying the beautiful purples which are so essential in albumen prints, and for which Salomon's are noted.

I shall, in your next, endeavour to state other matters which were brought out at the meeting, and will close for the present with the hope that the new process with the oxyfluoride of uranium and potassium will call forth further

experiments by photos. generally, and with Newton's silver bath, careful manipulations, and by using a good quality of paper, the American photos. will still maintain the lead in the beautiful art of photography.—*Humphrey's Journal*.

## Proceedings of Societies.

### LONDON PHOTOGRAPHIC SOCIETY.

THE closing meeting of the session was held in the Architectural Gallery on the evening of Tuesday, June 9th, Mr. SEBASTIAN DAVIS in the chair.

The minutes of a previous meeting were read and confirmed.

Mr. DUNMORE exhibited a commodious tent for field work, which he designated the "Truck Tent," the dark room and carriage being in combination, or capable of being detached at will. When packed up it consisted of an oblong box, and square box of chemicals, upon an iron truck or frame with wheels and handles. The tent, when opened and arranged for work, consisted of a wooden tray opening like a chess-board, and to which the sides of the tent, made of framework covered with American cloth lined with brown paper biaged together, were fastened by thumb-screws on the inside. The top, similarly constructed, was then laid on and secured by hooks-and-eyes. A tray of mackintosh material is placed on the table for the sake of cleanliness, through which a bent and pointed funnel is thrust to carry off waste solutions. A bag of material impervious to light, open at both ends, was then hung over the open end of the tent, to which it was fastened by tape, for the ingress and egress of the operator. The window consisted of several thicknesses of yellow calico saturated with lac varnish.

Mr. DUNMORE, in answer to various questions, stated that the tent when open gave a working space inside of three feet each way. The total weight of tent, box of chemicals, and contents was about three-quarters of a hundredweight. It was large enough for working 16-inch plates with comfort. He generally intensified and fixed, if necessary, at home. The tent was intended for standing to work. He had an arrangement of cords to which pegs were attached to place in the ground to prevent the tent being blown over by the wind, but he had never had occasion to use it. He could not move this tent about without repacking, an operation which could be performed in five minutes. For large plates it could scarcely be expected that a tent could, when erected, be moved about without packing.

Mr. FRANK GOODE said that Mr. Frith had an arrangement for working large plates 20 by 12, in which the tent and camera were one, all the manipulations being effected inside the camera. He thought that in using a tent standing was best, although some good photographers preferred sitting.—Mr. Frith for instance. He suggested that the chemical box might be converted into a cistern, and placed on the top of the tent with water.

After some general conversation,

The CHAIRMAN, in proposing a vote of thanks, said that the especial point of excellence about this tent seemed to consist in the large working space it gave when opened compared with the small space into which it packed.

After a vote of thanks to Mr. Dunmore,

Dr. MANN read a paper describing the mode of working employed by Professor Piazzi Smyth in producing his photographs of the Pyramids, and exhibited the apparatus, as well as some negatives and enlarged transparencies produced therefrom (see page 278).

Dr. MANN further stated that he, in conjunction with Mr. Dallmeyer, had compared the enlarged pictures produced from these negatives with some of the same size taken direct with a triple, and he was bound to admit that the definition was not so good in the enlargements as in the direct pictures; but still the results were exceedingly good. The especial necessity for the mode of working adopted by Professor Smyth was caused by the circumstances under which he had to work in the Pyramids. With ordinary appliances he would probably have got nothing. The dust would have been a serious obstacle if the plate had not been exposed in the bath. The portability was a great convenience; Professor Smyth was able to carry the bath about hanging on his little finger. The negatives were not quite free from stains.

Mr. SPILLER, referring to the measuring rod which Dr. Mann

had pointed out as included in all the photographs, said that the plan of photographing a rule to serve as a standard of measure in each picture had long been employed in the military photographs taken at Woolwich. In photographs of target practice they photographed a 2-foot rule to aid in estimating the size of the perforations made.

Mr. FOSTER suggested that enlarged collodion positives might be printed from the small negatives in the camera, and transferred to paper in the manner adopted by Mr. Disderi. He wondered that this method of enlargement was not more extensively practised.

Dr. MANN said the same idea had struck him, and he intended to try it with these negatives. He remarked that he had examined some faces in the negatives under an inch power, and in cases where, so examined, nothing appeared but transparent glass, detail and form appeared in the enlarged photograph.

The CHAIRMAN, in proposing a vote of thanks to Dr. Mann, referred to the enlargements as very satisfactory, and expressed a conviction that for amateur purposes the plan in question was worth more attention.

After a vote of thanks to Dr. Mann,

The CHAIRMAN said that the meeting would now stand adjourned until November, when the session would be opened by an exhibition meeting, to which he urged all photographers, members, and others to contribute, as it was only by the excellence of such exhibitions that the public could be made familiar with the real excellence and progress of the art, and become acquainted with its real powers.

The proceedings then terminated.

### OLDHAM PHOTOGRAPHIC SOCIETY.

The first out-door meeting of the above Society was held this year at Lyynn, on Thursday, June 4th.

The weather (with the exception of a slight breeze) being fine, the party, numbering 35, were in great spirits. Arriving at Lyynn, and, after refreshing the inner man, a group was taken, and then separated in search of the picturesque. The dry-plate workers got on very well with their camera and tripod; but, alas! for the wet-plate men, some of them quite agreed with Mr. Beverley on the dry-plate process, that

"Britons never shall be slaves."

At the next ordinary meeting the prints will be exhibited, when we shall have something more to say about the work. We are happy to say that no accident of any kind happened, the whole party arriving safe at Oldham about eleven o'clock, highly satisfied with their trip to Lyynn.

### NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE concluding meeting, for the present session, of this Society, was held on the 3rd inst., Mr. COOPER occupying the chair.

Mr. Fox (Stock Exchange) having been admitted a member, the Society proceeded to dispose of business of a private nature, after which the Chairman announced that the first meeting of the next session would be held on the 7th of October.

### PHOTOGRAPHIC SOCIETY OF MARSEILLES.

THE monthly meeting of this Society was held as usual, Mr. ARTHUR TAYLOR in the chair.

M. VIDAL, referring to a communication from M. Marion on his new pellicle, stated that he had made one trial with an old negative varnished with lac. The transparent pellicle, instead of being made to float on a plate wet with alcohol, as indicated by M. Marion, was placed on the negative, which had been previously covered with alcohol and allowed to drain. The adherence was perfect, and the water bath, after desiccation, brought about a complete separation of the negative film from the glass. No doubt with new negatives the operation could be performed with the utmost certainty, and there was great advantage in having these transferred negatives, which could be printed at pleasure from one side or the other, like negatives on waxed paper.

The CHAIRMAN showed some good results obtained by carbon printing direct through paper. He had studied the influence of a greater or less quantity of colouring matter introduced into the gelatine, and arrived at surprising results with only a very small amount of it. In these cases the parts impressed were very brilliant, whilst the image was so much deeper

according to the greater proportion of colouring in the gelatine. He had obtained good effects by washing the sensitive paper before printing. That washing (five minutes at most) was for the purpose of getting rid of an excess of bichromate of potash, which made the paper yellow, and was an obstacle in the way of rapid printing. By proceeding in this manner he obtained proofs of great delicacy.

M. VIDAL thought that the preliminary washing would be useful with rather thick paper, but he considered it not only useless, but injurious, when applied to tissues. He had tried it, and found that, in the latter case, the sensitiveness was almost completely destroyed; but he believed that in the case of thick paper there remained, in spite of the washing, sufficient bichromate of potash to maintain the sensitiveness of the layer to be impressed.

The CHAIRMAN said that on a sheet of paper of which one-half only had been washed and the other not, he had observed that the part unwashed exhibited a granular image, while the washed half was free from that imperfection.

M. VIDAL showed some photometric bands obtained in the Vogel photometer. He considered the different degrees of intensity were not sufficiently marked, and that his own plan, which consisted of a series of ten tints only, from white to black, would be preferable. He also showed some fine specimens obtained by the helio-engraving processes of MM. Placet and Baldus; of litho-photography by M. Lemercier; enamel photography by M. Lafon de Camarsac; proofs, carbon (in different tones), by Braun, of Dornach; and coloured photographs by M. Niepce de St. Victor. The engravings of M. Placet were considered the finest of the kind that had been submitted. The very remarkable proofs by M. Baldus were previously unknown. His fine copies of the engravings of Marc Antony were particularly admired. The litho-photographic proofs sent by M. Lemercier, though very fine, did not exhibit any new practical progress in that art, as they were old specimens. With regard to the splendid enamels of M. Lafon de Camarsac, though they were well known, they were not the less admired. The magnificent reproductions of drawings of the great masters, by M. Braun, of Dornach, above all claimed the attention of the Society. His work is already monumental, as the number of drawings reproduced amounts to 3,354. Amongst them are the red lead, sepia, and the grey tones of old china ink, by which the colours of the originals are admirably rendered; and now that we can affirm that all the fine drawings of Raphael, Albert Durer, Leonardo da Vinci, Greuze, &c., are reproduced by the carbon process of photography in a manner that is indelible, it is impossible not to be enraptured with such a result, and not to pay to M. Braun a just tribute of eulogy and admiration. These are the works which elevate the art of photography, and prove that no art ever possessed a more sincere and more powerful auxiliary. The heliographic proofs of M. Niepce de St. Victor, whose first efforts in this direction had already been communicated to the Society, showed fresh progress.

Some votes of thanks terminated the proceedings.

## Correspondence.

### PRACTICAL EXPERIENCE WITH SOME DRY-PLATE PROCESSES.

SIR,—Believing that landscape photographers in general feel the same interest that I take myself in the perfecting of the dry plate process, and having derived from almost every experience narrated in the *News* some benefit, I desire to return obligation, if possible, and throw the ray of my taper on the subject, still so much in the dark, of the preparation of that unattained desideratum, a perfect dry plate.

I have experimented for nearly four years on all the dry processes I have heard of, except the coffee, which I judge to be substantially the same as the tannin, the extract of coffee producing in action on metals very nearly the same effect as tannic acid.

I have made it a rule to stick to a process until I had mastered all the causes of failure, and produced practically normal results from it, and in so doing have many times exhausted a patience not easily tried. I believe, therefore,

that the result of my *hundreds* of experiments—indeed, I think I might safely say thousands—may be of use, at least in saving time and patience to some who, like myself, have had to work out their system alone, and far from any practical assistance.

I take it that the ideal dry plate must be possessed of the following qualities:—Firstly, it must develop so evenly that an open blue sky will be rendered without a vestige of clouding or unevenness. Secondly, that it should keep at least three months without deterioration or getting uncertain. Thirdly, that they should be equal in sensibility. And, fourthly, that it should develop quickly, and without any tendency to fog. Extreme sensitiveness does not seem to me of great importance, and if a plate will take an impression in less than ten minutes, with a tolerably certain result, I should be satisfied with it on that score.

For the first qualification, I have found the collodio-albumen approach nearest perfection; next to it, Gordou's albumen process; and then the old-fashioned Fothergill. For the second, I have found nothing equal the much-abused tannin. My experimental plates, prepared with bromized collodion, and by Sayce's process, have so invariably fogged or peeled, that I have not gone far in that direction. For the third, I find the tannin and Gordou's about equally reliable; and for the fourth, Gordou's and (except under alkaline development) the tannin; but, as everybody knows, all the albumen processes are free from fog, except with bromized collodion, or when the alkaline development is applied.

The Gordou (albumen) process, on the whole, has given me the most satisfactory results, and, with tannin for certain emergencies presently to be spoken of, will, I believe, satisfy general demands better than any others of which I have thorough knowledge. Nor am I willing to accept the commonly received estimate of either of those processes. I have found the Gordou plates keep longer and resist high temperature better than they are represented to, having obtained spotless and clear transparencies from plates that I have had in my dark room three months; and only a week ago, having some plates that I had prepared over two weeks before and brought back unused from an excursion at that time (since which time they were left in the slides), I took them with me on another, when I was using wet collodion, and exposed them in a difficult ravine, where I could not get my dark box even, and with one of the hottest days of the season (90°, judging from sensation, and for many days about 80° in average exposure). I exposed my four plates, and got four negatives, of one of which I send a proof. Not a spot or mark of decomposition was to be seen on either of them.

The only difference between my manner of preparing the plates and that prescribed in the *Year-Book* is, that after taking the plate out of the distilled water, I flow over it a very weak aqueous solution of iodine, just enough alcoholic solution being dropped into the water to give it the colour of golden sherry, pouring it over and throwing it off twice; and this I do for all processes which require entire ridding of the free nitrate. After the iodine, I wash with a jet of some little force, lest the particles of iodide should adhere. The weaker the iodine solution the better, so long as it converts the whole of the nitrate in the film, which will be shown to be accomplished by the solution retaining its colour. I develop with strong pyrogalllic acid solution, 4 or even 6 grains to the ounce, but never alkaline unless the picture refuses to come out for pyrogalllic, even of the strength of 8 or 10 grains per ounce, and then only add to the developer half a grain of carbonate in preference to liquid ammonia. It is so much easier to restrain than force development, and there is so much less tendency to stain with full exposure, that the waiting of two or three minutes more or less seems of no account. There are few cases in which exposure ranging from four to eight times that of wet collodion may not be perfectly met by the development without losing the value of the highest light. I begin with a solution of pyrogalllic of the strength of about 2 grains, and if the picture

comes out too rapidly with that, wash it off at once, and add to the same 4 or 5 drops of acetic acid; if not fast enough, double the pyrogallie, and continue the action until the details *begin* to appear in the deep shadows, and then strengthen with citro-nitrate of silver and a trace of pyrogallie.

I would always have a few tannin plates by me for interiors, glen scenes, &c., when there is no great amount of flat tint which it is necessary to keep free from spots requiring retouching, or when the sky and distance are unimportant. I am of opinion that more of the failures in this process result from want of cleanliness in the preparation of the plates, and especially in the cleansing of them. The preservative solution being at the same time a reducing agent, the energy of the chemical action is so great that it takes hold of the least provocation to commit irregularities. A glass that will produce a perfectly clean wet collodion negative may cloud and show all sorts of markings with tannin. I clean my plates with nitric acid and water, followed by tripoli, allowed to dry on, and if the plates are not absolutely free from clouding under the breath, follow that with old collodion. I was at one time in the habit of using papier Joseph to finish with, but it is unfit for cleaning for dry plates. I flow with iodine as above, and wash thoroughly, after the tannin, under a jet from a caoutchouc tube and clip, finishing with distilled water; and, in developing, never use ammonia if it can be avoided.

In the preparation of dry plates I never touch the plate with my fingers from the time it goes into the nitrate bath until it is dry. On taking it out of the bath I fold a bit of filtering-paper three or four times double, and, taking the corner of the plate in that, lay it on the atmospheric holder (one of Murray and Heath's, with a T handle), and, when the washing is all done, leave it to drain on the holder in a sloping position, collodion side undermost, until the water has nearly or quite ceased to drip; when, taking it in another piece of filtering-paper, I put it on one corner on blotting-paper (which should be carefully tested for sizing or impurities), resting on slips of glass, as I have had plates spoiled by impurities filtering from the boards under the paper on being wetted by the water from the plate. The draining completely done, and before drying, commence at the upper corner, put it on another strip of clean blotting-paper, and leave it till perfectly dry.

The drying should be done rapidly—as that increases the sensibility—and evenly, otherwise bands and striæ will appear. All apparatus which bring the heating instrument near the plate should be avoided, as one part of the plate will necessarily be hotter than another. I prefer drying on shelves in the dark room, depending on the heat of the room itself, increased, if not sufficient, by a brazier of well-lighted charcoal, introduced before the drying has commenced.

In preparing the tannin solution I shake it up with about a twentieth part of albumen before filtering, which clears it as perfectly as standing months would.

When neither of these processes will meet my wants, I fall back on the Fothergill pure and simple, with an old collodion equal proportions of bromide and iodide, no preliminary coating, short time in the silver bath, distilled water until greasiness disappears, and then about a minute of washing with a fine jet, and washing well after the albumen.

Mr. England's process I have not found so satisfactory as regards cleanness and equality of development as Mr. Gordon's. Much greater precision must be observed in the duration and evenness of the final wash. I think it may be admitted as a general rule that every additional operation merely doubles the chance of defects, and when we can use the nitrate and albumen in one application it seems preferable. For the same reason I have abandoned all preliminary coatings. They are unnecessary with a proper collodion, and give rise to many defects.

Mr. Gordon's gum process (rather, gallic acid process?) I find exceedingly subject to blistering and dust.

The morphine does not seem to me either simpler or

quicker than the tannin, and in my experience is equally liable to markings.

To those who have the necessary convenience for preparing collodio-albumen plates, keeping out of dust, &c., it is a process which can hardly be over-rated, and the means which I have employed successfully for drying the plates may be of interest to those who have not employed some similar experiment. I take one of the cast-iron blocks used for making the waxed photographs, and, putting it over one of the fire-places in the range, or on a common furnace (in the latter case resting on two iron rods across the furnace), and put a spirit-lamp under it. In this way I heat it until it will almost burn paper pressed on it, and then reduce the flame to keep it at this point. As soon as the plates are surface-dry I lay them on three or four folds of blotting-paper on the iron, cover them with a paper screen, which goes over the iron and rests on the rods at each side, removing each one as its place is needed for another. I employ the same after the second sensitizing, and have never found any bad effects from it.

The Norris dry plates I have used with fair success, and find that I can get about eight good negatives from a dozen. They will blister occasionally in spite of all precaution, and are not free from clouding in the skies. I recently exposed the last half-dozen of a lot I received two years ago, and, except for a band of about one-half to one inch wide at the edges, they were almost as good as when they were new. But when a photographer can only get two-thirds of the pictures he goes out for, and may miss the one he wants most, it is not satisfactory working, unless he can go back and try the subject of failure over again, which all tourists cannot do.

I am intending to order a lot of the Liverpool Company's plates, and if you care to hear the result of my experiments, will give it to you.

I have not discovered any new fact or material to constitute the general stock for dry plate information, but hope that my experience may benefit some beginners, and save them time for better things than experimental failures.

Perhaps a modified paper process, which I have found tolerably successful, may be new at least to some of your readers. It consists in using a paper albuminized with a bromo-iodized albumen, and sensitized by floating on an aceto-nitrate bath. It is as quick as the Fothergill process, and gives much more delicate definition than the common paper process, or even than the waxed paper in my hands. I have obtained the best results from an arrowroot positive paper for cleanliness of development, and for detail, with a batch of albuminized paper which had spoiled on my hands, and which I purposed for re-albuminizing for negatives by floating it on a bath of hot (nearly boiling) water to coagulate the albumen, then washing with a soft sponge and warm water, which effectually removes any decomposed albumen or other surface impurity. The albumen is the same as for the collodio-albumen plates, and the same bath. After the aceto-nitrate bath the paper is floated on two baths of distilled water, and hung up to dry. The keeping quality may be improved almost *ad libitum* by more washing, but the sensitiveness is decreased. The development is with gallic acid, but I have used, successfully, the alkaline pyrogallie solution.

I have looked in vain in the YEAR-BOOK and NEWS recently for some details of the glycerine process. Cannot some of the experimenters give us their experience? Will some wet collodion worker give us a formula for instantaneous collodion? I find doctors disagreeing on the proportion of bromide.

Hoping that my communication has not been too long for your patience, and may be of use, I remain, yours truly,

W. G. STILLMAN.

[The glycerine process was first published in our pages. It was contributed by Mr. Blanchard, in December, 1862. It will be found on page 578 of Vol. VI. of the PHOTOGRAPHIC NEWS, and in the YEAR-BOOK for 1863. It is

excellent as a preservative process; but the tendency of practice has been to pursue dry instead of moist preservative processes, on account of the risks from dust, &c., of the latter. We shall be glad to receive our correspondent's further experiences.—Ed.]

## Talk in the Studio.

**COMPETITION FOR PRESENTATION PRINT.**—With a view to secure the greatest novelty and excellence in a presentation print for distribution amongst their members, the Committee of the North London Photographic Association have resolved to advertise for suitable specimens. The detailed conditions of competition will be found stated in our advertising columns this week. From the excellence of the presentation prints this Society has hitherto distributed, a considerable amount of prestige will attach to the selection made in a case of competition. We hope that many very fine examples of the art will be submitted to the Committee.

**BIOGRAPHICAL PHOTOGRAPHIC ALBUMS.**—The *Stationer* says:—"The photographic album makers may perhaps take a hint from a novelty about to be introduced to the American trade. The article referred to is entitled the 'Biographic and Photographic Family Record, arranged for recording in detail the Personal Incidents of each Member of the Family.' The first page contains the record of the names, birth, marriage, &c., of both husband and wife, and spaces for the photographs of each, to be inserted at several different ages; also space for recording the name, date, place of birth, and death of the parents and grandparents of each, including three generations, and for other incidents in the life of each. The remainder of the volume is appropriated to the records of the descendants of the first-named parties, an entire page being devoted to each, containing the name, date, and place of birth, with space for five photographs at different ages; also for the character and period of whatever diseases they may have had, and the height and weight at different ages, with the schools at which they were educated, occupations, and other events of their lives. An additional blank page for each child enables the parents to record whatever other incidents may seem desirable to be remembered. Now that the album trade is beginning to wane, a new business might be created in an article such as is above referred to."

**THE CASE OF PIRACY—Graves v. Ashford.**—In this case a rule had been obtained calling upon Alderman Sir R. Carden and Mr. Graves to show cause why the former should not state a case setting forth the facts and grounds of his judgment or determination upon the hearing and conviction of Mr. Ashford, upon thirty-seven separate complaints made by Mr. Graves against Mr. Ashford, for unlawfully selling copies of certain photographs, in which the former claimed to have the copyright. Upon the hearing it was contended that the photographs sold by the defendant were not copies of photographs that had been registered by the plaintiff, but were original photographs, not from the engravings, and further that the particulars of the registration did not contain a sufficient description. Alderman Sir R. Carden, upon being applied to refused to state a case for the opinion of this Court, on the ground that he considered the objections raised by the defendant were frivolous. Mr. Coleridge, Q.C., and Mr. Montagu Williams appeared to show cause against the rule: Mr. Poland and Mr. Talford Salter in support of it. Rule absolute.

**NITRATE OF NICKEL IN PHOTOGRAPHY.**—It is stated that Herr Wothly, of Aix-la-Chapelle, whose experiments in uranium printing are familiar to photographers, has been recently engaged in working out a process in which nitrate of nickel plays an important part. The details have not been published.

**NEUTRAL NITRATE BATHS.**—We have received several examples of photography, since our last article on Mr. McLachlan's communication, to illustrate the result of using a perfectly neutral nitrate with bromo-iodized collodion. Several correspondents state that they have avoided free nitric acid, working successfully with perfectly neutral conditions.

**PREPARATION OF LITMUS PAPER.**—Mr. Vacher says, in the *Chemical News*:—"I have had much trouble in obtaining a thoroughly satisfactory litmus paper. When used with

blotting-paper it is not as delicate as could be wished, and on one occasion, when attempting to make it with sized paper, the blue tincture persistently turned red when it touched the paper. The latter reaction seemed to be due to the sizing material, and it occurred to me that if I sized some paper myself with pure gelatine, my object would be obtained. I can recommend the following receipt:—Digest 20 grm. litmus with 100 c.c. water for some time, shaking occasionally; then filter. To the filtrate add a slight excess of nitric acid, and boil; then neutralise exactly with potash. Now make a weak solution of gelatine by boiling 1 part of isinglass with 50 parts of water; draw white blotting-paper through this, and hang it up to dry. When dry paint one side with the above solution of litmus."

**THE FUTURE OF PHOTOGRAPHY.**—An able article with this title in *Once a Week* predicts that carbon printing must become universal in the future of photography. After entering into some detail, the writer concludes thus:—"Of the permanency of pictures thus obtained there can be little doubt; the material of them is carbon, one of the most stable pigments known to exist, and the constituent of all the black paints and inks in common use. But it is not necessary that this material alone be used—any colouring matter may be mixed with the gelatine to form the shadows of the print. This constitutes a truly wonderful element in the process, for it allows a drawing to be absolutely reproduced in the very pigment used by the artist. I have seen an Indian ink drawing copied in Indian ink, and a sepia one in sepia; and, better still, a red-chalk sketch duplicated in the chalk used to make it. Photography in its simplest garb is a marvel; but this multiplying of pictures, both in form and in material, by photogenic action, passes beyond the category of marvels, and becomes almost miraculous. As yet, not many photographs of this class are in the market; but they will soon come. Mr. Swan, finding his baby outgrowing his powers of attention, has sold his patent for England to a small company, which is preparing to inaugurate the new system gracefully by issuing copies of a few of the masterpieces of modern English art. Mr. Ward's 'Last Moments of Charles II.,' Mr. Poyuter's 'Israel in Egypt,' and some works of Millais, Ansdell, Maddox Brown, Linton, and others, are in progress of reproduction; and the impressions from these may be looked for as the pioneers of an invading army that must ere long drive the existing class of photographs off the field: copyright holders will then have more serious grounds for alarm at the speculations of the pirates. The forthcoming prints will be called autotypes. In the meanwhile the Continent has gone a little to windward of us. Mr. Swan some time ago sold rights of working the process to M. Adolphe Braun, of Dornach, and went over to give instructions and make arrangements for its practice on a considerable scale. From M. Braun's establishment five hundred prints have of late daily emanated, and arrangements have probably by this time been completed for trebling this number. This indefatigable artist has worked his camera through the galleries of Italy, Germany, France, and elsewhere, and secured thousands of negatives of treasured old masters' drawings. These he has multiplied in absolute *fac simile*, and now, for a few shillings, we may buy a study by Michael Angelo, a design by Albert Durer, or a sketch by Raphael, so accurately counterfeited, that were original and copy placed side by side the eye could scarcely detect a difference between them. Surely this is the greatest triumph that any reproductive art has yet achieved. The British Museum authorities have signified their opinion upon the merits of the new method by ordering the drawings under their charge to be copied by it. M. Braun, too, lately, in his way typified the relative values of the old and new systems by burning every silver print in his possession."

**HALO PRINTING.**—A correspondent of the *Philadelphia Photographer* says:—"I select a thin piece of glass the size of the negative printed from; next I make a block, either oval or whatever shape I wish it, bevel it on one side, and then glue it on the glass plate, bevelled side down. After I have made my vignette in the ordinary way, I take off the vignette-board and negative, and in their place lay on my glass with the block; this, of course, reverses the order of things, covering up the print where before it had been exposed, and exposing where it had been covered. The block, of course, must be on the centre of your glass, in order to cover up the image, and should extend over the edges enough to leave a white circle between the figure and the outside dark edge. I put to suit the taste, either dark or light. You will notice that this requires no extra printing-frame, as the same can be

used on which the print was made, the springs holding down the glass the same as they did the negative."

**AQUEOUS VARNISH.** By C. MEINERTH.—If we pour over a wet negative, just after it has been fixed and washed, the usual gum-arabic solution (1 ounce in 8 ounces water), it dries without any gloss, and the rubbing with the finger will produce a mark; but if the negative is allowed to dry first, then flowed with water and the gum solution quickly poured over it, it will leave a hard, glossy surface after spontaneous drying. The reason probably is, that the gum does not enter into the film so much in the latter instance as in the former, and remains a surface-cover, as it should be.

**"PHOTOGRAPHY CANNOT LIE."**—We have heard of a profligate son dressing himself in rags and being photographed in order to send his father the portrait, and so produce an impression of deep poverty and distress. A recent story illustrates how photography sometimes lends itself to false impressions in another direction. A young man, who received but 1,800 francs (about seventy pounds) a year salary, recently wrote from Paris to his unsophisticated country parent for assistance, and sent his photograph. The father replied, indignantly, "Rascal of a son, you cannot be as poor as you state, for in your photograph you are surrounded by vases, rich curtains, statues, and cascades in perspective. Not a sou from your affectionate father."

## To Correspondents.

**OXONIENSIS.**—From the recorded experience of those who have photographed Alpine scenery, the conditions of success appear to be much the same as in this country. In Switzerland the light is a little better than in this country. You will find it desirable to use a very fully bromized collodion, especially for subjects containing great contrast, such as snow scenery and pine forests. Avoid under-exposure in all cases. With snow and ice, give sufficient exposure and develop quickly. On page 532 of our Eighth Volume you will find some interesting information on the subject.

**THOMAS STOTHARD.**—The addition of chloride of barium referred to was to form chloride of silver, which, by its decomposition in the process of sunning, which was to follow, would generate hypochlorous acid, which, being a powerful oxidizing body, would assist in eliminating organic matter. Mr. Lea's proposed mixture for cleaning glasses is 1 ounce of nitric acid and 1 ounce of bichromate of potash in 1 pint of water. It is efficacious in cleaning glasses; but it is very corrosive if it touch the skin. We have not yet received the formula for using sulphate of zinc in development.

**W. J. A. G.**—Our experience with the collodio-bromide process is not very extended; but we have used it after it has been two or three days mixed without disadvantage. The film is generally thin and blue when dry. As a rule, red blotting-paper, if in perfect contact with the backs, will answer to check the abnormal action of light; but painting is better. The method to which you refer requires verifying before it can be recommended. It is doubtful whether it is as certain as the ordinary collodio-bromide process. Failure with England's process, or, indeed, most of the collodio-albumen processes, is scarcely possible.

**W. H.**—That to which you refer is decidedly the best; we cannot recommend any other.

**T. B.**—The only conclusion at which we can arrive is that the glass has changed colour by the action of light. The change from an exposure of four seconds to one of twenty-five or thirty seconds in a few years seems enormous; but we have heard of similar cases in which the change in the colour of the glass from the action of light was the sole cause. Are you quite certain that the glass is clean inside and out? Try removing a pane of the glass and examining it, especially comparing the edge which has been protected by the ash-bar with the other portion which has been exposed. The cost of reglazing, if the glass be the cause, will be repaid by the rapidity regained. We are glad that you find the articles on Pictorial Effect valuable.

**H. R.**—Thanks for the photographs of the Observatory, which are very good. We do not know of anything, but will let you know if we hear of anything suitable.

**R. M. L.**—The rapid discolouration of your printing bath and the dullness in the surface of the paper indicate that the bath is getting weak in silver, and is consequently dissolving the albumen. The weakness and poverty of your prints is probably due to the same cause; but the print you enclose also suggests that the negative lacks brilliancy, and is fogged in the shadows.

**B.**—In developing dry plates with iron, different treatment is necessary to that permissible when employing pyrogallie acid. If a

solution of protosulphate of iron, without any addition of nitrate of silver, be applied, it frequently injures or quite destroys the image. This is because it almost invariably contains some trace of free acid, and all acids have a tendency to destroy the latent image. Plain pyrogallie acid solution has no such tendency, because, although called an acid, it is not acid in its properties. Hence it is desirable, in using an iron solution, to add a little of a silver solution from the first. 2. We have not tried iron with collodio-albumen plates. We believe that Mr. England has found it possible to develop his plates by means of an iron solution.

**C. M.**—You mistake the purpose of adding alcohol to the printing bath. It is not to coagulate the albumen, but to take the place of water, and so reduce the tendency of the water to dissolve the albumen, which it undoubtedly effects. About 3 ounces in a pint of solution are sufficient.

**J. G.**—The peculiar qualities of the print you enclose are rather due to the lens than the process by which they are produced. The softness, roundness, and depth of definition, and the absence of sharp lines or crisp rendering of wrinkles and texture of skin, are all due to the presence of a certain amount of spherical aberration in the lens. This quality is often useful in lenses for producing large heads; the disadvantage is that, not being under the control of the photographer, it cannot in such a lens be modified at will. The degree in which it is present in the lens with which the large head enclosed has been taken would unfit it for smaller images requiring fine definition. 2. The tone is too cold, according to our taste, otherwise the picture is fine.

**B. L.**—If the base-line of the picture is the same length as the focus of the lens, the amount of angle included is a fraction over 53 degrees. 2. The triple will give very good effects in portraiture if you have light enough.

**X. Y. Z.**—Thanks for your well-meant letter; but the matter is unworthy of notice. The remarks to which you refer possess no weight in themselves, and derive none from their source. It is therefore waste of time to give them a second thought, and would be waste of space to enter into the question.

**LESSONS IN PICTORIAL EFFECT AND IN SILVER PRINTING.**—A correspondent signing "T. M. G.," who wishes to thank us and our contributors for the lessons in Pictorial Effect by Mr. Robinson, and in Silver Printing by Mr. Bovey, sends us some capital card pictures to show that their instructions are not thrown away. The groups are thoughtfully and well composed, and the printing and toning are excellent. Another correspondent writes to say that although he had been associated with art for many years before he became a photographer, he was deeply indebted to the instructions of Mr. Robinson for a much fuller knowledge of the applicability of art principles to photography than he had before possessed. We are obliged to these and other correspondents who write to a similar effect, but they will readily see that we cannot publish letters in full which are simply devoted to kind expressions of gratitude to our contributors and ourselves.

**VANITY.**—We have no practical experience with hair dyes. If sal ammoniac be employed before the nitrate of silver it will form chloride of silver, which is not required. A weak solution of nitrate of silver applied in the light, followed by a solution of gallic acid, will produce a good dye. Possibly we can give you more details in our next.

**J. C. B.**—See article in our next.

Several Correspondents in our next.

### MR. GORDON'S GUM PROCESS.

WE have recently had an opportunity of witnessing some of the exposures of some of Mr. Gordon's gum plates, and examining the negatives produced. It would be simply impossible for anything to be more technically beautiful than these negatives: they are so exquisitely delicate, clean, brilliant, and free from blemish of every kind. Mr. Gordon, who is one of the most extensive and able dry-plate experimentalists we know, after long trial, believes this take it altogether, the most perfect dry process he has tried. In recording this verdict, we ought to add that it possesses much weight from the fact that Mr. Gordon is not only a very extensive, skilful, and conscientious experimentalist, but he is not a claimant for the honours of invention. He has no foregone conclusions to vindicate, no pet bantling of his own, the pre-eminence of which he feels bound to maintain at all hazards. This process, as many others he has worked and improved, he has found in existence in some crude form. He has worked with it, carefully modifying various features, as extensive experience and a keen perception of dry-plate necessities have suggested. This kind of modification is, in many cases, inventing a process; and although, as we have said, Mr. Gordon repudiates for himself such claims, we are compelled for distinction, as the process is distinct from others, to call it Mr. Gordon's Gum Process.

The feature which has astonished us most is the extreme sensitiveness of plates which will keep almost indefinitely. Take a recent example: a portrait was tried on a wet plate with iron development, everything working well: the exposure was fifteen seconds. A gum dry plate was then tried under all the same conditions as the wet plate, and an exposure of twenty seconds was given. After development, both were found to be fully exposed, that on the dry plate being no whit less soft and delicate than that on the wet plate. This, it will be seen, was only one-third longer than the exposure of wet collodion. Mr. Gordon states as his experience that twice the exposure of wet plates is the outside time required. The plates we examined had received various exposures, from two seconds to two minutes; that which had received two seconds, we saw exposed on a group of cattle, and gave a capital negative. As a rule, great sensitiveness and good keeping qualities have been regarded as incompatible; but here are plates which will keep without deterioration during many months, possessing a degree of sensitiveness very rarely found in dry plates. The keeping qualities here, however, seem perfect. Mr. Gordon recently developed a plate which had been kept a month before exposure, and a fortnight after exposure before development. The result was perfect, no shortcoming of any kind indicating that the plate had suffered by the length of time elapsing before exposure and before development.

A recent modification which Mr. Gordon has made has

secured several advantages. Instead of using the alkaline development he originally described, he now uses the gelatino-iron developer. The use of the iron solution makes no modification in the time of exposure, but it is simpler, *materially decreases blurring, rendering the use of red paint or blotting-paper at the back of the plate unnecessary*, and yields a negative scarcely distinguishable from a wet plate in colour, delicacy, and all characteristics.

The iron developer consists of from 20 to 30 grains of protosulphate of iron, 15 minims of glacial acetic acid, and 1 grain of gelatine in an ounce of water. The gelatine is dissolved in part of the water and the acetic acid, and then added to the iron salt, which is dissolved in the other portion of the water. A trace of silver solution is added—about two drops for a cabinet plate—before commencing the development, and a little more as may be required to bring up the intensity. The negatives have small touches of bare glass on the shadows, showing that where light has not acted there is no reduction of silver. The gradations are delicate and crisp up to the highest light; excessive density or hardness being quite absent.

The iron development has another special advantage: it considerably removes the one failing of gum plates—a tendency in the film to leave the glass. This, with the alkaline development, is, in unskilled hands, at times troublesome, but with the iron is almost entirely absent. Some of our correspondents have complained of the occurrence of blisters during the progress of development, a defect which Mr. Gordon had not experienced. We suspect that the term blister is here employed to indicate the gradual loosening of the film from the plate, which occurs at times, leaving it only attached at the edges by the line of varnish rim round. However, we submitted the letters of two or three correspondents to Mr. Gordon, that they might secure the advantage of his experience as to the defects described. Here is his answer:—

"DEAR MR. SIMPSON,—I cannot account for the blisters your correspondents meet with in the gum process, unless they dry their plates artificially.

"They should always be allowed to dry *spontaneously*.

"An excess of nitric acid, or the use of acetic acid in the bath, is against adhesion of the film.

"I have never (as yet), I am happy to say, seen a blister on a gum plate; the adhesion is, perhaps, worse with it than with most other preservatives, but it does not with me show this in blisters."

In answer to a question as to the length of time necessary for the preservative solution to soak into the film, he adds,—

"It is quite sufficient just to swill the film for a few seconds with the gallic acid, and then apply the gum, and this latter to be worked about the plate (say) for a minute or so. —Yours faithfully,

R. M. GORDON.

For the convenience of readers, we repeat the manipulations and formula as given by Mr. Gordon in our Year-Book:—

"Any good collodion will answer. Mawson's and Thomas's I have tried, and with 2 grains bromide of cadmium added to each ounce they work well.

"Bath 40 grains to the ounce (*not less*), slightly acid with nitric acid: one drop of this acid to each pint is ample.

"The plates must be left in the bath not less than ten minutes in summer, and probably longer in winter.

"Wash in two baths of distilled water, after which thoroughly under the tap; in fact, all free silver must be got rid of *mechanically*. I do not like doing so *chemically*, either by means of salt or bromide. With the former the negative is never so bright, and, what is still more curious, the plate does not keep so well; while with the latter the sensibility is much impaired.

"Swill finally with distilled water, and flood the plate with a 3-grain solution of gallic acid; drain off slightly, and at once apply the preservative solution, composed as follows, and made up fresh:—

Gum arabic (picked) ...	20 grains
Sugar-candy ...	5 "
Distilled water ...	1 ounce.

This solution should be filtered through a sponge.

"If all the chemicals are in good order, as long again an exposure as for wet collodion will be ample in summer; in winter I find the *relative* exposure is considerably increased, and that three times will be nearer the mark.

"Although these plates will develop by the alkaline method, they do not do so quite to my liking.

"I have modified it in the following way, when it is everything that can be wished:—

#### "Developing Solution.

"These I believe will be found on every dry-plate worker's shelf.

No. 1. Pyrogallic acid... ..	96 grains
Absolute alcohol ... ..	1 ounce
No. 2. Carbonate of ammonia... ..	96 grains
Water ... ..	1 ounce
No. 3. Bromide of ammonia ... ..	8 grains
Water ... ..	1 ounce.

Previous to commencing the development, run a brush round the edges of the plates charged with a solution of india-rubber in benzole (thick), well wet the film with distilled water, and then take (say for an 8½ by 6½ plate):—

Distilled water ... ..	1 ounce
Solution No. 1 ... ..	10 minims
Solution No. 3 ... ..	5 "

Pour this over the plate; allow it to remain on a few seconds only, and then pour back again into the developing cup; now add to it—

Solution No. 2 ... ..	5 minims,
-----------------------	-----------

and again apply to the film. The development will now commence, and, if necessary, 5 minims more of No. 2 may be added after some time; if from under-exposure, more of the alkali is needed to bring out the details.

"The slight proportion of bromide added with the pyrogallic solution in the first instance quite checks any developing action that the pyro might, under certain circumstances, possess without it, and on the subsequent addition of the ammonia the image reveals itself slowly, evenly, and completely under command.

"When all the details are out, wash slightly, flush the plate with a little of acid pyrogallic solution as follows, to neutralize any alkali present:—

Pyrogallic acid ... ..	2 grains
Citric acid ... ..	2 "
Water ... ..	1 ounce;

then continue with this and as much of a 30-grain solution of nitrate of silver as may be found necessary to secure the necessary intensity.

"These plates keep perfectly well for months in summer before exposure, and I have kept them as long as ten days after exposure; nevertheless, a golden rule is to develop as soon as possible. All these things have been used before; indeed it would be difficult to find something that has not been recommended at some time or other as a final wash for dry plates; but some of your readers may perhaps not be aware of the very excellent results to be obtained by the use of gum *as above mentioned*; and to those I hope to have been of some service in calling their attention to the subject.

"NB.—The backs of these plates should *always* be painted with some non-actinic colour (such as burnt sienna, for instance), for the gum possesses in an eminent degree the property of rendering the film of collodion transparent on drying, causing what has been called 'blurring' to an unmanageable extent in plates not so protected."

#### PENALTIES FOR PIRACY NOT DEBTS.

An important decision has just been given which tends to make still more stringent the laws against infringing copyrights in works of fine art, and prevents the pirate evading the payment of penalties by becoming bankrupt. In case of failing to pay the amount of penalty inflicted, the alternative amount of imprisonment will, it appears, be strictly enforced. The case is reported as follows in the *Times*:—

COURT OF CHANCERY, LINCOLN'S INN, JUNE 12.

(Before the LORDS JUSTICES OF APPEAL.)

EX PARTE GRAVES, RE PRINCE.

This was an appeal from a decision of Mr. Registrar Hazlitt, acting as Deputy-Commissioner for Mr. Commissioner Goulbourn. The appellant was Mr. Graves, of Pall Mall, the well-known publisher of engravings; the respondent was Mr. William Banks Prince, a seller of prints and photographs in Holborn. On the 16th of May last, Prince was convicted by the magistrate at Lambeth upon nineteen summonses, obtained at the instance of Mr. Graves, under the Copyright Act of 1862, for having unlawfully sold copies of the "Railway Station" and other engravings, of the copyright of which Mr. Graves was the proprietor. Prince was adjudged to pay a penalty of £5 in each case, and was sentenced, under the provisions of the Small Penalties Act of 1865, to fourteen days' imprisonment in each case in default of payment. While the magistrate was giving his judgment Prince executed a deed of composition with his creditors, which contained a release by the creditors, and which was duly assented to, and was registered. Having been arrested under the magistrate's warrant and imprisoned, he applied to the Deputy-Commissioner for his discharge from custody on the ground that the penalties were a debt, from the payment of which he was released by the composition deed. The Deputy-Commissioner held that he was entitled to his discharge, and from this decision Mr. Graves appealed.

Mr. Sargood, in support of the appeal, contended that the penalties recovered under the Copyright Act were of the nature of a punishment for a criminal offence, and were not, therefore, released by the deed.

Mr. Reed, for the respondent, argued that, inasmuch as under the Act the penalties were payable to Mr. Graves, they amounted to nothing more than a debt, which would have been provable under a bankruptcy, and was, therefore, released by the deed.

Lord Justice Wood said that what Mr. Prince had done was, throughout the Copyright Act, treated as an offence—as a fraudulent act for which a punishment was to be inflicted. The penalty provided by the Act was not meant to be the measure of the damage sustained by the proprietor of the picture which had been pirated, as he was permitted to recover damages in another way. The object of the Small Penalties Act was merely to provide a simple method of enforcing the payment of penalties not exceeding £5. The penalty was, in his Lordship's opinion, a punishment for what was in the nature of a criminal offence, and the debtor was therefore not entitled to his discharge from custody.

Lord Justice Selwyn was of opinion that, whether the words or the spirit of the Copyright Act were looked at, the Court was necessarily brought to a conclusion differing from that of the Deputy-Commissioner, whose order must be discharged with costs.

#### PICTURES IN A CUP OF TEA.

Mr. G. Rockwood, of the Broadway, New York, has addressed a letter on photography to the *New York Evening Post*, in which he describes a tea dry process. The idea is not new, as both tea and coffee were proposed as preservatives

some years ago, but never carried out to any great extent. As Col. Baratti's coffee process has proved very successful, some of our readers will be interested in the precise formula for a tea process. The letter is as follows:—

"I believe you have a sufficient number of readers interested in and practising photography to warrant my sending you a new formula for preparing 'dry plates' for field work and making pictures of interiors. The necessary chemicals, baths, dishes, and paraphernalia for making pictures by the ordinary process are so extensive as to render moving about from place to place quite irksome. To do away with this disagreeable necessity, many processes have been invented for preparing the plates in a laboratory or 'dark room' with some preservative. So complicated have these processes been that amateurs, and, in fact, the professional photographers, are beginning to look upon them as almost impracticable. You will be tempted to smile when I tell you I found the great desideratum in a cup of *English breakfast tea*. Take eight ounces of tea of the ordinary table strength, and dissolve in it about three drachms of crystallized or lump sugar. ('No milk, if you please.') As soon as dissolved, filter, and let settle until clear and cold. Sensitize the plate in the ordinary manner, and thoroughly wash with clean water; then flow it with the saccharine tea solution two or three times, and set it away in a dark closet to dry spontaneously. When dry, expose the plate on the view, about four times as long as in practising with the wet process under similar circumstances. After exposure wash the plate with water, and flow it with a fifteen degree solution of nitrate of silver. Drain for a moment, and develop with photogallic acid. I much prefer the latter. The following is a good formula:—

Pyrogallic acid	...	...	...	2 grains
Citric acid	...	...	...	1 grain
Glacial acetic acid	...	...	...	10 minims
Water	...	...	...	1 ounce

Add no silver to the developer until it is found necessary to force the development to obtain the proper density. Use the plates within two or three days after preparing them. Our grandmothers used to find their fortunes in the bottom of a cup of tea; it is not impossible that we may find some new pastime and occupation there."

## PHOTOGRAPHIC PRINTING IN SILVER, THEORETICAL AND PRACTICAL.

BY W. T. DOVEY.

### TONING BATHS AND TONING DIFFICULTIES, ETC.

To obtain an accurate knowledge of the principles by which a given result is worked out in connection with chemical phenomena requires an absolutely free exercise of thought; and the chief reason why photographers have failed to comprehend the chemistry of their art arises from their proneness to shape their ideas by those of some popular individual, rather than to give free rein to their own perceptive powers, by seeking and striving for themselves. They readily endorse the axiom that nature is truth, but are not so willing to accept those truths which an earnest study of nature's laws alone can impart. There is no royal road to science; she must be sought vigorously and unceasingly, not by the "short cut" usually taken by the majority of men, who borrow ready-manufactured ideas, and consider themselves clever because of their borrowed plumes, but, as before observed, by personal study and independent action of the mind, without which it were vain to attempt one progressive step in the direction of a more perfect knowledge.

Bringing the above remarks to bear on the subject we are called on to discuss, I may here observe that the manifold difficulties connected with toning baths are the fruits of that lethargy or disinclination for the exercise of vigorous and independent research which have caused photographers to cling helplessly to those abominable and unscientifically concocted messes known as alkaline toning solutions,

which, from the tenacity their services are adhered to, seem to possess within them a syren charm to allure their deluded votaries into the most temper-trying difficulties it is possible for man to endure. Be it my business to break through that influence, and to endeavour to persuade my readers to follow me into straighter paths, and to facilitate the accomplishment of my earnest desires; and let me beg of each and all my readers to put aside all prejudices, so that they may follow up the array of arguments I have to offer. I ask no one to believe me because of my word, but I ask that truth may be permitted to prevail, if what I advance is more consistent with science than the doctrines now almost generally followed, and which are daily proved by bitter experience to be based on the extremes of error; and in pointing out the nature of those errors, be it remembered, I cast no reflections on individuals; I thrust every base and selfish consideration aside, and am content to abide by the decisions of mine own conscience.

And now to my task, in the performance of which I shall spare no pains to make the case I offer as comprehensive as words can make it; and by way of caution I ask my readers to avoid running off with an idea that the principles I lay down are erroneous because of their simplicity, or on account of their clashing with the opinions held by their most respected authorities. Allow me, in the outset, to assure you that the theories I hold are based on laboured observation. My observation has found ample exercise in numberless practical tests, and every test applied has been with an object of attaining perfection and a knowledge of the truth. He who would seek truth must dive deep; for

"Errors, like straws, upon the surface flow;  
He who would search for pearls must dive below."

We may now withdraw our print from the portfolio, and proceed with the washing. I return to the print singular, that the thread of my last article might be consistently continued. Having effected my object, we will sever the connection, and adopt the plural number, and write of prints in quantity.

Previous to toning operations, the prints must undergo a slight washing—"until all the free nitrate is removed," suggests old notion. No, I reply; I need a little free nitrate to accompany the prints into the toning solution. "But every existing authority condemns such an idea; every atom of free nitrate must be eradicated from the paper ere it is immersed in the gold bath, or farewell toning action." I readily admit those authorities are in some degree right, yet they are considerably in the wrong. Thus I offer a paradoxical nut which I hope by-and-by to crack satisfactorily.

A batch of prints, consisting of fifteen up to thirty sheets of paper, should be passed rapidly through three waters, taking each print singly and passing it quickly into the first water; then from first to second, and from thence to the third and last. With smaller batches of pictures two waters only need be used. The best guide, however, is the appearance of the water used for the washing: the last should assume an appearance similar to milk-and-water. Bear in mind the small amount of nitrate of silver retained by the print has a duty to perform, which will be described anon. Having reached the threshold of toning matters, I purpose, in some measure, dealing with the subject in the form of queries and replies, a mode of procedure which will, I trust, bring the information and descriptions within reach of the meanest capacity. A learned critic once observed that to write down to a reader's capacity is to offer a direct insult. I therefore crave pardon if I err in the plan I have elected to follow, the error I commit being on the safe side.

What is the meaning of the term "toning" as applied in a photographic sense? It is a modification or an entire change of colour produced by gold precipitated on the silver surface in an extremely minute state of division, which, in addition to a change of colour, imparts to the picture a richer appearance; and the original colour of the print may, at the will of the operator, be changed to a sepia, purple, or black.

Can every description of print be made to assume either or all of the tints described? Certainly not. The tone and brilliancy of a print depend, first, on the quality of the negative; second, on the working qualities of the toning bath. Here I would endeavour to correct a popular error concerning the part supposed to be performed by the gold. It is erroneously considered that the richness observable in a well-toned and vigorous print is entirely due to the precious metal deposited thereon. That the idea is incorrect may in a few words be conclusively shown. When a painter is desirous of adding additional richness of effect to any portion of his picture, he first paints a ground-work in some colour obtrusively bright. To subdue, without entirely destroying, the ground-work so produced, he has recourse to "glazing," which consists of a semi-transparent layer of a suitably sombre hue, which sobers down, but does not entirely destroy, the colour beneath. Now it will at once be perceived that the degree of concealment of the under-stratum of paint must depend on the opacity of the glazing medium employed; the more transparent the medium the more brilliant the result, and *vice versa*; and should a strong body pigment be employed, its opacity may be such as to obliterate all traces of the ground-work. Applying the arguments supplied by this illustration to gold toning, I must here observe that the toning bath must be regarded as a glazing medium which should subdue, but in no instance should the gold be permitted to destroy entirely, the red colour beneath. It is a noticeable fact, that the public, as a rule, prefer purple browns and blacks, because of their superior richness. These tints can never be obtained except a sufficient amount of vigour is found in the print when it is taken from the printing-frame. And a print capable of yielding a fine purple-black is capable also of receiving a sufficient body of gold to produce a black free from all warmth. A weak print, formed chiefly of middle tints, and no tint at all for the high lights, may be toned to a sepia: push for blacks, and slatiness results as the precipitate of gold varies with the amount of reduced silver that forms the picture. It is, of course, well understood that the precipitate of gold in any degree of thickness depends on the proper construction of the gold solutions. Some toning baths are capable of destroying the most vigorous of prints, and reducing it to the extremes of miserable slatiness, whilst others cause no visible change: this last would be described as inert, the first as over-active. Allow me to state that the great fault of toning baths generally is over-activity, which causes mealiness, and leads to diversified failures.

Stay! What is that abomination called mealiness? It is the removal of such portions of reduced silver as are situated on the projecting fibre of the paper.

By what agency are such portions of reduced silver destroyed? Bleaching.

From whence arises this devouring power called bleaching? It is introduced into the toning solution with the chloride of gold.

Its name? Chlorine.

Then we may simplify by stating the matter thus:—

1st. Mealiness is the removal of portions of the prints by the action of chlorine.

2nd. Chlorine accompanies the gold used by photographers.

3rd. Remove the cause, and the effect at once ceases.

(To be continued.)

## HINTS ON PORTRAIT PHOTOGRAPHY.

BY CHARLES E. PEARCE.\*

ALTHOUGH for some time past we have had art photography constantly held before our eyes, at the risk of being thought wearisome I have ventured to bring this subject again before you. I may at once state that it is not my intention to dis-

cuss the productions of men whose works have stamped them as art photographers, and which are well known to you, but rather confine myself to some of the shortcomings, as they appear to me, in the everyday commercially-produced photographs.

The card mania, while it has been the cause of the stagnation at the present time, has unquestionably raised the quality of work—in a technical sense at least—to a higher standard. At the height of the fever it would have been unreasonable to expect the over-worked photographer to pay a great deal of attention to the artistic qualities of his photographs; but now, as quality and not quantity is the one thing looked for, it behoves us to see how far we have improved since that time.

The most important requisites in a good portrait are the pose, the lighting, and the background. While the posing has greatly improved, there being more variety and less dependence on conventional attitudes, and while greater attention has been paid to the lighting, and not without success—for, however photographers may disagree about the form of their studios, yet they are all of one opinion as to the result to be obtained, and at the present time a well-lighted face and figure is rather the rule than the exception—the third requirement, the background, I cannot help thinking has been too much overlooked.

Hitherto, with some exceptions, a perfectly even tint of shade, extending from both sides of the figure to the edges of the picture in one monotonous tone, has been the great desideratum of the photographer, who would sum up all its good qualities in the word "clean;" but I think to this cause is due the uninteresting flatness and want of life to be seen in too many photographs. The lighting may be good, the objects composing the picture may be well arranged; but unless the composition be assisted by the background, there will be a feeling of incompleteness conveyed to the mind very detrimental to the success of the picture, and is, I believe, caused by the absence of the impression of space, which it is impossible to produce with a plain unbroken tint without gradation. As an instance of what a bald background can do, I would ask any one to imagine one of Salomon's pictures with a background of this kind; instead of the gradation of shade helping to concentrate the light on the principal focus, the head, and increasing the contrast, the richness and vigour would be at once lessened, and that completeness as a picture which is one of their characteristics totally destroyed.

I admit that this is one of the most difficult branches of art that the photographer has to encounter, far more than posing and lighting, and is only to be overcome by study of the great masters of portrait painting, of which, fortunately, there are no lack of examples both in the National Gallery and at Kensington. Sir Joshua Reynolds' opinion is well known. To a person who had told him his son was able to paint his own backgrounds, he said: "My good friend, if he can do that he stands in no need of my instruction." It is true that painters have the assistance of colour, and, by the juxtaposition of warm and cold tints, are able to increase contrast, where otherwise the effect would be flat; but the photographer has to depend upon light and shade pure and simple; and, after the light of his studio has done all it can, he must know how to assist nature by art, and be able to place masses of light or shade where needful to increase the effect. It is this power of making these arrangements at will which is so necessary for the photographer to acquire.

In very light backgrounds, if the form be broken, it is possible to obtain delicacy without any effect of tameness, as may be seen in the charming productions of Edge, Notman, and others. These subjects, of course, are not suitable for every person, and, when interiors are represented, I think more would be gained if the background were darker—not heaviness, but more contrast. I think there is a certain amount of truth in the complaint very often made by the sitter to the photographer, that the face is not made

\* Read at a meeting of the South London Photographic Society, June 11, 1863.

white enough, and in most cases the fault will be due to the use of a background of an unsuitable tone; and that it is not whiteness which is desired by the sitter so much as that the face should be seen clearly and easily, which is quite legitimate.

In these days of photographic depression, when the support of the public seems to be on the wane, I believe that something different should be attempted in order to keep up the interest, and in this, as well as in other matters, we should do well to remember that unless we advance we are actually going back. The card picture will always keep its place in popular estimation, on account of many qualities, as size and portability, &c.; and I venture to suggest that the old conventional style of *carte*, with its blank background and inevitable curtain, be discarded, and photographers set to work to describe new effects which will act as a fresh stimulus. We have seen that a great deal may be done in the way of double printing. It would be well, therefore, if photographers were to familiarise themselves with the operation; they would be less dependant upon properties and the scene painter, and gradually new ideas would be suggested. With regard to expression, I think more has to be done in that direction, and it is a matter which lies greatly under the control of the photographer. Men of equal ability differ greatly in the amount of influence they are able to exert over the sitter, on which depends a great deal of the success or non-success of the likeness.

I have noticed, on looking through albums, that most of the unfortunate persons who are there placed for exhibition either have the appearance of being in low spirits, or that they were preparing for some agonizing operation; and I am sure that if any means could be adopted to give more animation it would be very desirable.

I do not quite agree with the dicta laid down by some writers, that no friends should be admitted with the sitter into the studio. On the contrary, I have found—especially in those cases in which the face when in repose naturally assumes an uninteresting expression, but which when animated changes as if by magic—that the presence of a third person is very often of assistance, for the sitter naturally converses with less restraint with an acquaintance, and the operator is enabled to study the countenance of the sitter, and to catch a happy expression before it has died away. Of course, more than one or two persons would be very objectionable, and especially with children the rule of exclusion should be strictly enforced; that is, if the photographer values his nerves or peace of mind.

I believe, as a general rule—although I do not lay it down as an axiom—that every face has a predominating expression by which the likeness will be best known. It is this expression which we should endeavour to secure. Care must, however, be taken not to overstep the modesty of nature, and to portray some transient play of the features which, however suitable at the time, would be very undesirable to perpetuate. Simplicity and unaffectedness, although the countenance may be utterly commonplace, will be always sure to please.

In conclusion, I would say that the discussion which ensues after the reading of a paper is often of more value than the paper itself; I have no doubt it will be so in the present instance; and if we gain any instruction and information, the object of this paper will be attained.

## PHOTO-ZINCOGRAPHY IN PRACTICE.\*

BY J. WATERHOUSE, R.A.

### APPARATUS.

I SHALL first consider the special apparatus required for copying, and then enumerate the materials, &c., necessary for the zincographic part of the process. The essential point

to be observed in regard to the apparatus for copying by photography is *absolute rigidity*. The least unsteadiness is fatal to fine results.

The camera must be supported on a firm solid stand; the plan must be fastened to a wall, or carried on a strong stand free from vibration. It is better to have the studio on the ground, as there is always more or less vibration on an upper floor, especially in a city.

*Camera.*—The camera should be square, of first-rate quality, and is better rigid than of the bellows form. It must be fitted with cones to increase the focal length at least sufficiently to be able to copy a drawing to the same scale, or twice the focal length of the lens.

The lens should be fitted accurately, so that its axis may correspond with the centre of the focussing screen. It will be found convenient to have the screen marked with 1 inch squares round the centre; 4 inches, or 16 squares, will be found sufficient. Their use is to test the squareness of the copy, and also to furnish an aid to the reduction to any given scale; lines passing through the centre at right angles to one another, and divided into inches, will also be found useful.

*Lens.*—In order to produce perfect copies, a lens must be used which will give a sharp, clear image, perfectly free from distortion. Mr. Dallmeyer has constructed a new lens especially for copying. Several of these have been made for different Governments, and have, I believe, given great satisfaction. The different forms of triplets, the rectilinear lens, and Ross's doublet, may all be used when an image is required perfectly free from distortion. For ordinary work a good portrait lens, or the orthoscopic and similar lenses, may be used. It is generally necessary to use a stop about 5.8 inch, and the image should be focussed midway between the centre and margin. A larger lens should be used than the actual size of the subject requires. Thus, to reproduce a subject 10 by 8 to the same scale, a 12 by 10 or 15 by 12 lens should be used.

*Camera Stand.*—A solidly made studio stand, with adjustments for giving the camera motion in altitude and azimuth, is required; the base should be rectangular or square, and may be furnished with castors or wheels to run on, or between rails placed at right angles to the plane of the plan-board.

*Apparatus for Carrying the Plan while being Copied.*—If the subjects to be copied are to be reduced on one plate, or are not of large size, there is no necessity for any special apparatus. A board may be fixed on a wall in a convenient situation, and the drawing fastened to it with the tapes before mentioned, or, if small, it may be pinned on. When, however, it is required to reproduce large plans on the same scale, several negatives must be taken, and an apparatus is required which will enable the plan to be moved vertically and laterally, so that the sections may be brought in front of the lens without altering the position of the camera or unfastening the plan. I devised an apparatus of this kind for the Surveyor-General's Office, Calcutta. It consists of a rectangular iron frame travelling in two vertical grooves, its height being regulated by parallel rackwork, with a detent to stop it at any required height. The iron framework has two horizontal parallel rods fixed in it; on these rods the part carrying the plan-board slides. The plan-board is fixed on a pivot in the centre of two diagonal arms, the ends of which terminate in four arcs, with circular slots in them through which screws are attached to the plan-board, and serve to clamp it in any position. Between these arcs and the centre are fixed the tubular sliders, which run upon the parallel rods. The accompanying diagram will give a better idea than any verbal description.

For use in England this apparatus might be constructed partly in wood, which would be cheaper than iron.

When circumstances will permit, and it is only required to copy small engravings, or to reduce subjects not exceeding about 18 inches square, it is preferable to have camera, stand, and plan-board combined in one solid piece of apparatus,

\* Continued from p. 281.

which may be done in several ways according to the size of the camera.

A good form would consist of a strong table frame supported on four or more legs, according to the length. At one end of this the plan-board would be firmly fixed, so as to be at right angles to metal grooves fixed in the sides of the frame, in which the part carrying the camera would travel by means of metal runners. If necessary, the other

end could be left open to admit the operator when focussing, the sides of the frame being held together by iron bracings at points between the part usually occupied by the camera and the board, the legs being cemented together near the bottom.

The plan-board should be marked in one-inch squares, which, with the squares and lines marked on the focussing glass, will be a great aid in ascertaining that the image is perfectly square and of the proper size. A set of Holtzappel's engine-divided scales, on cardboard, will be found useful in measuring the reductions.

A spirit level will be required for adjusting the camera. No other special apparatus will be required for the photographic part of the process.

The following zincographic apparatus will be necessary for those who wish to lay down their own transfers:—A lithographic press; inking table, constructed as a cupboard, to hold the rollers, inks, &c.; inking stones, one for transfer ink, the other for printing ink; lithographic rollers; one or two palette knives for mixing the inks; zinc plates, one polished, others according to requirements; graining sand; mullers for graining the plates; a lump of snake stone and some snake slips; a scraper and eraser for corrections; old linen cloths for damping, &c.; litho printing ink; retransfer ink; turpentine; gum arabic; nutgalls; phosphoric, nitric, muriatic, and sulphuric acids; strong solution of potash; stout demy paper, for offset sheets, &c.; plate paper and enamelled paper for printing; thick bank post paper for transfers: all these may be obtained from Messrs. Hughes and Kimber, of West Harding Street, Fetter Lane, or other dealers in lithographic materials.

I shall give a fuller description of such of these articles as require it when treating of the zincographic part of the

process. Having now described the apparatus required, I will proceed to the details of manipulation.

#### PREPARATION OF THE NEGATIVE.

As I have observed before, in this process success mainly depends on the quality of the negative, and without perfect negatives perfect results cannot be obtained. It will often happen that copies are required of some subjects of which perfect negatives cannot be obtained. In this case the only thing to do is to obtain as good a result as the subject will permit. The manipulations are the same as those of the ordinary wet collodion process, with which I assume my readers are familiar.

The first point that needs attention is the *focusing*. It is better to do this before fastening the drawing on the board. The first thing to do is to adjust the camera, so that the image of the centre of the board may coincide with the centre of the focusing screen, which, in a properly constructed camera, will occupy the position of the centre of the sensitive plate. Now compare the images of the squares. We will suppose it is required to produce a copy half the size of the original: to do this, the position of the camera must be altered till a square eight inches in the side *exactly* occupies the square of four inches in the side marked on the focusing screen. When this is the case, the surface of the board and that of the sensitive plate will be perfectly parallel. The drawing is now fastened on the board, and the sensitive plate got ready. The glass plate, being thoroughly cleaned in the usual way, is coated with bromo-iodized collodion containing very little bromide (only just sufficient to secure cleanness in working is required; a good iodized collodion may sometimes be used with advantage when everything is in good order); it is then sensitized in a 35-grain bath of nitrate of silver, faintly acid with nitric acid. The exposure must not be prolonged, or there will be danger of deposit on the lines; it must be carried just far enough to produce as much intensity as possible on the ground of the negative, while the lines remain perfectly free from deposit. The developer is as follows:—

Protosulphate of iron	...	...	...	1 ounce
Glacial acetic acid...	...	...	...	1 "
Alcohol	...	...	...	1/2 "
Water	...	...	...	1 pint

I have found the addition of gelatine or glycerine, as recommended by Mr. Nelson Cherrill, advantageous in keeping the lines clear, and increasing the density. The development must not be carried too far. The plate is fixed in a 15-grain solution of cyanide of potassium, and examined by daylight. If the lines are perfectly clear, the re-intensification may be proceeded with; but if the lines are not quite free from deposit, Mr. Osborne's *clearing* process may be used with great advantage. The cyanide having been well washed off, the following solution is applied to the plate:—

Iodide potassium	...	...	...	2 grains
Iodine	...	...	...	1 grain
Water	...	...	...	1 ounce

It is allowed to act about a minute, and washed off; the plate is then covered with a weak solution of cyanide, the effect of which will be to clear the lines very much. If this treatment should not produce the desired effect, it will be better to try another negative, giving less exposure, or not carrying the development so far. The plate is washed, and again covered with the iodine solution, which is washed off almost immediately; and care must be taken to wash the plate thoroughly before proceeding to the re-intensification.

#### Re-intensifying Solutions.

1.—Pyrogallie acid	...	...	...	4 grains
Citric acid	...	...	...	4 "
Acetic acid	...	...	...	15 minims
Water	...	...	...	1 ounce
1.—Nitrate of silver	...	...	...	20 grains
Water	...	...	...	1 ounce

Two or three applications of the re-intensifying solutions

will, in most cases, give sufficient density, but there is great danger of clogging the lines. It is better only to apply the pyro and silver once, and obtain the necessary density by a change in the colour of the deposit, rather than by any additional deposit. The pyro having been thoroughly washed off, the plate is immersed in a saturated solution of bichloride of mercury, where it remains till it is quite white; if there are fine lines, the action should not be carried beyond the dark grey stage. It is then well washed, and a diluted solution of hydrosulphate of ammonia is poured over it, which instantly changes the colour to a dense russet black. The plate is again thoroughly washed, and, when dry, varnished in the usual way.

In the course of my experience in India I found that if citric acid was used in the re-intensifying solution the film was extremely liable to split when immersed in the bath of bichloride of mercury. I therefore sought a means of replacing the bichloride of mercury, which is undesirable for several reasons, using the following solution, recommended by Mr. Carey Lea.

Cold sat. sol. bichromate pot.	...	3 fl. drachms
Hydrochloric acid	...	1 drachm
Water	...	6 ounces

This solution is poured on after the plate has been re-intensified with pyro; it quickly changes the colour of the film to a bright lemon yellow, and appears to somewhat clear the lines. It is washed off, and the hydrosulphate of ammonia is applied, which changes the colour to a dense chocolate brown.

The only point to which attention need be drawn is the necessity of thoroughly washing the plate after each stage of the operation, for unless this be done the lines will be stained or covered with deposit, and the negative rendered useless.

Faults in the negative may be partly remedied by dusting out transparent spots and stains with lampblack, &c.; and when the nature of the film will admit, broken and closed lines may be opened by the dexterous use of a sharp needle or etching point.

(To be continued.)

#### PICTORIAL EFFECT IN PHOTOGRAPHY; BEING LESSONS IN COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS. BY H. P. ROBINSON. CHAPTER XXI.

*"Grouping."*—My advice to photographers on the subject is something similar to *Punch's* celebrated advice to persons about to marry: 'Don't!' Except in very small pictures, it is almost impossible to secure a satisfactory group of more than two persons at once by photography. It tasks the skill and attention of the photographer quite enough to see that the arrangement, lighting, and expression of one figure are perfect."—*Refrinder*.

#### PORTRAITURE—continued.

The composition of a portrait group depends very much upon the character of its constituents. Two or three children, if they are not excessively stupid samples, are very easy to group together, and, when well done, make the most agreeable and natural pictures; while two adults, especially of the male kind, although easier to photograph, seldom make an effective composition.

The great art in the composition of a group is in so arranging the figures that they shall have some relation to each other, as well as the ordinary elements of pictorial construction. There should be some bond of union between those who compose the group; some incident should be represented in which they are mutually interested; or something must be imagined out of the picture to attract the attention of both, if only two are represented, or of many of them, if there is a number. The figures should be massed together, and not scattered over the picture so as to make it necessary to examine each portrait in detail, until it has been seen, and the effect agreeably felt, as a whole. Nothing has a more disagreeable effect than two figures in one pic-

ture which may be cut in two without much injury to either half. Two figures, like Enid and Geraint in the wild land,—

"Apart by all the chamber's width, and mute  
As creatures voiceless, thro' the fault of birth,  
Or two wild men supporters of a shield,  
Painted, who stare at open space, nor glance  
The one at other, parted by the shield."

It is not necessary in representing two persons in conversation, that they should be looking at each other; the effect of listening can be rendered without that. It constantly happens that in conversations even on the most important subjects, the talker and the listener do not look at each other, although, even if the sounds were not heard, it would be obvious from their appearance that the persons were in conversation. One point which should command the attention of the student is, that there should be variety in the heads, not only as regards profile, three-quarter, or full face, but in their position on the paper. Thus, it is difficult (although possible) to obtain much pictorial effect out of two figures of exactly the same height standing together; in such a case variety must be got in the lines of the different figures by varying the direction of the bodies, by the arrangement of the arms and hands, and by the disposition of the accessories and background.

As an example of the possibility of this, I give an illustration taken from a photograph of two young ladies, alike in height and general appearance. It will be noticed that the subject is extremely uniform—two young ladies standing, with an upright post and mass of foliage, very nearly alike, forming the entrance to the arbour, on each side of them; yet a very slight alteration in the almost corresponding sides of the picture has made it a pleasing and agreeable composition.\*

It is by the amount of perfection with which he succeeds with groups that the photographer will discover the power that is within him. If, after repeated attempts, he fail, or do not succeed to his satisfaction, he will do well to confine himself as much as possible to vignette or medallion heads, a style demanding some taste and care, but taxing the artist much less than more elaborate compositions. Many photographers have so studied the best methods of treating the

\* Our engraver has given the background a more pronounced character than it possesses in the photograph, which is not an improvement.—Ed.

head, and the head alone, that they have succeeded to admiration, and attained high reputation by this class of work. They have preferred to succeed by doing a simple style well, rather than a more complex style imperfectly.

Some artists prefer to have to make a group of three persons rather than two. I confess that the more figures I have to deal with in portrait photography, the more difficult I find my task. More than three or four figures should never be attempted in one negative, if it is necessary that every person should be a good portrait. I leave out of consideration here, large out-door groups taken on the hit-or-miss principle. It is impossible to get more into an upright carte-de-visite without crowding. I have seen a dozen or more figures in a card portrait; but we are speaking of composition here, not of figures thrown together in a heap, with a head appearing here and there just as it gets the opportunity. If more than four figures must be included in the small dimensions of a carte-de-visite, it would be much better to turn the camera on its side, and make a horizontal picture of it. I have seen some most delightful little gems of pictures of this kind by Angerer, in which the interior of a large drawing-room of people—full, without crowding—was represented. I should much like to see pictures of this kind introduced into England, but the large size of the glass room required would, I fear, prevent all but a few attempting them.

When the picture is larger than a carte-de-visite or cabinet size, it is always better and much easier to produce a group by combination printing. Photographers appear to have been afraid of the difficulties of this method; but I am glad to see it is coming very much more into use, as photographers obtain a more intimate knowledge of the capabilities of their art. To accomplish this, a sketch should be made of the composition, no matter how roughly done, so that the artist knows what he intended by it, when he looks at it a second time; or the figures may be placed in position, and a small photograph taken of the arrangement. They should be so grouped that the joinings should come in unimportant places. Although it is possible to make a perfect join, even in such a difficult place as down the line of a delicate profile,\* it is better, if possible, to keep the mechanism of the art out of sight. When a sketch or small photograph of the complete arrangement is obtained, the groups or single figures should be photographed in detail, by preference against a white or very light screen, if a background is also to be put in. If the background is to be an interior, it will be found most convenient to take it with the figures, the accessories being so arranged that the lines of junction will not be seen.

A natural background may be introduced behind a single figure with great effect, and Mr. Edge has lately shown that it may be used with advantage for pictures so small even as a carte-de-visite.

#### PROFESSOR SMYTH'S "GREAT PYRAMID" BATH.

BY DR. MANN.†

Through the kindness of my friend, Professor Smyth, of the Royal Observatory, Edinburgh, I had the opportunity and pleasure of showing the members of the Society the bath with which the Professor made the miniature photographic pictures in Egypt when preparing his work on the "Great Pyramid;" and also to submit to the observation of the Society a small series of the miniatures themselves, and of the enlargements made from them.

In order to prevent any misapprehension, it may be right that I should here state what has been distinctly said elsewhere, that Professor Smyth does not claim originality either for making very small photographs, or for the exposure of the plate when in the nitrate of silver bath.

\* In the presentation print I am now doing for the Photographic Society, I have purposely arranged a join down the outline of a profile, to show that it is possible. The copies are being printed entirely by assistants, and not five per cent. are discarded for defective joining.

† Read before the London Photographic Society, June 9th.

I believe the Professor himself frequently speaks of Mr. Skaife as having been before him in the suggestion and making of very small pictures under brief exposure, and of exposure while in the bath having been one of the ideas of an early age of the photographic art. If there had been time and opportunity, I would have made an endeavour to bring Mr. Skaife's proceedings into review in connection with Professor Smyth's mode of working upon this occasion. I may possibly find some other occasion to do this. My immediate purpose at this time is simply, as I had recent occasion to allude to the Professor's mode of working, 1st, to show our London friends the bath which the Professor used in his Egyptian campaign; and, 2nd, to afford Mr. Dallmeyer, and any others who may feel interested with him in that bearing of the question, to examine the optical character of the small pictures.

It may be necessary, before drawing attention to the bath and the pictures, here briefly to recapitulate the peculiarities of the process adopted on the occasion of this Egyptian excursion by Professor Smyth. The camera used was made of tin, 8 inches long, of which  $6\frac{1}{2}$  inches was composed of a hood or sun-shade. The lens was a kind of locket-lens, a double combination of 1·8 inch focal length, which was worked with apertures one-tenth and one-twentieth of the focal length. The focus was adjusted, not by the eye, but by the instrumentality of a graduated scale determined beforehand. The light was cut off from the picture by a screen of blackened tin, placed, not in front of the lens, but just before the sensitive plate, and so contrived as to qualify the exposure of different parts of the plate and moderate the "sky-action."

The bath, which I here produce, is made of ebonite, and is externally 4 inches high, 2·5 inches broad, and 1 inch thick. Its internal capacity is 3 inches by  $1\frac{1}{2}$  inch and  $\frac{3}{4}$  inch. The bottom is so inclined as by its form to keep the plate in contact with two platinum pins provided for its lower end. A third point is so placed above as to enable a wedge inserted behind to bring the picture-plane into its proper position and keep it there. In front of the plate there is a little window 1 inch square, composed of a piece of very carefully prepared glass, having exactly true and parallel sides, and possessing a brass shutter of its own, which is closed when the bath is not in use. The bath has a cover of ebonite, with a ring on the top, by means of which it can be carried upon the little finger when the operator is at work.

The Professor's battery of apparatus consisted of half-a-dozen broad-mouthed bottles, and a pair of steel and of ebonite pliers. The glass upon which the picture was made was simply the microscopic object-slip, measuring 1 inch by 3 inches. This was inserted into the bath and wedged into position, one end downwards, so that the inch square picture ranged transversely across its middle third. The operation consisted mainly in a series of dippings. The plate was first dipped into one of the bottles containing the collodion, then dipped into an ordinary nitrate of silver bath contained in bottle No. 2. It was thence transferred to another portion of the same solution contained in the exposing-bath, next placed in the camera, and there exposed for a period varying with the aperture from a fraction of a second to twenty seconds. After the exposure there was a third dipping, in the iron-solution bottle; a fourth dipping, in a water-bottle; and a fifth dipping, in cyanide-of-potassium solution, followed by a final washing.

The difficulties which Professor Smyth turned the flank of, or avoided, by his mode of working were:—(1) the partial drying of the plate at the edges in temperatures sometimes as high as 90°, with 25° of difference between the readings of the wet-bulb and dry-bulb thermometers; (2) the dusting of the moist plate with clouds of dust and fine sand otherwise unavoidable in the circumstances in which the Professor worked; and (3) the encumbrance of the more complicated apparatus ordinarily employed in excursion photography.

It was stated upon the authority of Mr. John Nicol, who presented a detailed account of Professor Smyth's apparatus and mode of working to the Edinburgh Photographic Society in the year 1866, that some of these inch-square miniature negatives bore magnifying up to 15 feet very much better than the best pictures of larger size ever before shown to that Society.

Two of the miniature pictures shown—those, namely, of the broken corner of the coffer in the king's chamber of the Great Pyramid—were taken with the magnesium light, with an aperture one-fifth of the focal length of the lens. Nine others of the miniatures were taken with an aperture one-tenth of an inch focal length, and five others with an aperture one-twentieth of the focal length.

Professor Smyth has drawn my attention to a curious fact in regard to these negatives. Some of them were intensified with persulphate of uranium, and have been solarized and become quite translucent, but are not at all solarized to chemical rays, as they still give intense pictures, with sharp black-and-white detail.

#### NOTES ON THE CARBON PROCESS.

MR. A. J. DRUMMOND, writing to *Humphrey's Journal*, says:—

In the last number of your valuable Journal, a carbon printer asked for information, "to prevent Swan's carbon tissue cracking before and after sensitizing; also, to prevent bubbles on the tissue when developing?"

My experience with Swan's carbon tissue has been the same as that of your correspondent; so much so that on sensitizing in the evening, in the morning I found it curled and cracked so badly that it was almost impossible to use it. I tried various remedies; my first was to sensitize in the morning, and expose when sufficiently dry, without adhering to the negative; this worked well for a few sheets; but where a number were to be done, the result would be as above, owing to the length of time required in exposing. Then I resorted to another expedient, steaming, and that I found to be very dangerous, as it was apt to adhere to the negative. At last, almost discouraged by my numerous unsatisfactory experiments, I made a trial of rock candy, which resulted in a highly satisfactory manner. Let your correspondent try this formula, and report the result. To every 12 ounces of bichromate of potash solution I added 4 ounces of rock candy. The weather was very cold; but the mercury in my room stood at 60° F., and the tissue, with the addition of the rock candy, was quite pliable, and answered every purpose. When sensitizing Swan's carbon tissue—No. 3 grade, which as a heavier coating of gelatine—the proportion of rock candy may be increased to 6 ounces to 12 ounces of solution. The bubbles can only be prevented by a proper consistency of rubber solution, and being careful to brush the solution with an even-flewing coat. Care should be taken not to get any of the rubber solution on the back of the tissue.

I have also found a sample of paper which gives better satisfaction in my hands than any I have hitherto used for the first transfer. The paper alluded to is that known among paper dealers as "Law Point," weighing 35 pounds to the ream. The desirable qualities of this paper are its absorbent properties, and the heaviness of texture, which makes it invaluable to the carbon printer for transferring the tissue.

I immerse the picture to be developed in a water bath about 80° F. After allowing it to soak for a few minutes, raise the temperature to 90° F.; the tissue in all probability will be ready to transfer. I am greatly in favour of developing in as low a temperature as possible, as it preserves the half tones; when the water is too hot it will invariably cause bubbles.

Insufficient pressure will cause bubbles; this no doubt is the cause of your correspondent's trouble.

I recently received from Mr. Swan some fine tissue, prepared of various colours and of different degrees of strength, to suit the several classes of negatives. The principal shades are black, brown, and purple; these are distinguished by the letters A, B, and C, and the strength by numbers.

No. 1 is suitable for good negatives, but slightly inclining to hardness in those which yield prints with a little too much contrast of light and shade.

No. 2 is adapted for all good negatives having the following qualities, viz.:—The average degree of density, and delicate

gradation in the half tones; and also those which are very clear in the deep shades.

No. 3 suits negatives which give prints with abundant half tones, but somewhat deficient in vigor. The size of the sheets is 18 by 23.

I cannot but admire the highly creditable manner in which Mr. Swan has put his tissue in the market; and I would beg leave to suggest to him, when preparing carbon tissue for this climate, that he make it more pliable; for it is so brittle before sensitizing that it cannot be handled unless slightly steamed in order to soften the gelatine; and great care must be observed in so doing, or the gelatine may soften, and discharge the pigment into the bichromate solution.

#### Proceedings of Societies.

##### SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE annual meeting and last meeting of the present session was held on the evening of Thursday, June 11th, at the City of London College, Leadenhall Street, the Rev. F. F. STATHAM, M.A., F.G.S., in the chair.

The minutes of a previous meeting were read and confirmed.

MR. WHARTON SIMPSON exhibited some fine cabinet portraits, consisting of large, brilliant vignette heads by Reutlinger. He also called attention to some paper pulp made from deal, and suggested that it might be worth while to ascertain whether it possessed any value in the manufacture of pyroxaline.

The Secretary then read the report as follows:—

##### ANNUAL REPORT OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY, 1868.

YOUR Committee, in submitting their Annual Report of the proceedings of the Society for the session 1867-68, beg to congratulate the members on the renewed vitality which the record of the past session so fully evidences.

From circumstances which were under discussion towards the close of the last session, it might have been inferred that the interest hitherto felt by members of the S. L. P. Society would possibly become lukewarm, and thereby endanger its success. Actual events have, on the contrary, shown that the same spirit which has always pervaded this Society is still embodied in a "healthy pulsation;" and your Committee, looking forward to a still higher degree of interest amongst the members, now refer to the proceedings of the Society during the past year.

Your Committee have much pleasure in stating that in the number of papers read there has been an increase compared with the number read last year, and whilst expressing their thanks to those gentlemen who have come forward to read papers, your Committee would still wish to see some fresh recruits to swell the ranks of these members who devote much time and thought to such matters. The following are the names of the gentlemen and the subjects of their papers:—

MR. MEAGHER, on the Breaking of Negatives.

MR. BLANCHARD, on the Preservation of Prints by means of Collodion.

MR. E. COCKING, a Suggestion for Raising the Position of Photographers.

MR. F. HOWARD, on the Introduction of Clouds in Landscape Photography.

MR. J. R. JOHNSON, on Natural Clouds in Landscape Photography.

MR. J. T. TAYLOR, on the Oxyhydrogen Light, and means of Avoiding Explosions.

MR. S. FRY, Omnium Gatherum.

MR. PEARCE, a few Thoughts concerning Portrait Photography.

Your Committee also have much satisfaction in alluding to a novelty in the history of the Society, and which has met with great success, viz., the introduction of a "Question Box," which, on the occasion of using its contents, proved to be one of the most interesting meetings of the session.

The experiment of an exhibition of photographs amongst the members, with conversation thereon, also proved to be a step in the right direction, and your Committee anticipate that on the next similar occasion the result will be still greater in importance.

The Committee are indebted to the following gentlemen for interesting specimens, photographs, and other matters; viz.:—MR. G. WHARTON SIMPSON, MR. BLANCHARD, MR. H. COOPER, MR.

Meagher, Mr. J. T. Taylor, Mr. Nash, Mr. Leake, Mr. T. Sebastian Davis, Mr. J. K. Johnson, Mr. Booty, Mr. Dallmeyer, Mr. Hunter, Mr. Werge, Mr. Henderson, Mr. Rejlander, Mr. E. Cocking.

Your Committee have another source of satisfaction in having obtained for the presentation prints for this session specimens of such well known art photographers as Messrs. Rejlander and H. P. Robinson: from the former, a photograph in silver, entitled "Homeless," and from the latter a large photograph in carbon entitled "Going to Market."

Your Committee desire to thank Messrs. Elliott and Werge for allowing the Committee to hold their meetings at their warehouses.

In conclusion, your Committee hope that, as hinted in last year's report, the possibility of shadows occurring having passed away, the future of the Society may be all sunshine and success.

The Treasurer's account was then read, and showed a balance in hand of £4 3s. 7d.

The Officers for the ensuing year were then elected as follows:—

*President:* The Rev. F. F. Statham, M.A., F.G.S.

*Vice-Presidents:* Mr. T. Sebastian Davis, Mr. G. Wharton Simpson, and Mr. V. Blanchard.

*Committee:* Messrs. Bedford, Bockett, Elliott, Hart, Johnson, Pearce, Werge, and J. T. Taylor.

*Treasurer:* N. Edgar Fitch, Gwydyr Villa, St. John's Road, Brixton.

*Honorary Secretary:* Edwin Cocking, Queen's Road, Peckham.

After votes of thanks to the President, Treasurer, and Secretary, for their valuable services during the year,

Mr. CHARLES E. PEARCE read a paper on Portraiture, (see p. 292).

The CHAIRMAN, in proposing a vote of thanks to Mr. Pearce for his able and interesting paper, referred to a recent article in *Cassell's Magazine* on photographic portraiture, in which the prevalence of a "put on" expression in photographic portraits was regretted. He thought that, to avoid this dazed, solemn, and unusual expression was well worthy of consideration. Sometimes it was true that by skill or good fortune a photographic portrait was obtained without it, but the opposite was the rule. Possibly if instantaneous effects could be produced it would be better. He thought it a pity, too, that something more was not attempted in backgrounds: such as the introduction of natural objects as accessories instead of the common stock appliances of curtain, column, balustrade, table, and chair.

Mr. DAVIS said that Mr. Wharton Simpson had, at a recent meeting, exhibited some charming examples of portraiture with natural backgrounds.

The CHAIRMAN also thought that it would be possible for the photographer to keep in his studio some articles of drapery by which he might modify the dress of the sitter. He referred to the portraits of Gainsborough and Reynolds, in which the sitters were often represented in character, so as to communicate pictorial interest to the portrait, independent of its likeness.

Mr. WHARTON SIMPSON exceedingly regretted that he had not known that the subject would be brought before them, otherwise he would have brought with him various examples of the class of work to which the Chairman had referred: portraits with natural backgrounds, and portraits which, without being theatrical, or without attempting strained or unreal characters, were so treated as to give them pictorial value apart from mere portraiture. The cards by Mr. Edge were known to many, and some of Mr. Robinson's recent cabinet pictures would have admirably illustrated what the Chairman had described. It was, however, impossible to get natural effects to any extent without double printing; whilst, however, the variety of effect which natural backgrounds gave was valuable, it should be borne in mind that with few and simple accessories very valuable background effects were possible. M. Salomon—who had, perhaps, more than any other photographer shown the effect of the background in giving value to the head—confined himself to a few of the simplest and most common-place accessories. He showed that in the mode of using them, rather than the objects themselves, all the importance of the subject rested.

Mr. BLANCHARD asked Mr. Pearce if he had brought some of his own fine examples with him, referring to some excellent effects in backgrounds produced by using the gloom of a dark-

ened room, seen through an opened door, instead of a screen for the background.

Mr. PEARCE had not brought the examples with him.

Mr. BLANCHARD did not think that very great rapidity in portraiture was desirable. If portraits could be taken quite instantaneously it would be very well; but as that was impossible, he preferred in portraiture an exposure of 15 or 20 seconds to one of 5 seconds, as time was thus allowed for the sitter to get over the twitching or rigidity of the first few moments of sitting. He thought, too, that a quiet sober, expression was better than a simper or a smile.

The CHAIRMAN complained of a want of intelligence or interest in the expression of so many. He thought the practice of asking the sitter to look at a definite point like a nob was injurious. What interest could a sitter have in his countenance when told to look at a nob?

Mr. BLANCHARD would not ask him to look at a nob; nor was that, he thought, the practice of skilled portraitists. He would prefer to engage the sitter in a conversation which interested him, and then seize the opportunity of exposing when a satisfactory expression was on the face.

Some desultory conversation on the subject followed.

Mr. HOWARD said, that in the earlier days of photography, stiff expression and want of character were common enough. A photographer seeing his sitter for the first time, and taking the portrait at once, could scarcely be expected to do it much justice; but now sitters as well as photographers were getting more educated in regard to photographic portraiture, and he thought that a large class would willingly pay more for better work. He thought that if the sitter had an interview with the photographer previous to the sitting, so that the latter might have time to make up his mind as to the best mode of treatment, superior results would often be secured. Of course, higher charges would have to be made; but the result would be worth the cost, and many would be glad to pay the higher rate for the superior portrait. Of course, unless the sitter aided the photographer by properly entering into the spirit of the thing, very good results could scarcely be expected. He believed that by judicious double printing much better pictorial effects in background could be secured.

Mr. BLANCHARD said that his dark room window was arranged so that he could, unseen, study the sitter; and he found a great advantage in the arrangement.

Mr. DAVIS said he thought it was a great mistake for high class photographers ever to take sitters under any but the most favorable circumstances. If they would only do this, and never send out any but really first-class work, the public would learn that photography was something more than a merely mechanical art. Unfortunately, the ablest men would sometimes send out bad work, and so people lost faith in them. He believed that many of the public would gladly pay high prices if they could be certain of receiving first class work.

Some general conversation followed, in which the CHAIRMAN again referred to the introduction of a variety of natural objects, such, for instance, as were found in many Dutch paintings, those of Gerard Dow, for instance.

Mr. SIMPSON said that there were two serious difficulties in the way of doing this. First, the multiplicity of accessories which would be necessary to avoid uniformity of result, inasmuch as the photographer could only introduce such objects as he could place absolutely before his camera; and secondly, that by photography, the accessories placed in different planes could not be produced in focus. The only mode of effecting the object would be to use double printing. A few well selected background negatives might be made to produce a variety of effects by using different parts of the plate with different figures.

Mr. BLANCHARD deprecated the use of a multiplicity of objects in portraiture, and quoted an apothegm by Mr. Cherrill from the *Year-Book of Photography*, to the effect that as photographs are always elaborate in finish, the subjects of photography should always be simple in design.

After some further conversation on the subject,

Mr. PEARCE agreed, at the suggestion of the President, to provide a paper on the subject of double printing in portraiture for next session. Mr. Blanchard also promised a paper for next session.

After some discussion on the subject of out-door meetings, it was agreed that a meeting should be held on the first Saturday in September, at Hampton Court, the members meeting at "The Mitre" Hotel, at 5 p.m.

The PRESIDENT invited the members to spend an evening with him at his residence on the first Saturday in July. —  
The proceedings then terminated.

## Correspondence.

### INTENSIFYING NEGATIVES—NEUTRAL TONING BATH.

SIR,—Seeing an account in a late number of your Journal that forcibly drying negatives increases their density, I beg to say I have long used the plan of drying the negative before fixing, either by standing it up to dry by itself, or otherwise. The density is most decidedly increased, which is easily proved by letting one-half of the plate dry, and then fix and dry as usual. It will be seen that the part dried before removing the iodide is much darker than the part fixed in the moist state. I use cyanide for fixing.

Mr. W. Bartholomew asks you whether magnesia is much used in the toning bath? I beg to say I have tried it, and found it do very well, but not any different from the prepared chalk bath I described in this Journal two or three years since, and you repeated in the following YEAR-BOOK. It suits any gold. If mixed in the morning, it is ready in the evening. In frosty weather, it is better mixed the night previous. It will keep for days at least, and can be used over and over again, adding more gold, and perhaps, also, more chalk, if there should be no excess of that substance remaining from the previous mixing. An excess is not of the slightest consequence, and it is scarcely possible to have too little, so small is the quantity required. No weighing is necessary. I cannot see any difference in the tones obtaining between chalk and the other formula, and believe it is purely imaginary. My bath is always in order, and the simplest possible. T. S. REEVES.

### APPROXIMATE NATURAL COLOURS IN PHOTOGRAPHY.

SIR,—As this desideratum is now receiving much attention, the following may be worthy of a place in your Journal. I have many times, in my out-door practice, obtained landscapes in natural colours by the following manner:—Expose a little longer than required for a negative; develop with the pyrogallic developer, and stop the developing when the picture has arrived at the stage of a positive; wash, and fix with a strong solution of cyanide of potassium; and you will find the sky blue, the road-way a yellow tint, and the trees of a green tinge. I have done some remarkable pictures, but the colours being bad, I have not followed it up with experiments, having so little time on my hands; but it is worthy of attention.—I am, yours, &c., C. KENIG.

450, Edgware Road, June 10th, 1868.

## Talk in the Studio.

PHOTOGRAPHY MADE CHEAP AND EASY.—We were struck on passing along a public thoroughfare in the City a few days ago, by an announcement in a stationer's shop window, "Complete photographic apparatus, with material for fifty pictures, for sixpence." We at once invested the sum in question, and, on opening the packet supplied, found that we had received a quarter-plate piece of glass and a piece of cardboard the same size (the two being held together by a couple of india-rubber rings), and a paper containing something less than a drachm of bichromate of potash in powder. A paper of instructions directed the photographic tyro to make a solution of the salt, float writing paper thereon, and then produce a negative by placing the prepared paper in contact with an ordinary print, pressing the print and sensitive paper together between the glass and card, and duly exposing to light. From the negative so obtained any number of prints might be produced on the prepared paper, the only fixing necessary being soaking in warm water. The picture produced was an image, of course, of brown oxide of chromium.

PERMANENT PHOTOGRAPHS.—A recent number of a very ably conducted critical and satirical journal, entitled *The Censor*, in the course of an interesting and kindly notice of Mr. Wharton Simpson's work on the carbon process, has the following remarks:—"But will it wash?" was the question with which Mrs. Siddons startled the draper. A modification of this enquiry we have all addressed to the smiling photographer as he has emerged from the little dark room with a serene self-satisfaction in having achieved a beautiful negative. 'But will it stand?' we have all demanded, and have all received the comforting assurance, given with more or less confidence, that under favorable circumstances it would stand, though its permanence could not be guaranteed. With this assurance we have perforce been content. And then we all know what has happened. After a year or two, signs of distress have appeared in the charming likeness. My lady has, to all appearances, taken to patches, if indeed those black spots do not indicate some cutaneous eruption. As for Sir John, he is dismayed to find himself the centre of a new planetary system, beams of light radiating from his head, as if he were another Phœbus, while comets and uncertain fudicrous nebule, are developing all over and around him. This is not pleasant. Nobody cares for a photographic apotheosis in this kind; and to go down to posterity all blurs and scars, smudges and eruptions, is something terrible to contemplate. Thank heaven, we have now changed all this! Swan's process has reformed it all together."

PHOTOGRAPHIC EVIDENCE.—In the course of the recent action for libel by Risk Allah against the *Daily Telegraph*, photographs of various documents were admitted as evidence.

POISONING WITH BICHROMATE OF POTASH.—Most photographers are aware that this substance is a dangerous poison, but it may be well to remind them, as accidental poisonings have more than once recently occurred. On Monday an inquest was held at Cheltenham on the body of Mr. T. B. Gilling, an auctioneer, who had died from drinking a quantity of bichromate of potash. Deceased had sent for a bottle of Bass's pale ale, which bore the usual label; but, not wishing to drink it at the moment, it was placed beside a number of other bottles in a carpenter's shop. Amongst these was one containing bichromate of potash, which had been put into an empty ale bottle, with the label carelessly left on. The similarity in the appearance of the bottles led to the fatal mistake.

MR. WOODBURY'S PATENT.—We noticed some weeks ago an error in our able contemporary, the *Art Journal*, in relation to the origin of the photo-relief printing process. The number for this month has the following handsome *amende*:—"Disderi's Patent. Under this title appeared, in our April number, a notice of a photographic process which was stated to be one 'based on the invention of Mr. Walter Woodbury.' The PHOTOGRAPHIC NEWS states, and Mr. Woodbury himself has also informed us, that the process is entirely his own invention, and that he somewhat recently sold the patent to a company, of which Mr. Disderi is managing director. Mr. Woodbury has long been known among photographers as one of the most skilful and scientific practitioners of the art, and we are glad to render him the justice that is his due."

SOLAR HEAT AS A MOTOR.—The *Scientific American* says:—"It has been proposed to employ solar heat in generating steam. By using a lens of small diameter, the sun's rays have been concentrated in a vessel containing water to such a degree that enough steam has been generated to drive a small engine. Increasing the size of the lens will, he contends, have the effect of still further intensifying the solar heat, and the power that may be obtained is only to be limited by the dimensions of apparatus employed. Should the plan of this engineer be generally adopted, the old proverbial injunction for promptness will take a mechanical turn—'Make steam while the sun shines,'—instead of its original agricultural significance."

THE SOLAR ECLIPSE.—It is expected that many photographic records will be made of the eclipse of August 18th. The phenomenon of a total obscuration is of rare occurrence, and as it can be observed to advantage in India, the astronomers will not allow this opportunity for making several interesting and valuable observations to pass disregarded. The Indian Government has made great preparations for obtaining a photographic record of the phenomena presented during the eclipse, and the time of its duration—over six minutes—will be long enough to take a large number of negatives, so that much information respecting the physical constitution of the sun may be obtained.

## To Correspondents.

G. B. writes as follows:—"I address you on a subject which is to me of considerable importance; and without taking up room with preliminary remarks, I at once enter on it. I have for a number of years been engaged professionally in photography with considerable success. I have had many visitors to my studio, and my work has given general satisfaction. It has been said, however, 'that there is a skeleton in every house.' I am not without one, albeit the skeleton that troubles me takes the form of noxious vapours. Some months ago, a person in possession of the garden next to mine (in which I have my studio) commenced the trade of a butcher. The offal and blood from the slaughtered sheep (from ten to fifteen weekly) he puts into his garden, covering it slightly with earth. For the last six weeks he has put it all on a narrow strip of ground, running parallel to my studio, and within six yards of it. Since the hot weather commenced the smell is intolerable. I find my chemicals have not been working so well lately; this I attribute to these vapours. Would you, Sir, oblige me by stating in your next paper what effect this impure state of the atmosphere is likely to have on the chemicals we work with." Decomposing animal matter will produce ammoniacal and other fumes, decidedly injurious to perfect photographic action. Your proper course is to apply to the officer of health or inspector of nuisances, or other authority, according to the constitution of the local government under which you live. Such a nuisance as you describe, if satisfactorily proved to exist, will doubtless be put promptly down.

SILEX.—The Wothlytype process was attended by more uncertainty and difficulty than the albuminized paper process, and hence never came into extensive use, although it had some undoubted advantages. 2. We believe that the patent was suffered to lapse. 3. We believe that our collodio-chloride process has all the advantages of the Wothlytype process without its uncertainties. 4. We cannot direct you where to purchase pyroxyline for any purpose. It is a difficult thing to purchase good. You can only acquire certainty by trying a sample, and then purchasing a quantity if necessary. Thanks for your remarks on collodion varnishes and carbon. We shall make use of them.

X. W.—In working the morphine process, and using iron development, it is important to add a few drops of nitrate of silver solution to the iron developer before applying it to the plate. If you apply the iron solution without silver the latent image is partially destroyed by the acid present; but this does not occur if the silver solution is added to the iron solution before applying it to the plate. Try again, bearing this in mind, and let us know the result.

W. J. A. G.—The sample of protosulphate of iron you enclose is a little oxidized, but it is not seriously injured. Make your developer as usual, and after adding the acetic acid and shaking for some time, filter before using, to remove any turbidity which may remain. You will find that the developer will give you a little more intensity and cleanness in the shadows than one made from a perfectly pure and clean sample of the iron salt. The black pyrogallie acid is worthless; return it without attempting to use it. The citric acid may possibly be all right. The carbonate of ammonia without smell will scarcely be good; that you can get fresh of a local chemist. The only explanation we can offer is that you have ordered them of some one having very little sale for such things, who has supplied you with articles long in stock, and spoiled by age and careless preservation.

G. NICHOLSON.—The only catalogue of stereoscopic pictures, besides those you mention, which we remember, are those of Mr. Blanchard, of 12, Camden Cottages, N.W., and Mr. England, Notting Hill Square.

MANTON.—The defect in your print is not *measles*, but *meatiness*. The former is the result of imperfect fixation, and is manifested in mottled yellow spots in the texture of the paper. *Meatiness* consists of a somewhat irregular, granular effect in toning, due to a variety of causes. It is at times due to nitric acid in the printing bath; at times to the use of a new toning bath not sufficiently ripe; at times to the use of carbonate of soda in the toning bath, which we never recommend; at times, and very commonly, to the use of a weak negative, which does not permit sufficient reduction of silver to form rich blacks before the lights are over-printed. Use your printing bath quite neutral; avoid carbonate of soda in your toning bath; and do not use the bath too new or too strong. Above all, use negatives sufficiently vigorous. We see no reason to believe that the paper is in fault; but we do not know the maker. We are glad to learn that professional photography is improving in a business sense in your neighbourhood.

INQUIRER.—No apology was necessary for making the enquiry, although, as you remark, the matter is not of sufficient interest for public discussion. The leading fact in the statement to which you refer is true; the minor statements given in the way of comment and explanation are quite untrue. Discourtesy is a matter of taste upon which every one can form his own opinion. Truth or untruth is a matter of fact, and remains unaffected by assertion or

opinion. The attention of the committee was called to the matter by an outside member, who pointed out that if such untruthful and discourteous reports were permitted, no matter how unimportant the authority or how limited the audience, it must tend to check the freedom of discussion and social intercourse which had distinguished the proceedings of the society. The fact that a meeting of the committee unanimously adopted such a resolution under the circumstances affords tolerably satisfactory assurance of the propriety of the step. The statement that the matter was due to our action at all is, it is scarcely necessary to say, untrue. The report you have heard as to the cause of withdrawal is quite true; but we do not agree with you as to the propriety of publishing it. We do not care to brand a man publicly with his private faults or misfortunes unless he insist on the disclosure.

J. C. B.—See article in the present number.

MORPHINE.—The solution of acetate of morphine can be used over and over again as a rule; but of course it suffers gradual deterioration by dilution with the water on the plate. Your loss of sensitiveness is doubtless due to the exhaustion of the strength of the morphine solution, which, you must remember, is very weak, even at the outset. Beaufoy's acetic acid is intended. We are glad that you profit by the articles on Pictorial Effect.

Z.—It is possible to estimate the amount of chloride of gold in a solution, but not by specific gravity with an instrument like the argentometer. Such a method would not be sufficiently delicate, and would not distinguish between the presence of pure chloride and the double chlorides of gold and various alkaline metals. The most delicate test is oxalic acid, precipitating the gold from a measured quantity of solution by means of a standard solution of oxalic acid. The process requires care and familiarity with such manipulations. We have not space to enter into details in this column, but we shall probably take an early occasion of disclosing the method in question. 2. You complicate the operations and waste permanganate of potash if you add it to a bath containing free nitric acid, which will at once decompose the permanganate.

A CONSTANT READER.—Mr. Spiller found that the example of nitrate of silver recommended by Mr. McLachlan was really pure neutral nitrate of silver discoloured on the outside, probably by contact with the vapours of chlorine. Any pure sample of nitrate of silver will serve.

F. M. P. wishes for information as to the manufacture of a portable glass house, which can be packed into comparatively small compass, and which shall not be very costly. We fear that the data are too indefinite to enable us to help him much. Can any of our readers give any hints?

SUBSCRIBER.—You could at any time obtain information by writing to a member of the committee; but the matter is of too limited interest to occupy our pages by frequent explanations. We announced some time ago that the balance would be returned to the subscribers *pro rata*; no other intention has ever been entertained. The delay in doing this has been owing to causes beyond the control of the committee, but will probably be effected shortly. The matter concerns the two or three hundred subscribers, all, or the majority, of whom trust the committee. It does not concern the meddlesome persons you name.

G. ROBERT FITT.—The exposures you describe are undoubtedly enormously long, four or five times too long, at least. The example of the work which you forward is very fine indeed, and shows that the quality and character of the lighting are good; but it is quite clear that, from some cause, the exposures are much too long. Ten seconds for a card picture, with a good lens and aperture small enough for covering, is the outside exposure we should think necessary. We do not see anything in the quality of the glass, on a cursory examination, which can justify the long exposure, but will examine further. So far as we can suggest at present, the cause may be in having too much of the top-light obscured. As the season has advanced the sun has become more vertical, and as you obstruct almost all vertical light you have gained nothing in rapidity with the advance of the season. We will give the matter attention, and add more another week if anything strikes us.

BLACKHEATH.—The dirty yellow colour produced by adding permanganate of potash to rain-water is caused by the oxide of manganese formed by the decomposition. It will gradually precipitate. To be certain that all organic matter has been oxidized, add the permanganate until a faint permanent pink tint is produced in the water. Rain-water so treated will be fit for making a silver bath. 2. Permanganate of silver added to water containing chlorides ought to have thrown down a precipitate of chloride of silver. We cannot explain its failure to do so. It is not necessary to the reaction that the water should have been rendered alkaline. The safest mode of purifying the water in question is to add a few grains of nitrate of silver and expose for a few days to sunlight. This will throw down both chlorides and organic matter. 3. There is an undoubted difference between the results in the tannin and coffee processes; but a resemblance in the processes so far as the active principle of coffee resembles tannin.

W. T. B.—We do not, unfortunately, remember the address of the society in question, but will try to ascertain. Several Correspondents in our next.

## DIRTY PLATES.

PERHAPS few troubles are more mortifying to the photographer than those arising from dirty glasses, a mortification which is much intensified if a few good new glasses to fall back upon are not in stock, or readily procurable. We recently spent some hours in the studio of a first-class photographer in the provinces, who had suffered seriously from the trouble in question, and witnessed its operation under more than usually irritating circumstances. A stock of patent plate had been ordered and received from a reputable London house. On trying the glass, however, it was found impossible by any mode of cleaning the plate to obtain a clean negative. The defects were unusual in character, and bath and collodion were at first in turn condemned. Unlike the well-known defects produced by dirty glasses, these consisted in fine, straight, transparent lines, varying from half an inch to 2 inches in length, sometimes vertical, sometimes horizontal. The most careful examination of the glass before producing the negative showed no indication of a defective or imperfectly cleaned surface; but whilst the chemicals were working very well in all other respects, giving rich, vigorous negatives, it was impossible to get rid of these markings.

As it became manifest that the glass was in fault, recourse was had to a stock of old patent plate-glass from which some negatives had been cleaned. This glass had undergone a careful treatment with the bichromate of potash and sulphuric acid mixture recommended by Mr. Carey Lea. But now a new series of troubles arose: the ordinary markings of dirty plates were plentiful. The powerful detergent action of the above preparation was insufficient to remove the traces of former use, and mottled stains of increased opacity were apparent in every instance, chiefly noticeable in plain backgrounds, where stains are fatal to the character of a picture. Other modes of cleaning were tried, employing strong acids, and strong alkalis, tripoli, &c.; but in no case was perfect immunity from stains secured on the old glasses.

In the meantime a new stock of patent plate had been ordered from another house, and after a hasty cleaning a plate was tried, and a perfectly stainless negative was the result. We saw half-a-dozen negatives tried with plates taken at random from each group of glasses. The first in every instance gave the straight lines first described; the old glasses invariably gave mottled stains; and the new lot of patent plate invariably gave perfectly clean negatives.

The only conclusion to which we could come regarding the first examples of the patent plate giving the fine lines was that it was imperfectly polished in the manufacture, and that little grooves existed in the surface too fine for observation, but in which lodged some trace of the cleaning or polishing material, which, lurking there, was inimical to photographic action, and so caused the transparent lines. Dealers and pho-

tographers alike should be on their guard against such a sample of glass; but not knowing its history we can only offer a vague caution. It was a little cheaper than the sample patent plate upon which perfectly cleaned negatives were taken; but the difference in price was not sufficient to account for marked difference in quality.

Regarding the old glasses which had been cleaned, it is to be observed that it is difficult to prescribe a plan of cleaning which shall be certainly efficient in all cases, inasmuch as in some samples of glass the dirt is not merely on the surface, but in combination with it, and can only be removed by the removal of the outer surface of the glass. We have at times had striking illustration of this in opal glass, which, after having been used and carefully cleaned, has, on standing in the light, gradually shown traces of the image which had been in the collodion film long since cleaned from its surface. The silver salts in some cases clearly enter into combination with the glass; the salts of iron also have a special action on the surface, the effects of which are difficult to remove. The best detergent we have used in such circumstances has been nitric acid and water in equal parts, applied with a rubber of woollen cloth or druggist rolled up and tied tight, so as to permit the end of the roller to be used on the glass. This, followed by rotten stone and alcohol, has rarely failed in our hands; but it is possible that it may not be efficient in all cases. Perhaps in the most obstinate cases the use of dilute hydrofluoric acid would be the most certain cure. By the careful application of this dilute acid the first surface of the glass will be removed, leaving another polished surface underneath. The difficulty to be guarded against is the production of an uneven though polished surface, not equal to the perfectly plane surface secured by the mechanical grinding and polishing which patent plate undergoes. In using hydrofluoric acid its exceedingly corrosive action on the skin should always be borne in mind.

An excellent piece of advice in regard to old glasses has at times been given, to the effect that the best treatment to which they can be submitted is to place them under a hammer and destroy them. The cure is certain, but costly. Photographers who are in the habit of using patent plate glass in sizes of 12 by 10 and upwards naturally hesitate before deliberately destroying plates of glass, each of which may have cost two shillings or more. A more economical remedy is therefore desirable.

Happily, under the worst of circumstances, a cheap, simple, and certain remedy is at hand. Dirt was defined by the late Lord Palmerston as "matter in the wrong place." This definition admirably meets the case in point. The matter which is on the dirty glass is in the wrong place emphatically, because it possesses chemical action, and either increases or reduces the amount of silver reduced, and so causes an opaque or transparent mark. If it were quite

inert it would do little harm. The remedy, then, consists of covering over with an inert substance the surface from which we cannot remove the actinic substance. A little pure bees'-wax dissolved in ether and rubbed over the plate has the happy effect of coating the surface with an almost imperceptible film, which is quite inert in itself to photographic action, and effectually interposes a barrier between the collodion film and the chemicals it contains, and the glass surface and the active dirt which rests unseen upon or in combination with it. Whilst no photographer will willingly work with dirty glasses, he possesses in this coating of wax a relief from the immediate annoyance of bad plates when perfect ones are not immediately procurable.

#### COLLODIO-CHLORIDE FOR PRINTING ON IVORY.

THE enquiries of several recent correspondents as to a simple method of printing on ivory have induced us to repeat some experiments with our collodio-chloride of silver process for that purpose. Mr. Fry published in our pages, a few years ago, a method of silver printing on ivory, excellent in result, but somewhat troublesome in detail. We also published, some years ago, a method of securing good results by means of the Wothlytpe process. But after some experiment in this direction we arrived at the conviction that there is no method of printing upon ivory by which such good results can be obtained with so much ease and certainty as by the collodio-chloride of silver process.

No modification of the formula is required: a sample of collodio-chloride which works well on paper or opal glass will give admirable pictures on ivory. One condition only is of importance: to secure the best results the collodion should not be made of a sample of pyroxyline giving a very horny, repellent film. The sample we have used is such as we should choose for a negative collodion, neither very powdery nor very horny. It adheres perfectly to ivory, giving a hard surface, less easily scratched or abraded than the same film on glass, and the appearance of the image does not differ perceptibly from one on the surface of the ivory itself without collodion intervening.

The prepared ivory is coated with collodio-chloride, and when dry is printed, toned, and fixed in the same manner as a picture on opal glass. The film adheres with sufficient tenacity to render any edging of varnish unnecessary. A more perfect washing to remove the hyposulphite is necessary than with opal glass, because of the more absorbent character of the ivory.

A somewhat unexpected fact may be here noted, which may prove of service to some of your readers who may have in hand the materials for collodio-chloride of silver apparently spoiled. About twelve months ago we received from a correspondent two bottles containing the unmixed collodio-chloride as supplied by a manufacturer, one bottle containing collodion with nitrate of silver in solution, and the other containing collodion with a chloride in solution; the labels instructing that the contents should be mixed in equal parts to form the collodio-chloride. Unfortunately, collodion containing nitrate of silver is subject to decomposition, and that forwarded to us had, after a few months' keeping, turned quite brown, and our correspondent wished to know if it were fit to be used. At the time we condemned it as useless; but, a few weeks ago, in the course of some experiments, we were induced to try the mixture of the contents of two bottles. The result was, of course, a discoloured sample of collodio-chloride of silver; but what was our surprise on examining it again, after it had stood a few hours in the dark, to find that the dark-coloured collodio-chloride had become perfectly milk white! The chlorine liberated in the decomposition had acted on the decomposed, darkened salt of silver, converting it into pure white chloride of silver. This fact may prove as useful to those of our correspondents who have a decomposed sample of the nitrated collodion on hand as it is curious and interesting.

In our next we shall detail the results of some experiments with the paper prepared with collodio-chloride of silver manufactured commercially by Herr Obernetter, which is used considerably, we understand, in Germany.

#### PERMANENT ALBUMINIZED PRINTS.

Our attention was called a few days ago to some examples of unusual permanence in albuminized prints. Those in question had been printed six years, a period not unusual, of course, for photographs to remain without fading, but, nevertheless, a period at the expiration of which most silver prints have generally lost their first bloom, that especial purity of the whites and rich velvet-like depth in the blacks which are the glories of fine silver prints. The prints in question were printed on a distinct sample of paper, and could each be readily picked out from a number of others printed at the same time on other samples of paper, the distinction being found in the fact that whilst the other prints, without being absolutely faded, had all lost their first freshness and beauty, and were less brilliant in the whites and less rich in the blacks than at first, these seemed wholly unchanged. As all had received the same treatment and were printed at the same time, it became worth while to enquire to what the difference was due.

The only difference consisted in the fact that the permanent prints were printed on a sample of albuminized paper prepared in Germany, which was popular a few years ago, and the use of which at the time we were strongly tempted to condemn as, *a priori*, likely to yield unstable prints. It was manifestly prepared with albumen which had undergone decomposition, and the smell was most offensive. Two questions arise as to this source of permanence: Is it possible, however unlikely, that the use of the decomposed albumen could in any way conduce to increased permanency? or is it more probable that the permanency is due to the special quality of the sample of paper upon which the decomposed albumen rested? The paper was exceedingly thin; so much so that until the prints were mounted on a good white board they looked poor and wanting in brilliancy; and if mounted on a tinted board the whites were somewhat degraded by the tint showing through. The thinner the paper the more easily it is permeated by the fixing and other solutions, and the more easily perfect washing is effected. Possibly, therefore, the extreme thinness of the paper was an element in the stability of the prints. The subject is certainly worth examination; and, at Mr. Blanchard's suggestion, we bring it before our readers, to permit the comparison of notes on the subject. Possibly other photographers may be able to examine prints produced on the same paper, which was at the time somewhat extensively used. It will be interesting to learn if the experience of Mr. Blanchard in this matter is confirmed by that of other photographers.

#### KEEPING AND DATING COLLODION.

THE advantages of ripe collodion, and the troubles contingent upon the use of samples newly mixed, are too well known amongst photographers to require enforcing. It is not a little singular, however, that it is at times difficult to procure a sample sufficiently ripe to work with desirable vigour and brilliancy. A correspondent recently called our attention to this fact as a ground of complaint against manufacturers of collodion. Having just received a parcel from a first-class manufacturer, whose collodion he had used some time with advantage, he found in the new sample none of the qualities of the old. It gave a thin image, which did not readily intensify, had a tendency to fog, with other concomitant defects of newly-mixed collodion. On complaining to the manufacturer of these defects, he received the somewhat facetious reply that it would work capitally in the course of a couple of years,

We have often urged upon manufacturers the importance of appending to the labels of all samples sent out ready salted the date at which the collodion was mixed. This plan would often afford the photographer data for forming an opinion, without a series of trials, of the probable fitness of each sample for different kinds of work for which it may be required. Failing to secure such advantages as this system of dating would give them, photographers may materially secure their own convenience by purchasing the plain collodion, and either adding the iodizing solution supplied by the manufacturer, or such iodides and bromides as their experience may induce them to select from the various formulæ we have published. A quantity so mixed, dated, and laid down to ripen, say once in six months, would enable the photographer to have a constant supply in uniform condition, instead of being subject to the fluctuations in the age and working qualities of his collodion which must inevitably arise when he must use to-day that which he purchased yesterday from the manufacturer.

## PICTORIAL EFFECT IN PHOTOGRAPHY ;

BEING LESSONS IN

COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXII.

"By the choice and scenery of a background we are frequently enabled to judge how far a painter entered into his subject, whether he understood its nature, to which class it belonged, what impression it was capable of making, what passion it was calculated to rouse. Sometimes it ought to be negative, entirely subordinate, receding, or shrinking into itself; sometimes, more positive, it acts, invigorates, assists the subject, and claims attention." —*Fuseli*.

### BACKGROUNDS AND ACCESSORIES.

IN portraiture the background, often neglected and considered as but of little moment so that it be clean and smooth, should hold a very important place when the composition and chiaroscuro of the picture is considered. The backgrounds of his portraits was thought to be of so much consequence by Sir Joshua Reynolds that he frequently declared that whatever preparatory assistance he might admit in his draperies or other parts of the figure, he always made it a point to keep the arrangement of the scenery, the disposition and ultimate finish of the background, to himself. The most carefully manipulated portrait, exhibiting the most delicate photography, and the most refined light and shade and composition, may be destroyed, or its beauty much impaired, by an ill-chosen background; or it may be efficiently aided and supported by a proper and suitable arrangement of form and light and shade in this important portion of the picture.

The general practice with most photographers, until lately, has been to employ a perfectly plain, even-tinted background, or badly painted representations of interiors or landscapes; but last year the large collection of pictures by Adam Salomon in the Paris Exhibition convinced photographers of the extreme value of light and shade, gradation and tone, behind the figure, to relieve some parts and to hide others, to give breadth and concentrate attention to the principal feature, the head. Other photographers have known the value of this effect, and have exhibited their results, but never so large and convincing a collection as the one I have mentioned.

In using a plain background, without any variation of light and shade, the photographer throws away a great advantage. Nothing could be more antagonistic to breadth, atmosphere, and richness—nothing could so surely scene a flat, inlaid effect of the figure—than a plain background. It would be difficult to find a surface without gradation in nature. Take the plain surface of the wall of a room as a background, and you will not find it easy to discover a sufficient space for a background on which a shadow modifying its even tint does not fall. The cloudless sky is marvellously graded from the zenith to the horizon; and so you may go throughout all nature till you surprise yourself with the discovery that the only plain, blank thing in this world is a photo-

grapher's background, on which the equal light falls from a broad expanse of glass. Ruskin, in his "Elements of Drawing," has a fine passage on gradation of colour, which is equally applicable to light and shade, and, therefore, to our subject. It is so just that I need not make any apology for introducing it here:—"Whenever you lay on a mass of colour, be sure that however large it may be, or however small, it shall be graduated. No colour exists in nature, under ordinary circumstances, without gradation. If you do not see this it is the fault of your inexperience; you will see it in due time if you practise enough. But in general you may see it at once. In the birch trunk, for instance, the rosy-grey *must* be graduated by the roundness of the stem till it meets the shaded side; similarly, the shaded side is graduated by reflected light. Accordingly, you must, in every tint you lay on, make it a little paler at one part than another, and get an even gradation between the two depths. This is very like laying down a formal law or receipt for you; but you will find it merely the assertion of a natural fact. It is not, indeed, physically impossible to meet with an ungraded piece of colour, but it is so supremely improbable that you had better get into the habit of asking yourself invariably, when you are going to copy a tint, not 'Is that graduated?' but, 'Which way is that graduated?' and at least, in ninety-nine out of a hundred instances, you will be able to answer decisively after a careful glance, though the gradation may have been so subtle that you did not see it at first. And it does not matter how small the touch of colour may be, though not larger than the smallest pin's head, if one part of it is not darker than the rest, it is a bad touch; for it is not merely because the natural fact is so that your colour should be graduated; the preciousness and pleasantness of the colour itself depend more on this than on any other of its qualities, for gradation is to colours just what curvature is to lines, both being felt to be beautiful by the pure instinct of every human mind. \* \* \* What the difference is in mere beauty between a graduated and ungraded colour may be seen easily by laying an even tint of rose-colour on paper, and putting a rose-leaf beside it. The victorious beauty of the rose, as compared with other flowers, depends wholly on the delicacy and quantity of its colour gradations, all other flowers being either less rich in gradations, not having so many folds of leaf, or less tender, being patched and veined instead of flushed." Further on he says:—"You will not, in Turner's largest oil pictures, perhaps 6 or 7 feet long by 4 or 5 high, find one spot of colour as large as a grain of wheat ungraded; and you will find in practice that brilliancy of hue and vigour of light, and even the aspect of transparency in shade, are essentially dependent on this character alone: hardness, coldness, and opacity resulting far more from *equality* of colour than from nature of colour."

It is thus with photographs and pictures in monochrome: an isolated mass of dark is not rich, neither is a separated space of light brilliant; it is opposition and gradation of the one with the other that produces richness and brilliancy. Therefore a plain background is the most destructive to pictorial effect that could be placed behind a figure. A glance at the illustrations to a recent chapter will show that one of the effects of a plain background is to represent the figure as cut out and stuck down on a piece of plain grey paper.

Haydon called the background the most hazardous part of the picture, and a subject that required as much consideration as the figures, because, be the figures ever so good, their effect may be seriously injured by ineffective support. There is a story told of Rubens by which it will be seen that he also considered that to the effect of the picture the background is of the greatest importance.

A young painter being anxious to enter Rubens' studio as a pupil, induced an influential friend to recommend him, who did so by informing the great painter that he was already somewhat advanced in art, and would be of immediate assistance to him in his backgrounds. The great painter, smiling at his friend's simplicity, said, that if the

youth was capable of painting his backgrounds, he stood in no need of further instructions; that the regulation and management of them required the most comprehensive knowledge of art.

It would be impossible to give definite instructions for the management of the background, but the treatment of different artists may be alluded to. The system adopted in most of his pictures by Adam-Salomon, following the plan of many of the most famous portrait painters, appears to be that the lightest side of the figure shall be relieved by dark, and the darkest side by light. The upper corner of the picture, on the side from which the light comes, is intensely dark, which is graduated diagonally across the picture into middle tint behind the head, which is again more abruptly opposed and carried away into dark by the accessories, or is again allowed to die away into shade.\* He also appears to appreciate the value of a vertical line in the background to give stability to the composition, usually obtaining it by the straight lines of a fluted column (an objectionable accessory, in my opinion, for reasons which I shall give in the next chapter). There can be no doubt that these pictures of M. Adam-Salomon are the most effective portraits, containing all valuable qualities, that have yet appeared in photography, and afford a most valuable lesson to photographers.

The backgrounds to the portraits of Sir Joshua Reynolds are always worthy of study, whenever they can be seen. Some of his finest and richest pictures have a dark ground, on which the head shines like a jewel; many are relieved in the manner employed by Adam-Salomon; and it is to be noticed that in nearly every picture in which the background is graduated, he has introduced one or two vertical lines to aid the composition, generally a dark line and a light one, a mere suggestion of a pilaster. His landscape backgrounds were always singularly appropriate and natural, although the horizon in many instances is lower than we should feel justified in representing it in such a truthful art as photography. Although his practice was to relieve the dark side of the figure with light, and the light with dark, in his discourses he advocates an opposite treatment, one which is to be found in the work of Coreggio and other painters of his school. In commenting on the precept of Leonardo da Vinci, that the shadowed side of the figure should be relieved by light, Sir Joshua says:—"If Leonardo had lived to see the superior splendour and effect which has been since produced by the exactly contrary conduct—by joining light to light and shadow to shadow—though without doubt he would have admired it, yet, as it ought not, so probably it would not, be the first rule with which he would have begun his instructions."

On whichever principle the photographer arranges his background, he must remember that it should relieve the figure, and not produce an inlaid effect, and that it should present with the figure an agreeable breadth of light and shade.

When will background manufacturers supply graduated screens? They all tell you that it is impossible to produce them. This I know to be an error. They are difficult to paint, but I know from actual experience that the thing can be done. If photographers would insist upon having what they wanted, they would get it. They should not be content to use anything with which the manufacturers choose to supply them.

## PHOTOGRAPHIC PRINTING IN SILVER, THEORETICAL AND PRACTICAL.

BY W. T. BOVEY.

### TONING BATHS AND TONING DIFFICULTIES, ETC.†

THEN, by what means do the toning methods usually employed perform the desired work? Chlorine having an affinity for the alkaline base known as sodium, such base, in connection with some acid, is employed.

First, carbonate of soda demands attention.

When chloride of gold was first introduced into photography as a toning agent for silver prints, it was employed in connection with hyposulphite of soda. Of that form of toning bath I shall have more to say anon; at present I need only remark that certain defects caused the hypo bath to be almost generally discarded in favour of the alkaline toning solution devised by Mr. Waterhouse. In the absence of direct evidence, I must only surmise that the use of carbonate of soda was suggested in this wise. It was found that a silver print immersed in a solution of chloride of gold mixed with a moderate quantity of water was immediately rendered unsightly by the over-active chlorine, and free acid was suspected of evil doing. To curb the acid, carbonate of soda was introduced, when it was perceived that the action became more steady and regular, and pleasing tones resulted. Hence it was put down as a matter of certainty that to secure good tones the solution must be in a decidedly alkaline condition. Unlucky decision!—false, yet not unreasonable—drawn in days of inexperience. And bitter have proved the fruits of that unfortunate concoction of gold and alkalinity so imported.

To collect clear water from a mud-stained stream the taint must needs be removed by some process of filtration. In like manner, by the exercise of reasoning, I shall endeavour to filter out the obscurity connected with the unsatisfactory soda methods of toning, and lay bare the principles which need only be clearly understood to make toning difficulties a thing of the past. From the fact of a concentrated chloride of gold solution (without an alkaline adjunct) proving too powerful for toning purposes we learn that the silver print exercises a disturbing influence which decomposes the gold combination when the print is exposed to its power; in other words, the prints, when immersed in a gold bath, attract and separate chlorine. By observing this fact we rid ourselves of the erroneous yet prevailing notion that carbonate of soda has anything to do with setting up toning action. The part played by the alkaline adjunct is clearly a retarding, not an initiating or accelerating, influence. Accept this argument, and I proceed to argue the whole matter in plainer detail.

The chloride of gold of commerce consists of gold in combination with chlorine and free acid. In that state it is supposed to be quite unsuited for toning purposes; recourse is therefore had to (first) carbonate of soda. When this alkaline substance is added to the gold, the free acid is neutralised, and chloride of sodium is formed, whilst carbonic acid is set free. Now if the quantity of the carbonate of soda added is so nicely adjusted as to destroy the free acid and leave no excess of soda, we have a carbonate of soda bath in its best form, so that on introducing the silver prints into the solution they directly withdraw the chlorine from the gold, and the metal is deposited on the surface of the paper.

But "prints so treated turn up bleached and fearfully mealy," suggests experience. Granted; but the solutions misguided experience has been from the first in the habit of using are too concentrated—too strong by many degrees. Dilution would remedy the evil. "Then why not do away with soda altogether, and destroy the evil tendencies of the acid as well, by drowning it with a still greater supply of water?" Just what I am aiming after. We shall succeed, doubtless, by-and-by; at present I have to show the result of decided alkalinity, produced by an excessive quantity of carbonate of soda. When a quantity of soda is added to a gold solution above that requisite for neutralizing the free acid, a second force is introduced, which battles for precedence with the attraction exerted by the silver surfaces of the paper. Silver has a desire to embrace the chlorine; so has the soda, which, however, enjoys a better chance by prior combination, as the soda must be added to the toning bath before the prints can be admitted. Between these opposing forces a kind of equilibrium is for some time preserved, until soda finally gains the day, and

\* An admirable and lucid description of the studio arrangements by which this effect is obtained appeared in the account of M. Salomon's studio, in the *Photographic News*, January 24, 1868.

† Continued from p. 292.

the bottom of the dish enjoys the precipitate of gold intended for the beautifying of the prints. Condensing these arguments into their narrowest compass, we learn—

1st. That alkalinity is an error that should give place to a more comprehensive and practical measure—which may be understood as a neutral condition.

2nd. That as two samples of chloride of gold rarely contain the same amount of free acid, any strict formula is altogether an error on which no reliance should be placed.

3rd. Seeing that a strictly neutral bath is a difficult thing to manufacture, any method that would enable the gold to be employed without the uncertain aid of an alkaline adjunct would prove a boon to photographers generally. To a feeble extent this want is provided by acetate of soda, to which substance I now direct attention.

Acetate of soda, as is pretty generally known, possesses the same kind of base as the carbonate of soda; but instead of the unstable carbonic acid, it is combined with the stronger acid from which it takes its name. That the more stable acetic acid cannot be so easily dislodged as the carbonic acid is made self-evident; that such is a practical fact is proved by the behaviour of an acetate toning bath. All who have had occasion to use the acetate bath must have observed that, when newly prepared, the action of the chlorine is as violent as a gold solution without any restraining adjunct. That goes to prove the argument I adopt; viz., that decomposition, which occurs in the acetate bath, does not commence at once if the acetate of soda is pure, but requires time to enable the chlorine to dislodge the acetic acid, also for the free acid to be neutralized; hence the reason why it is recommended that an acetate bath be kept a few days previous to its being employed for toning purposes. The principles of the acetate bath, as far as theory goes, are correct; but in practice, the elements of uncertainty are found to prevail; oftentimes, in lieu of the gold being preserved in a fit state for toning, it is found precipitated at the bottom of the bottle. The premature decomposition referred to I have discovered is often occasioned by carbonate of soda being present in considerable quantity with the acetate of soda, but under the most favourable circumstances, I am inclined to think that a toning bath of any description, which needs the ripening process of keeping, must prove more or less uncertain in its working qualities. It is advised, that when the bath of which we are speaking is found to be inert, a little fresh chloride of gold should be added, which, by the catalytical action it possesses, causes the gold rendered inactive to be restored to toning vitality. I have directed much attention to this point, and am of the opinion that the only gold precipitated on the print is the quantity freshly added, as I have invariably found that the toning action is stopped, after a brief interval, as suddenly as it commenced. Once more indulging in a brief summary, we may reckon up the acetate bath as follows:—

1st. An acetate bath is unfit for use when freshly prepared.

2nd. The keeping requisite to rob the gold of its bleaching power, though theoretically correct, proves in practice uncertain, and frequently the results obtained are unsatisfactory.

3rd. As the acetate of soda of commerce is found to vary in purity, this of itself is reason sufficient that a toning solution yielding precisely similar tones without any uncertainty about it would be the *summum bonum* of a photographer's aspirations in the direction of silver printing.

4th. Whether pure or impure, the acetate and gold combination has proved the greatest enemy to the paper albuminizers, whose preparations are, as a rule, accredited with all the defects which must attend the use of toning solutions whose constitution is, after all, of a decidedly empirical character.

Much has been said and written concerning the admirable tones produced by an acetate bath, and the virtue is supposed in some way to arise from the acetate of soda. The facts, however, are widely at variance with the supposition, as we shall endeavour to show in another brief summary. The tone of a picture depends,

1st. On the amount of reduced silver that forms the ground work.

2nd. On the integrity of the ground work being preserved from the reducing influence of liberated chlorine.

3rd. The tone produced by the toning solution must depend—1st, on the colour of the basement; 2nd, on the amount of gold precipitated.

This last division points out the nature of the excellencies attributed to the acetate bath, which makes it a popular and fashionable photographic agent, adopted, as a rule, in preference to any other form of toning solution. It must have been observed that a brilliant tone is only of occasional attainment with any kind of toning bath now in use. A brief study of the subject will expose the reason why. I have endeavoured to show the results obtained from an acetate bath in the two extremes of conditions, viz., in the onset, over-activity; in a prolonged keeping stage, inertness. Now it will be noticed that an acetate bath prepared with suitable materials must be in the best working condition when it approaches the intermediate stage; neither too fast nor too slow. When used in this state of happy medium (difficult to attain and know the exact moment) the gold is precipitated in a fine state of subdivision. The stratum of silver is not reduced, and its warm colour gives life to the tone produced by the deposit of gold.

Were it possible to concoct such a satisfactory acetate bath at will, I had been saved the labour attending the preparation of this article. Its not being so will perhaps induce photographers to overlook the simplicity of the bath I have devised, and now proceed to explain—first asking exemption from the task of examining the phosphate of soda, the tungstate of soda, magnesia, and other toning baths of the same nature, as the main points I have dwelt on are precisely similar to the principles I have traced in each of the solutions last referred to. The hypo and sulphocyanide toning solutions are, however, exceptions. First, they waste any amount of gold; second, they yield a tone quite different from the ordinary tones derived from a precipitate of gold; the modification I regard as no permanent advantage, as I believe it to arise from sulphur deposit, not from any change in the precipitate of gold. Let the case rest as it may; uncertainty is also the characteristic of the solutions last named. Mix it as you may; make it even more empirical than the absurdly constructed formulæ which have of late been highly recommended, it will prove a sorry servant; so my advice is, do not try it. I will now to my method, the excellence of the results of which, I can assure the reader, is equal to the simplicity.

Use the orange coloured sample of gold, which is a double salt, consisting of chloride of gold and sodium; pay special attention to this, or do not blame me on account of your failures.

Keep your gold in concentrated solution.

Chloride of gold	...	...	...	1 grain
Water	...	...	...	1 drachm

I have already shown that gold requires no acceleration; the adjuncts employed serve as retarders. Then, in lieu of employing uncertain alkaline agents, we make use of the more stable substance known as water. When a physician desires to administer an active poison as a medicine to his patient, he adopts an infinitesimal quantity of the poison, which he rids of its destroying properties by diffusing it through a comparatively large body of water; I embrace a similar principle in the construction of my toning bath, which I prepare as follows:—

1st. Measure out 2 gallons of water (rain or river water if at hand; well water should be previously boiled).

2nd. Measure into a jug (porcelain) 12 grains of gold, add about 1 grain of fine table salt, and pour over the whole  $1\frac{1}{2}$  pints of boiling water; allow this to stand awhile, until lukewarm; then add to the 2 gallons of water previously measured out. Your bath is made, and ready for use. Go to work.

How ridiculously simple! Never can work. Now if there was only an addition of some substance that costs a guinea a grain, it might answer; but as it stands—pshaw!

Stop, friend; I have not explained all the wonders connected with this—in my hands—unerring toning solution.

1st. It improves with age. It must after each day's work be returned to a jar, and strengthened always before use by adding gold and a minute trace of salt treated with boiling water as at first. The quantity of gold required is, however, widely different.

To keep at working strength, measure out 4 grains of gold, add a minute trace of fine salt, pour over it about half a pint of boiling water; allow it to stand a bit, add the gold mixture thus prepared to the toning bath, and if you have a batch of ten, twenty, or thirty sheets, place the prints quickly, one by one and face downwards, into the solution. Tonic all at one time, remember. Do not hurry yourself; the toning will be regular, and the tones should turn out satisfactorily.

To preserve the solution in good condition I add daily about a pint of plain water, which renders the bath, like Paddy's nether garment, indestructible, although it is being continually renewed after an imperceptible fashion.

The quantities above stated will, perhaps, prove too great for amateurs and photographers with a small business; they may commence with 1 gallon, but, in strengthening afterwards, the proportionate amount of reduction in the amount of gold used must not be made. For 2 grains of gold  $\frac{1}{2}$  gallon only of the stock solution must be employed.

In concluding this lengthened article I do not promise success invariable to those who neglect principles; nor can I hold out hopes of a freedom from failure being secured by the inexperienced. I have been closely engaged in photographic printing for years; to that branch of photography I have applied my whole mental powers; yet a week never passes over my head but I observe and note something new. If my mountain seems to some to have produced only a mouse, I would have them remember that little things are only neglected by very little minds. I have seen a cloud no bigger than a man's hand rise from beneath the horizon; I have watched that cloud, and have seen it extend and cover the heavens. A brief instant, and the shrieking blast swept o'er the face of the waters, whose placid surface was at once transformed into crested ridges and threatening gulfs; yet all this wild tumult commenced with a small cloud as described. I must now conclude; and my next I purpose devoting to a further consideration of the principles connected with my toning bath, a knowledge of which will tend to secure uniformity of success, considerations which must be regarded as aids to experience. Meantime I shall be glad to receive all enquiries and particulars of experience from those who desire further information. The replies I propose embodying in a special paper devoted to any correspondence I may receive.

## PHOTO-ZINCOGRAPHY IN PRACTICE.\*

BY J. WATERHOUSE, R.A.

### THE PREPARATION OF TRANSFERS IN GREASY INK.

THE object in this part of the process is to obtain a positive image in greasy ink on paper, which may be transferred to a zinc plate or lithographic stone, and printed off in the ordinary way.

The rationale of carbon processes in general is now well known, and depends on the property possessed by the alkaline bichromates of rendering gelatine, gum, albumen, &c., insoluble under the influence of light. If we coat a piece of paper with a mixture of bichromate and gelatine to which some pigment has been added, and expose it to light under a negative, we shall find on washing it in water that the parts acted on by light have remained insoluble, forming a

positive image in pigment, while the unexposed parts, which retained their solubility, have been washed away, leaving the paper perfectly clear. The effect is the same if the paper be coated after exposure with a thin layer of greasy ink, and then washed; and this simple fact is the foundation of all the photo-lithographic processes.

The first thing to consider is the paper, the quality of which is of importance. The paper found to answer best for this process is that known as bank post; it is made from linen, and, being hard and tough, stands the washing well. A medium thickness should be chosen; if it is too thin it is liable to tear, and if too thick, too much of the solution is absorbed. If bank post paper cannot be obtained, ordinary Rive paper will answer.

### PREPARATION OF THE SENSITIVE PAPER.

There are two ways of preparing the sensitive paper: either by floating it on a warm mixture of bichromate of potash and gelatine, or by immersing paper previously coated with gelatine in a cold solution of bichromate of potash.

I prefer the latter plan, especially for amateurs. A quantity of the paper may be prepared with gelatine at any time, and one operation only is required for the sensitizing, which may be done in the evening, and the paper will be found dry and fit for use in the morning.

The proportions of the bichromate and gelatine are influenced by several considerations. The bichromate should not be more than sufficient to render the gelatine wholly insoluble under the influence of light; excess of bichromate produces crystallization on the surface of the paper, and rapidly causes the spontaneous decomposition of the gelatine without the aid of light. In India, so rapid was the decomposition under the combined influence of great heat and moisture, that the proportion of bichromate was sometimes reduced so low as 3 drachms to 40 ounces of the gelatine mixture, but with a corresponding loss of sensitiveness.

The coating of gelatine must not be too thick, or the finer lines will not be impressed through the coating, and will be washed away in the after operations, and when damping the transfers before transferring to zinc, it will be found that the gelatine under the lines will soften by absorbing too much moisture, and will be liable to spread on the plate. On the other hand, the coating must not be too thin; otherwise, when the paper is inked in the press, the ink will be forced into the substance of the paper, and the ground will be irremediably stained. I have obtained sharper results by using a moderate thickness of gelatine than with a thin coating. The quality of the gelatine is important. The ordinary cooking gelatine is not suitable; Nelson's patent fine cut is the best. The French gelatine, sold in thin transparent sheets, will answer, and so will the substance sold under the name of Russian glue, at a much less price than gelatine.

For the preparation of the paper, a metal hot water dish will be found useful. It should be similar in form to the trays used for waxing paper in the days of the waxed paper process. The upper tray should be made of zinc or enamelled iron, and should fit into a metal box one inch larger every way, supported on iron legs, so that heat might be applied by means of a spirit lamp or gas jet, &c., so as to keep the temperature of the solution at about 100°.

I will now describe the details of both methods of sensitizing. The proportions given below will be found to answer well for general purposes.

The formula for the mixed sensitizing solution is,—

Bichromate potash	...	...	...	2 ounces
Nelson's gelatine	...	...	...	3 "
Water	...	...	...	50 "

The bichromate is dissolved in 10 ounces of hot water and added to the gelatine dissolved in 40 ounces of water; the mixture is then strained through flannel into a flat dish placed in another containing warm water. The paper is care-

\* Continued from p. 295.

fully laid on the solution so as to avoid bubbles, and allowed to remain about three minutes; it is then hung up to dry. When dry it is floated again, taking care to hang it up by the end which was lowest before; this is necessary to secure an even coating of the proper thickness.

The paper is then passed through a copper-plate press, to make the surface perfectly smooth. All these operations must be conducted in a dark room.

In the separate method the paper is coated in the same manner with two coats of

Gelatine ... ..	3 ounces
Water ... ..	50 ..

passed through the press, and put away in a dry place. To sensitize it, it is immersed for one minute in a cold solution of 1 ounce bichromate of potash in 12 ounces of water; it is again pressed, and is ready for use.

The paper prepared by either method will not keep good very long. It is better not to use it quite fresh, but about a day old; in dry, cold weather, it will keep for a month, but it can seldom be relied on after a week, and in very hot damp weather must be used almost as soon as prepared.

The sensitizing must be carried on in a dark room, and the paper must be carefully kept from the influence of light, as it is far more sensitive than the ordinary silver paper.

#### EXPOSURE TO LIGHT UNDER THE NEGATIVE.

This is an important part of the process, and one in which experience alone can be a sure guide. With very sensitive paper and a perfect negative, in strong sunshine, from 20 seconds to a minute will be found enough. In dull weather, or with bad negatives, the time may be increased to ten minutes or a quarter of an hour, or longer, but is in all cases much less than could be required by a silver print. The conditions affecting the exposure are, the amount of bichromate in the paper (the sensitiveness being increased by the addition of bichromate), the chemical intensity of the light, and the quality of the negative. If a negative is denser in some parts than others, the clear parts may be covered over, while longer exposure is given to the rest. The only rule I can give for exposure is to print till the fine lines are visible. The colour of the lines is the best guide; they should appear of a dark reddish brown on a bright yellow ground. During the exposure, care must be taken not to expose the ground of the prints to light when examining them. The next stage is the

#### INKING OF THE PRINT.

The prints have now to receive a coating of greasy ink. The composition of the ink is important. It must not be too soft, or it will clog the sponge when washing it off, and it will be very difficult to obtain fine, clean lines. If the ink is too tough, some difficulty will be experienced in clearing it off the ground, especially if the paper has been kept for some days. I have found the ordinary retransfer ink answer very well.

The following is the formula for the ink used at Southampton, and the mode of preparing it:—

Litho printing ink ... ..	8 ounces
Middle varnish .. ..	4 "
Burgundy pitch ... ..	3 "
Palm oil ... ..	$\frac{1}{2}$ ounce
Wax ... ..	$\frac{1}{2}$ "
Bitumen ... ..	1 "

To prepare it, grind the ink and varnish well together with a muller on a stone slab. Melt the Burgundy pitch in an iron pot over a clear fire till the water is driven off, then add, by degrees, the wax, in small pieces; when that is melted add the palm oil, and stir well together with a spatula; when they are well melted, light a piece of paper and try if the vapour will catch fire; if it does, it shows that the heat is sufficient to melt the asphaltum, which is then added in fine powder. It is afterwards set fire to again. Now add the

ink, little by little, and well mix it. The saucepan is then taken off the fire, and, when cooled, pour out the contents, and well mix them on the slab with a muller, taking small quantities at a time. It should then be put away in tins. Ink for half tones is heated more, so as to make it a little harder; the ingredients remain the same. If the ink should harden in time, the addition of a little palm-oil will be found to improve it.

When about to ink the prints a quantity of the ink is taken and melted with sufficient turpentine to give it the consistency of honey. This is well worked on the inking stone with the roller, and an even coat of it is spread on a polished litho stone or polished zinc plate. The prints are laid face downwards on the inked surface, a sheet of paper is placed over them, and they are passed through the press with a lighter pressure than is used for printing. After being passed through once the prints are examined, and if the coating appears perfect they are removed; if not, they are taken off, turned end for end, and laid down again; if necessary the plate should be rolled in with ink again; they are then passed through the press, and when again examined should have a perfect coat of ink through which the detail of the subject is faintly visible. Care must be taken not to allow the ink to stain the back of the prints; the paper covering them must be changed as often as necessary. This mode of inking the prints is the most cleanly and convenient, but there are other modes which in some cases may be preferable, especially if the work is fine and the coat of gelatine thin. The best of these methods is to apply the ink with a piece of sponge. A tolerably even coating can be given in this way. The ink may also be applied with a small hand-roller. The print is pinned down, face upwards, on a board covered with paper, and the ink applied with the roller till an even coating is obtained. By whatever mode the print is inked the object is to get a thin, even coating of ink, and it must be borne in mind that the thinner and closer the lines the thinner the coat of ink should be. The amount of ink on the print should not be in excess, or else there will be a tendency for the lines to spread under the press.

This operation must be carried on in a dark room.

#### DEVELOPMENT OF THE TRANSFERS.

The transfers, having been inked, are taken into a dark room, and floated on the surface of water at about 90°; it should not be warmer. They are allowed to remain till the unaltered gelatine is softened and the detail becomes clearly visible in intaglio. They are then taken off the water and laid on a sloping plate of glass in another tray; warm water is poured over them, and the soluble gelatine is gently removed by rubbing with a very soft sponge. There is no necessity to clean the transfers entirely at this stage, but when most of the ink has been removed they are placed in a dish of warmer water and allowed to soak for an hour or so, and then washed again with the sponge very gently till they are clear; this may be done by daylight. If the paper has been kept for some time, or has become decomposed from any other cause, the ink will not leave the ground of the print; in this case the transfer may be left in soak for some hours, or till the next morning, and then washed in hot water, which will generally remove the ink; but if it does not do so it is better to throw the prints away and try again with fresher paper. In washing the transfers, care must be taken to keep the sponge full of water, so as to ensure a constant flow of water over the surface of the print, to wash off the ink as it becomes disengaged; if allowed to rest on the paper after the gelatine has been removed it is liable to stain. When the transfers are perfectly clean they are finally washed, front and back, in a dish of clean, cold water, and hung up to dry.

They are now ready for transfer to stone or zinc, but it is better to keep them twenty-four hours before they are transferred.

(To be continued.)

## REMARKS UPON THE CARBON PROCESS

As PRACTISED IN THE PHOTOGRAPHIC LABORATORY OF THE  
ROYAL INDUSTRIAL COLLEGE AT BERLIN.

BY DR. H. VOGEL.\*

## I.—Recent Experiments in Carbon Printing.

SOME time since I communicated the fact that I had been enabled to dispense with the use of gelatine in transferring carbon prints.† At the time I made known this modification of the process, I myself had some doubt of its practical value, so incredible did the results appear; but after eight weeks of continued experiment, during which time several hundreds of pictures have been produced and transferred without the aid of gelatine, the importance of this innovation in the method has been fully established. The disagreeable operations of preparing, filtering, and applying the gelatine solution, as likewise the delay involved by allowing the same to dry, the risk of the formation of air-bubbles in the solution, and the difficulty of re-dissolving, are some of the time-taking operations which are thus avoided. On two occasions only did I experience a difficulty in removing the picture, after treatment with benzole some portions of the prints remaining attached to the india-rubber. In one of these instances I subsequently removed the picture by means of rubbing both sides well with benzole; but in the other I was not so successful, inasmuch as a portion of the print became torn during the operation of dissolving off the rubber. To obviate a recurrence of this difficulty, I discontinued the operation of dissolving, and placed a number of the prints in a dish under a piece of plate glass, pouring over them a quantity of benzol, and allowing them to become perfectly saturated with the same. The evaporation of the benzole was prevented by placing the vessel containing it into another larger dish, in which a certain quantity of water had been poured, and then covering over the prints with an inverted shell which dipped down into the water. After remaining immersed in the benzole for ten minutes, the pictures were dissolved off with the greatest ease. Recourse to this mode of proceeding need, of course, only be made when it is found impossible to dissolve away the india-rubber in the ordinary manner; but, in any case, very little benzole is expended in the operation.

The reason of this occasional difficulty in removing the pictures lies in the quality of the india-rubber sheet and solution employed. It is not every description of rubber, even if it dissolves entirely in benzole, that is suitable for use, and it becomes therefore the duty of dealers in photographic requisites to obtain a material of requisite quality. If the rubber sheet and solution employed is of the proper kind, it is necessary merely to moisten the side of the rubber sheet with benzol in order to bring about a perfect separation.

Another great advantage of the non-employment of gelatine is the guarantee it affords of the security with which the rolling-press may be used. When employing the method of transferring with gelatine I frequently had misfortunes with the roller, the pictures being crushed and thus rendered blurred and even quite worthless, and it was for this reason that I had recourse, like Mr. Cherrill, to the screw-press. But without gelatine, manipulation with the rolling-press answers admirably; nor is there the slightest risk of accident to be feared from its use; it is necessary, however, that the roller should be well fitted and perfect in every respect. The following will be found the most successful manner to manipulate:—On the steel plate I place a smooth piece of four-sheet cardboard, and upon this a square of cloth or felt; the white transfer paper, which has been immersed in water for about a minute and then quickly dried upon blotting-paper, is placed, together with the developed india-rubber picture, between the cardboard and the felt, and run through the machine. One single rolling operation is sufficient, but the india-rubber picture should be pressed by

hand evenly down upon the transfer paper before the piece of felt is placed over it and the operation of rolling takes place. For small pictures the screw-press is more convenient; the rolled pictures dry very rapidly, and may be treated with the tanning solution (chrome alum 1 part to water 300 parts) within half an hour of their being pressed. Instead of coating the picture with the alum solution, it is better to immerse it bodily into the liquid for a period of one minute, and then to allow it to dry in a temperature of about 15° Reaumur. In an hour the prints are ready for the application of benzol.

One more advantage secured by the abandonment of gelatine in transferring yet remains to be mentioned. It is the possibility of being able to preserve the india rubber dissolved from the prints, and to utilize it a second time.

## II.—The Carbon Process without the use of India-rubber.

In the last number of the *Mittheilungen* I mentioned that I had been enabled to produce carbon prints with only one transferring operation, dispensing thereby with the employment of india rubber tissue. Experiments in this direction have likewise been made by M. Marion, of Paris; but that gentleman employs not ordinary paper upon which to transfer his pictures, but albuminized paper, such as was suggested some four years ago by Henderson for the same purpose.

M. Marion's mode of proceeding is to lay the exposed carbon print in cold water, changing the latter frequently until the whole of the chromate has been discharged, and thus to bring out the image in relief. A sheet of albuminized paper is then floated upon water (face uppermost), the carbon print is placed upon it, and both removed from the water at the same time, and pressed. A large number of prints may be placed one upon the other in this fashion, and the whole pressed in one operation. After being under pressure for about two hours the pictures are hung up to dry, and afterwards placed in a hermetically closed vessel, where they are exposed to the action of steam. By this means the albumen becomes coagulated, and there remains nothing further to be done than to develop the prints more fully, and to wash them in warm water, the picture, of course, remaining firmly attached to the albuminized paper. The image is, however, reversed.

Although the albumen is unnecessary as a cementing material, I was of opinion that, on account of the homogeneous and brilliant surface which it presents, its employment presented many advantages over ordinary paper. For this reason I instituted a trial of this transferring process with albumen, although I went to work on a different plan from that pursued by M. Marion. The albuminized sheets were first coagulated and immersed in water, then blotted upon filtering-paper, and passed through the roller, together with a dry carbon print, in the same manner as when manipulating with ordinary paper; after drying for about an hour, the pictures were placed in cold water for a like period to develop, and subsequently in warm water. The pictures developed well, and with fewer air-bubbles than when ordinary paper was used. They possessed a certain amount of brilliancy, and had somewhat the appearance of silver prints upon albuminized paper, but they did not possess the beautiful glossy black tones presented by carbon prints produced in the ordinary way, and the whites were certainly less pure than those of prints transferred upon ordinary paper. At the same time, the pictures on albuminized paper exhibited less tendency to tear than the others.

The transfer process is always best conducted (if either albuminized or ordinary paper is used) by having the transfer paper of somewhat smaller dimensions than the carbon print, so that the latter may overlap on all sides to the extent of a quarter of an inch. I likewise essayed the transfer of the exposed carbon tissue, after saturation in water, to dry coagulated albuminized paper, but found it difficult in this case to avoid creases in the picture, a difficulty, however, which is overcome by previously moistening the albuminized paper.

\* *Photographische Mittheilungen*,

† See page 200.

## MAGNIFIED PHOTOGRAPHIC PICTURES.\*

If it were possible to take a photograph, say of the moon, and then to take a second one of a portion of the first, and of the same size as the first, and to repeat the process as often as required, a picture might at last be obtained that would show the minute details in the structure of that body; and in the same way the minutest details in the structure of other bodies, now beyond the reach of the most powerful microscopes, might be shown and examined at leisure. In the present state of science it is not possible to accomplish this, for several reasons.

First, the photographic picture is painted by the deposit of metallic silver, which, in a minute state of subdivision, gives a general grey tone to the picture when it is not magnified; but when the entire picture, or a small portion of it, is inspected by means of lenses, the white lustre of the silver appears more and more plainly as lenses of higher power are used, and the picture assumes a frosted and crystalline appearance, which obscures the finer details beyond a certain limit. The limit is reached by a lens of quite low power, and photographic pictures when viewed in stereoscopes show more or less of the silvery frosted-looking surface texture. To obviate this difficulty a substance must be discovered as sensitive to light as the salts of silver now in general use for photographic purposes, and that will in its decomposition leave a perfectly amorphous coating upon the paper, where the light acts, and in proportion to the strength of its action, from the lightest grey tint to the deepest black.

A second difficulty is the roughness of all surfaces upon which pictures can at present be taken. If we attempt to magnify a photograph, all the roughness of the paper or collodion which is imperceptible to unaided vision becomes apparent, and mingles its own images with that of the finer details in such a way as to make complete confusion. The remedy is the discovery of new materials capable of receiving a polish so fine as to show a perfectly smooth surface under the highest magnifying powers.

The third and the greatest difficulty is the fact that in enlarging small pictures the amount of light reflected by them is constantly diminished, each picture becoming more indistinct than the one of which it is a copy, until finally the original image is completely extinguished. Formidable as this difficulty appears, it is within the range of possibility that it may be completely overcome. The reinforcement of the galvanic current obviates a similar difficulty which at one time threatened to interfere greatly with telegraphic communication. The reinforcement of a sound can make it audible through a large space where it apparently had totally ceased to exist. It remains to discover a means for the reinforcement of light. We believe that in time to come all the obstacles we have mentioned will be surmounted, and the photographic art will become the means of revealing the yet hidden mysteries of nature's grand laboratory.

Another difficulty, that relating to the imperfection of lenses, we will hereafter discuss.

## PRINTING BY DEVELOPMENT.†

THE paper is made to float upon the sensitizing bath for the space of three minutes, and is then allowed to dry. While yet damp it is exposed under a varnished negative, or upon the screen of the solar camera, for a few seconds. No image whatever should be visible, but in dull weather, with feeble lighting, an exposure of half a minute is necessary. The picture is developed by pouring over it, in the manner already indicated, a saturated solution of gallic acid containing about one-third of its volume of aceto-nitrate of silver. If the development is of long duration, then the exposure has been too limited; or if, on the other hand, the picture appears

very rapidly, the image has been over-exposed. When all the details of the picture are distinctly visible, it is plunged into water and carefully washed to eliminate all trace of gallic acid, and it is then put into a solution of hyposulphite of soda prepared as follows:—

Hypsulphite of soda	...	...	60 grammes
Water	...	...	300 cub. cents.
Chloride of gold	...	...	0·13 grammes.

If the exposure has been of sufficiently long duration, the aspect of the print will not change materially when treated in the hyposulphite bath; but if the exposure has been inadequate, the dark portions of the picture will change to a pale red colour. Sometimes it will happen that the tone of the shadows does not darken sufficiently in the developing bath, owing to the gallic acid not containing enough aceto-nitrate of silver, and it is therefore best to add a small quantity of the latter material, by degrees, during the process of development, whenever it is found that there is an absence of vigour in the print. The addition of chloride of gold may be dispensed with in the fixing bath if the pictures tone sufficiently black in the hyposulphite alone.

*Method of Sensitizing by means of Nitrate of Uranium*  
(Niece de St. Victor's method).

The paper used in this process should be kept in the dark, or, at any rate, well screened from light, some time previously to its preparation. It is sensitized by floating upon a solution prepared as follows:—

*Sensitizing Bath.*

Nitrate of uranium	...	...	30 grammes
Distilled water	...	...	150 cub. cents.

After remaining in contact with this liquid for three minutes, the paper is removed, drained, and hung up to dry. Thus prepared, it may be kept for a considerable period, if carefully protected from the action of light. The time of exposure under a negative varies, of course, with the intensity of the light at the time being, but may be estimated at between one to ten minutes in the sun, and a quarter of an hour to an hour in weak diffused light. The image is slightly visible after exposure, and is developed with the following:—

*Developer—Formula No. 1.*

Nitrate of silver	...	...	4 grammes
Acetic acid	...	...	1 or 2 drops
Distilled water	...	...	60 cub. cents.

The development is very rapid, the image coming out in all its vigour very soon after its immersion in the bath. When it has been sufficiently developed, it is immersed in cold water, washed, and afterwards fixed.

*Formula No. 2.*

Chloride of gold	...	...	0·65 grammes
Hydrochloric acid	...	...	1 drop
Distilled water	...	...	365 cub. cents.

## Correspondence.

## PHOTOGRAPHS OF THE MOON.

SIR,—A detailed description, with illustrations, has recently been published by the *Engineer* of Mr. Warren de la Rue's apparatus, machinery, and method of procedure in obtaining photographs of the moon and other celestial bodies. This description, with the diagrams, has been reproduced by some photographic journalists; and I take the liberty of begging to be allowed to call attention to one part of the narrative which affects myself, and, as I apprehend, does me rather scant justice. It is known that in the year 1853 I produced a stereoscopic transparency of the moon, published by Messrs. Horne and Thornthwaite. I devoted nearly three years to the production of lunar photography, and was, I believe, the only one besides Mr. De la Rue who produced, either privately or on a commercial scale, a stereoscopic transparent combination, enlarged from the original negatives (of 7·86 in diameter), and which were truly and absolutely stereoscopic from the laboratory angle at which each picture was taken. I think, then, it scarcely does justice to the time I devoted, or the success I am acknowledged

\* *Scientific American*.

† Continued from p. 115.

to have achieved, to read that, "after 1854 more or less has been done in astronomical photography by Messrs. Hartnup, J. A. Forrest, McInnes, Crookes, Fry, Huggins, W. Allan Millar, and Padre Secchi." True, it may be thought to be sufficient honour to be classed at all with names of men several of whom are of European celebrity; but although there are large numbers of your readers who would not fall into error on the matter, still some might be misled, and for that reason I beg the use of your widely-extended columns on the matter.

There is, of course, a very wide difference between actual stereoscopic coincidence and mere lenticular rotundity. If two exactly identical pictures are placed in an adjusting stereoscope, many persons really believe they are stereoscopic, and on this principle a lunar combination on paper was issued. I had means of knowing that the person who produced it only had access to the Observatory a few consecutive days, and when such was the position of the satellite that a true combination would have been impossible. In the case of the picture I published, the whole result was anticipated by careful astronomical calculation: about thirteen months intervened between the taking of the two pictures which coalesced, and I had prognosticated the very hour when success would be achieved, if only the atmosphere permitted. Every available spot in the Observatory and adjoining apartments were filled at the appointed time by scientific men, many of whom came a long distance to be present; and when at 3:25 in the morning a picture was obtained, having in every detail the most complete coalescence with the first taken, I was congratulated on all sides.

Sir, every man has in the course of his life certain occurrences the reminiscences of which are pleasant, and over whose details he warms up in after years, just as did the old soldier when he "shouldered his crutch and showed how fields were won." I am free to confess, then, that—justly or otherwise—I look back with undiminished pleasure at what I did when experimenting on lunar photography; it may have been "more or less," but considering the great length of time I devoted to it, and that all I had in view was accomplished most fully, I feel a little jealous at what seems a rather depreciatory expression.

SAMUEL FRY.

[It is an unfortunate fact, that the long and arduous work involved in securing reasonably good results in the more purely scientific branches of photography rarely meet with adequate recognition; but it is, on the other hand, a fortunate fact, that they are often labours of love, and prove to the earnest experimentalist their own reward. Mr. Fry's admirable stereoscopic transparencies of the moon are, however, well known to and appreciated by most persons practically familiar with the history of astronomical photography.—ED.]

#### THE TRANSMISSION OF ACTINISM BY LIGHT.

DEAR SIR,—Being desirous to keep you informed on some humble experiments of mine on the comparative power of different kinds of glass to transmit the chemical rays, and it not being convenient to take many sensitive paper impressions, or to send so large a sheet to all of my correspondents, I sent you some time ago a reduced photograph; i.e., copy of one of my most interesting prints. By an oversight of mine, I did not inform you of the points of difference between the original and the copies, which did not truly represent the former, and led to the wrong and curious appearances to which you refer in your News of April 3rd. In the first place, in all of my original sheets, the ground glass cuts off a very large amount of the actinic rays, leaving beneath it a much lighter impression on the sensitive paper than under the unground glass. In the second place, the Belgian sheet in the copy showed so dark an impression as to appear superior to all the other colourless glasses; while in the original, the French plate displayed an equal or greater actinic power. In the copy, from reflected light or some other causes, some portions appear much lighter, and others comparatively darker, than they did in the sensitive paper sheet.

The curious fact about the yellow showing some actinic power is explained by my having used stained glass in making the sheet sent to you. In another sheet, in which I used pot-metal, no impression was made under the yellow specimen. I think that many mistakes may have been made in scientific observations and in photographic studios from using stained instead of pot-metal glass. In the latter the colour permeates the whole body of the glass, while in the former it is only

burnt upon the surface, and frequently in a very thin layer. Photographers, I think, should always use the pot-metal.

I have made one sheet with a row of pot-metal glasses of various colours, and another row of stained or flushed glasses of the same colours, and another sheet with special reference to the comparative actinic powers of ground and unground glass. I have also made other experiments of a similar character, involving some time, thought, and labour, of which, when completed, I shall be most happy to write a full account. I shall endeavour in future to send you original sensitive paper sheets, or to note carefully the slightest variations or defects which may occur in a photographic copy, and thus avoid any wrong impressions which might otherwise be made.

I do not make any pretensions to scientific knowledge or photographic skill, but I shall be exceedingly gratified if my humble investigations, pursued at intervals snatched from business and private cares, shall give light or aid to any class of my fellow-beings in their daily round of labour or of thought.

T. G.

Boston, June 6th, 1868.

[We shall at all times have pleasure in receiving the interesting communications of Mr. Gaffield on this important subject, which has hitherto received but too little attention.—ED.]

#### PERMANGATE IN THE NITRATE BATH.—THE COFFEE PRESERVATIVE.

SIR,—Permanganate of potash for rectifying the negative bath turns out in my hands a complete failure.

I have during the past week tried it upon three baths in succession with exactly the same results in each case. That it clears the solution from organic matter there is no doubt, but at the same produces a condition of the bath that renders it susceptible of derangement in an incredibly short time.

The following is my mode of proceeding:—About a drachm of a 10-grain solution of permanganate of potash was added to the bath, 30 ounces, agitating between each addition, and exposed to sunshine. In a short time the solution assumed a coffee-coloured hue. After standing all night a lightish brown sediment had fallen to the bottom, leaving the solution clear and bright. This was filtered into the bath, and a plate tried: the negative turned out all that could be desired—bright, clear, and vigorous. Two or three other negatives were taken during the afternoon, all of which were satisfactory.

But—could you believe it?—the first plate coming out of this identical bath the following morning showed the most wretched case of fogging I ever beheld. Two other baths (I always use three) were treated in like manner, with the same result in each case—all right for a few plates, and after standing all night, worthless from fog. In all the three cases the baths were slightly acid to litmus paper. Can you explain this phenomenon?

I was somewhat alarmed on Saturday afternoon by a violent explosion in my laboratory. On seeking to ascertain the cause, I found it to have proceeded from a bottle containing a solution of coffee which had been prepared for the coffee dry process. The bottle, a very strong one and tightly corked, was shattered to fragments; and had I been near at the time, I might have suffered injury from pieces of the bottle which were driven with great violence in every direction. I did not know before that there is anything in coffee so powerful as this. Fermentation, I suppose, would be the cause of the explosion. I had noticed a few days before mould floating on the surface of the liquid.—With thanks for past favours, I am, yours, &c. R. M.

Preston, June 21st, 1868.

[The probable cause of the failure of the permanganate is the addition of excess; and by the decomposition following, acetate of silver has been formed, which is often a cause of fog. A few drops of a 10-grain solution are generally sufficient. The only probable cause of the explosion is the fermentation of the liquid containing sugar. We see no reason for supposing that the coffee played any part in producing the result.—ED.]

#### WET PHOTOGRAPHY IN THE FIELD WITHOUT A TENT.

DEAR SIR,—You have often spoken in favourable terms of my apparatus for photographing without a tent, but I am afraid that either such an apparatus is not required, or that there is a disinclination to attempt to make it from the description in the

first volume of the *News*. However complicated it may appear from that description, the apparatus itself is perfectly simple, and if any manufacturer should feel disposed to make it, I can only say that both the single and stereoscopic apparatus are quite at his service. Five minutes' explanation would make the working perfectly intelligible. Having given up the "camera" for the "brush" for some years, I have not used any of the new developers, some of which I think would be peculiarly adapted to the working this process. Perhaps, however, the developers I described would have some advantage over the others, inasmuch as with that the negative does not fog by exposure to light after the developing action is once set up. Probably organic matter might cause it to fog if exposed to light before fixing.

However, it is very desirable to get sufficient density in the negative at once.

There has been much written lately upon enlarging from small negatives, but nothing can be more simple and inexpensive than the camera for that purpose, which I described also in the first volume of the *News*: the process being to take a perfect positive in the camera from the small negative, either the same size or a little larger, and from that, before varnishing, to take a negative for printing up to the size required, if that size be not too large for sharpness on the ground glass.—I remain, dear sir, yours truly, THOMAS BARRETT.

Red Hill, Reigate, 19th June, 1868.

#### MODES OF TONING.

SIR,—I have read with much interest the papers from the pen of Mr. Bovey, but last week I was surprised, not so much with his manner of toning, as with the sweeping assertions conveyed in that paper. He lays down his theory as the only correct one; the proving of this rests with himself, but it does seem strange that so many high authorities should for so long a time have been altogether wrong.

Without classing myself amongst those authorities, nor yet amongst those "who borrow ready manufactured ideas, and consider themselves clever because of their borrowed plumes." I ask leave to state my own experience, which is directly opposed to that of Mr. Bovey.

I wash my prints well in six or eight waters, and then rub each one with a bit of cotton wool till no trace of silver can be observed in the last water. I then put them into one of "those abominable and unscientifically concocted messes known as alkaline toning solutions," which Mr. Bovey says "will inevitably produce meanness, &c."

I have not seen any of Mr. Bovey's work, so cannot judge of its superior merit; but I take the liberty of enclosing three prints from my last batch. Your opinion of them will oblige.

We have a proverb here, in the North country, that "doctors differ, and so do divines;" so also do photographers, and it may happen that truth lies between the differing parties.—I am sir, your obedient servant, G. B.

[In toning, as in many other branches of photographic operation, practice is considerably ahead of theory, and most of the toning formulae are empirical rather than scientific. Very little has been written, and very little is commonly understood, about the theory of toning. Not one photographer in a thousand, perhaps, knows why he adds acetate of soda, chloride of lime, carbonate of soda, &c., &c., to the solution of chloride of gold; whilst many thousands, by carefully following the various formula which experience has proved to work well, succeed in producing good results. The prints sent by our correspondent are excellent. He does not state the formula employed: possibly the term "alkaline" may be a misnomer in reference to it, as it is to the bath with acetate of soda. We think that Mr. Bovey's theory is open to discussion, but as a practical printer of very great skill and much practice, and a thoughtful observer, his opinion is entitled to careful consideration. His practice, we know, produces admirable results. In any case it will be wise to read carefully the complete article, finished this week, before discussing the question.—Ed.]

#### Talk in the Studio.

PATENT ARTISTIC PRINTING PROCESS.—An interesting exhibition of examples of a process patented by Mr. Frederick Piercy is now open at Mr. Graves' Fine Art Gallery, No. 11, Haymarket. The portraits consist chiefly of large vignetted heads in various proportions up to life size. The result is

obtained by a mode of applying lithographic printing to the photograph, which, in conjunction with skilful artistic labour, produces a singularly pleasing effect of modelling and finish. In some respects the pictures have the appearance of a careful and elaborately worked crayon picture on a tinted ground; but there is beyond this an effect *sui generis* which we have not seen produced by any other means. We hope shortly to publish the details of the process; but although it consists in the application of a mechanical method of printing, the results are dependent on the employment of a high degree of artistic skill which Mr. Piercy has brought to bear in the very admirable examples now on exhibition, of which we recommend an examination.

CABINET PORTRAITURE IN AMERICA.—We have recently had the pleasure of examining a selection of cabinet portraits by Mr. Fassett, of Chicago, which are amongst the most charming examples of this style of portraiture we have met with. Original, graceful, and spirited in pose, they illustrate how admirably the cabinet size permits the rendering of pictorial effect in portraiture. The lighting is very perfect indeed, producing exceedingly brilliant and perfect effect of light and shade, and, at the same time, great delicacy and fine modelling. Some examples, with painted background, of an interior are capital in effect, the design being quiet, natural, and unobtrusive, and in all cases preserving a correspondence with the lighting on the figure. With such examples as those before us we can readily understand that the cabinet portrait must become a very decided favourite with the public, as we understand that they have already done in the United States.

LEATHER COLLODION.—Mr. Arthur Taylor recently called our attention to the fact that M. Schonbein, when he visited this country shortly after his discovery of gun-cotton, exhibited some examples of what he termed "malleable glass," which resembled the pellicles recently introduced to photographers under various names, such as "leather collodion," "vitrified india-rubber sheet," &c., with the difference that whilst quite colourless, transparent, and flexible, they were thicker than the modern pellicles. These were supposed to be products of his new discovery, but their composition was not explained; there can be little doubt that they consisted really of thick collodion films, but whether the collodion had received any addition—such as castor oil—now common, or whether they were formed from a simple ethereal solution of gun-cotton, we have no means of judging.

THE PROGRESS OF PICTORIAL ART.—The *Daily Telegraph* says:—"Our whole social life has become, through the development of art, much more pictorial than it was. Thirty years ago none but rich men had family pictures; now there is hardly a servant girl that has not a portrait gallery packed up in her box: her mother, her sister, her sweetheart, her cousin at sea, her friend, her former mistress, or the baby she nursed, are there, in photographs, to give her vivid memories and brighten up exile or loneliness. Our illustrated contemporaries report events in pictures. Sketches in 'Punch' or photographs make us familiar with every line of the faces of our eminent men. Carlyle often laments that there are so few good portraits of the great men of old; but a similar complaint cannot be made by the generation that will follow us to criticise our doings and estimate our work. Is all this wrong? We do not believe it."

PERMANENCY OF COLLODION FILMS.—A correspondent says: "About eight years ago I coloured some cards in powder colours by Mansion's method, and instead of varnish I poured over them some plain collodion. They have been exposed to damp, heat, and sun, and not a single film of collodion has ever been affected in any way, so that I believe a collodion film as permanent a material as possible to be for photographs. The collodion film in a spongy state, as it is as an unvarnished negative, when it can easily be rubbed off with the finger, is another matter altogether."

VARNISHING ALBUMINIZED PRINTS.—A correspondent says: "I find by ten years' experience of varnish, and also collodion, upon albuminized prints, that neither the one nor the other will prevent them from turning yellow."

THE COMING SOLAR ECLIPSE.—We learn from our friend and collaborator, Dr. Vogel, that he proceeds next month to Arabia, as one of a commission sent out by the Prussian Government to photograph the coming solar eclipse.

THE PHENOMENA OF LIGHT.—A number of experiments, as illustrating the phenomena of light, are described in an American contemporary, by Professor Henry Morton. The

following, among others, were especially interesting:—"The Professor placed himself and apparatus on a platform secured to one of the stage traps, and then was raised to a great height above the floor, at which elevation he burned in the compound blowpipe a piece of thick steel wire rope. The fountain of scintillating sparks and drops of melted steel which, descending in a broad sheet some fifteen feet in height, poured upon the stage and rolled in a torrent of fiery hail toward the foot-lights, was a sight never to be forgotten. A wheel five feet in diameter, supporting electrical tubes, was rotated, while flashes of electric fire from the largest induction coil in the world, belonging to the University of Pennsylvania, were passed through, producing a dazzling star of constantly changing coloured rays. The drop curtain, descending for a few moments, rose again, displaying a beautiful palace scene, illuminated by numerous lime lights, judiciously placed. There then marched in a great number of masked figures, in costumes representing the colours of the rainbow, and bearing banners with brilliant devices. These, taking positions, formed a tableau equal in brilliancy and beauty of general effect to anything we have ever seen upon the stage. At a signal the white light was extinguished and its place supplied by pure yellow light, equally bright, when every trace of colour disappeared, and the entire phalanx became a ghastly company of spectres bearing banners of white and black. The means for producing this yellow light is a device of Professor Morton's, entirely new and eminently efficient; in fact, the entire house was illuminated with it from the stage, so that the same wonderful change was manifest in the faces and costumes of the audience.

**NEW ENGRAVING LATHE.**—The *Scientific American* describes an ingenious and effective lathe for engraving upon copper, steel, wood, and other substances now in operation in New York, which is worthy the attention of all who are interested in the reproduction of art. To engrave by means of this machine the operator sits with a copy of the drawing, photograph, or whatever design is to be engraved, directly in front of him. A small pointer rests upon the drawing, and the whole operation consists in moving the pointer over the several lines of the copy. The pointer is operated by two small cranks, one of which produces a vertical and the other a lateral movement; the simultaneous operation of both cranks producing a circular, inclined, or any desired irregular motion of the pointer, which is thus made to "follow copy." All the movements of the pointer are imparted by means of a very simple arrangement of levers to a graver which cuts or engraves the design upon the surface of a copper plate or block. Thus, in a rapid manner, even an unskilled person, having a drawing before him, may engrave the same in superior style. The swelled lines as well as hair lines of copper plate writing may be produced with the utmost freedom, and there seems to be no limit to the execution of the finest and most difficult as well as the simplest kinds of work.

**ANTIDOTE TO CYANIDE.**—A daily contemporary says: "Photographers will be glad to hear that the painful ulcers and other bad symptoms produced by cyanide of potassium may be effectually prevented by rubbing the hands, when soiled with it, with a mixture of protosulphate of iron, reduced to a very fine powder, and linseed oil."

## To Correspondents.

A. C.—Brown paper of great width and in continuous lengths, suitable for backgrounds, is generally kept by dealers in paper hangings.

ALEX. TAYLOR.—It is a somewhat difficult thing to say which is the best and simplest dry process, as there are so many which are both good and simple. The requirement of keeping well before and after exposure limits the choice somewhat. Perhaps the gum process, described in our last, will meet your requirements best in this respect. The coffee process is also a simple and good keeping process. The morphine process is very simple, and gives excellent results, but the plates do not keep well. Mr. England's process is simple, and gives fine results, and the plates will keep moderately well. All these are tolerably rapid; but the gum plates most so.

A. Z. II.—Unless there is some peculiarity or imperfection in your materials, the acetate bath should not tone too slowly at the expiration of twenty-four hours. We have frequently used one for weeks with advantage. Possibly your example of acetate of soda is alka-

line, which would account for your bath rapidly becoming inert. If it suit your convenience, however, and your bath work well a few hours after mixing, there is no reason whatever why you should not use it then.

J. KEENE.—Thanks for the charming Eburneum portraits; they are very excellent, and, when compared with the albuminized prints from the same negatives, admirably illustrate the superiority in delicacy and detail which pictures by this mode of printing possess over albuminized paper prints.

W. J. A. G.—The lenses of a binocular camera are generally placed from 2½ inches to 3 inches apart, the rule being that they should be at a similar distance as the human eyes, and when so placed they will give images producing a similar amount of relief to that seen by the human eyes. If they are placed at a greater distance they will give images which, in the stereoscope, have an exaggerated effect of relief, greater than could be seen by the human eyes; but that exaggerated effect of relief tends to dwarf the object, and make it look like a toy or model. If, for instance, you stand in front of a large building like St. Paul's, you can only see one side at a time; but if you stand at the same distance from a model of the building, only a foot in diameter say, you then may see all round it. So if you place your lenses in such a position that one sees one side and the other the other side of a large building, the stereoscopic picture produced will suggest the effect of a diminutive model. This is an old and much discussed question: the advocates of truth maintaining that the lenses should be in the same position as the human eyes; the advocates of startling effect recommending an increase in their separation for views and some other effects. The single lens camera you have has, we presume, the Latimer Clark's sliding parallel bars. The bars should be arranged for a ratio of convergence, so that they move through the arc of a circle of which the sitter or principal part of the subject is the centre. When properly adjusted, the sitter is focussed in its proper position on the ground glass, with the camera at one extremity; and when the bars are moved to the opposite extremity, the image will still be found to occupy the same place on the ground glass. Commence the exposure with the laths in a position which places the camera to the right-hand side, the slide carrying the plate also being at the right-hand end of the groove. After exposing, cover up the lens, move the laths to the left, and the slide carrying the plate to the left, and expose again. This will give you the images in their right position, needing no transposition.

SILEX.—We have never met with anything like fading in a carbon print. Some examples we have seen with a greenish tint from imperfect washing; but this has been the case as much when first produced as after long keeping. No doubt if an unframed carbon print be submitted to the heat of a hot sun it will cockle and curl, but this is a kind of treatment to which no work of art should be submitted. Destruction from an outward cause is altogether different from fading from internal or inherent causes.

Y. Z.—We saw the observations to which you refer, and we have also seen the old blocks in question, which, as you remark, appeared originally in an extinct journal; but the matter is not one of sufficient public interest for comment.

F. POWER.—Both will give perfectly straight lines, and both include a wide angle; but No. 1 is, we believe, the most rapid, and includes a little the widest angle.

L. M. D.—A slight washing only is necessary before toning; prolonged washing, or the use of salt and water, renders the toning more difficult, and the result is often wanting in richness. The chief disadvantage of toning without washing at all is that it causes an unnecessary waste of gold. Wash well after toning and before fixing. The grey tone and want of depth in the print enclosed are due to over-toning a print from a weak negative. In order to secure a rich deep black it is imperative that the negative be vigorous and the impression deeply printed.

B.—The chief reason of the simple albumen dry processes without collodion falling into disuse was not any lack of excellence in the results, so much as the necessity of great care in the preparation of the plates, the process being more troublesome than most of the dry collodion processes. M. Ferrier used albumen plates for his transparencies, but collodio-albumen for his negatives.

R. F.—The tendency in the albumen to crack when perfectly dessicated may be avoided by mounting the prints before they are thoroughly dry. Thanks.

C. D. V.—You cannot secure the copyright if copies have been sold before registration. 2. It is necessary to register a copy of each portrait which is in the slightest degree different from the others. 3. You cannot secure a copyright in the photograph of an old non-copyright engraving. Registration on your part will be no barrier to any one else copying the same engraving and selling copies of it. Several Correspondents in our next.

\* \* All photographs forwarded to the Publisher for registration receive attention at once; but the pressure on our space sometimes compels us to defer the acknowledgment in this column. It should be borne in mind, therefore, that non-acknowledgment at once does not necessarily imply non-receipt or non-registration.

### EXPRESSION IN PORTRAITURE.

IN the discussion which followed Mr. Pearce's excellent paper on Portraiture at a recent meeting of the South London Society, the Chairman deprecated the practice common amongst some photographers of requesting the sitter to fix his eyes on "a knob," rightly adding, that whilst there was nothing interesting in the knob, there was nothing reassuring in the adjuration to "keep quite still," which generally heralded the commencement of exposure. Mr. Blanchard suggested that a portraitist of judgment would, he thought, avoid both courses; he would merely request the eyes to be directed in a given direction, which seemed easy and natural for them, and he would carefully avoid startling the sitter by any stern injunction not to move. He would rather endeavour, by conversation, to interest the sitter, and when a pleasant expression was secured, would seize the opportunity of exposure, possibly requesting the sitter to maintain *that* expression and position for a few moments.

The management of the sitter in securing ease and naturalness is a thing which can scarcely be taught, as it depends more upon natural temperament and general culture than upon any rules which can be laid down; nevertheless it is a subject well worthy of the most careful study by all portraitists. A true and pleasing expression is the last and highest grace in any portrait, photographic or otherwise; most difficult to attain, and most prized when secured. Its presence will condone many technical shortcomings; its absence will often make the highest technical excellence valueless. In a painting, it is attributed to the skill of the artist; in a photograph, it is supposed to be due only to the sitter. In both cases it is, however, the result of combined action; the painter must see the expression before he can paint it; and, to see it, he must often, by interesting his sitter, elude it. The photographer must also see the expression before he can photograph it, and he must also often elude it before he can see it. The painter possesses, however, two special advantages over the photographer in this respect: he sees his sitter on several occasions, has opportunity for conversation and for studying his sitter, and, having once seen the face properly lit up with feeling—seen "the mind, the music breathing in the face"—he possesses the facility of transferring the fleeting expression to his canvas from memory. The photographer sees his sitter generally but once, and that once often for a few minutes only. Moreover, the camera has no memory, and can only fix the expression worn by the face during the moments of exposure. The desired expression must therefore be secured just at the critical moment, or it cannot appear in the photograph.

The hint thrown out by Mr. Howard, if practicable, might assist in giving the photographer some of the advantages

of the painter. He suggested that as technical difficulties had, to a great extent, been mastered by professional portraitists, and higher demands were made by the public than in the infancy of the art, he thought a higher standard, involving more time, greater ability, and more cost, might, without impropriety, be aimed at by first-class portraitists; that instead of taking each sitter just when he came to sit and with the hasty estimate of the best effect for each portrait which could be found in one often hurried sitting, the photographer should have a previous interview with his sitter, in which he could form a deliberate idea of the result most desirable, and some degree of acquaintance or familiarity—or, at least, mutual confidence—between the artist and his sitter be established. Of course, to render such opportunity for previous thought and arrangement of any avail, the photographer must be, in some degree, master of the difficult art of portraiture; but with an understanding of its requirements there can be little doubt that such a course would conduce to the production of higher results; and the suggestion is worth the consideration of portraitists who aim at the highest results, and can command the terms which would be remunerative for the expenditure of the time and consideration necessary for carrying out such a project.

The possibility of securing the portrait whilst the sitter was unconscious of the ideal has often been desiderated by nervous persons, and has generally been regarded as an unpractical thing. It is, however, not altogether impossible. A lady recently sitting to Mr. Robinson expressed considerable apprehension as to the possibility of preserving a natural expression when the moment of exposure came. She had been requested to rest herself without any concern on that head until the preparations were made; and when, a short time afterwards, she exclaimed, "If you could only take me when I didn't know it, I am sure the result would be better," the answer returned was, "Madam, I have obtained four portraits of you already!" some of which were, to her great delight, in every way satisfactory. She had been placed at the outset, with little fuss and circumstance, in an easy, quiet position, and, the light being good and chemicals working well, the four portraits were secured whilst she imagined that the photographer was merely arranging his camera. We have seen Mons. Adam-Salomon effect a similar result. Having duly arranged the sitter, who was requested to remain tranquil, and not speak for a few moments, he continued the conversation, to which the sitter listened with a look of interest, expecting to be informed in a few moments that the exposure would commence, only to be informed that it was over. To attain results of this kind it is scarcely necessary to say that the photographer must study something more than photographic processes, and that, whilst his technical conditions should be perfect, his knowledge of human nature, and of portraiture as an art, must be sedulously cultivated.

## Critical Notices.

**A MANUAL OF PHOTOGRAPHIC MANIPULATION;**  
Treating of the Practice of the Art, and its Various Applications to Nature. By LAKE PRICE. Second Edition.  
(London: John Churchill and Sons.)

THE name of Mr. Lake Price is known to photographers throughout the world as associated with some of the earliest and most successful triumphs of photography in the domain of fine art. His recognized position in the art world silenced cavil when he put forth the noble productions of his camera, and proved to doubters that photography was capable, in the hands of an artist, of rendering a wide range of pictorial effects. His work also illustrated in a high degree the happy combination of great practical and technical skill with artistic culture; hence, when he gave to the photographic public a manual of instructions, it was eagerly read, and, in natural course, passed out of print. When a book of interest is out of print, it is generally quickly reprinted; but a mere reprint of a work relating to a growing art like photography is comparatively useless. The constant change and modification going forward must be noted, to give a manual of instruction value. Unfortunately, the changes in some phases of the art were not—or, at any rate, did not seem to Mr. Price—improvements. The race for cheapness rather than excellence set in, and he retired from the active pursuit of the art with something like disgust.

It rarely happens, however, when a man has attained the mastery over an art which Mr. Lake Price had attained over photography, that he can entirely abandon it or lose interest in it. Mr. Price has watched the course of events, and has for some time past been renewing his intimate acquaintance with the art, and has been induced, as a result, to partly rewrite, revise, and issue a new edition of his work, first published ten years ago, and the result is now before us.

A glance over the pages of the new edition just issued will satisfy the reader that although the author has ceased for the last few years to publish the productions of his camera, photography must necessarily have secured a full share of his attention, as all subjects both of current and permanent interest belonging to the pages of a manual are fully and freshly treated. All the important novelties in the optical appliances are fully and practically considered, the chapter on lenses being most valuable and exhaustive, the result of careful examination and trial of the various new instruments introduced during the last few years. The series of chapters devoted to "Subjects: their Nature and Treatment," will perhaps be read by experienced photographers with the most profit and interest, and will be found to abound with the suggestions of ripe culture and art experience. The demands upon our time and space preclude our giving a fuller notice of the work, or extracts from its pages; to which we shall, however, shortly recur. We conclude by adding, that in addition to all the subjects included in the former edition, carbon printing, astronomical photography, microscopic photography, are here fully treated, the present work containing about fifty more pages than are found in the first edition.

## ECHOES OF THE MONTH.

BY AN OLD PHOTOGRAPHER.

PROGRESS OF CARBON PRINTING—NORTH LONDON PRESENTATION PRINT COMPETITION—IMPRISONMENT FOR PIRACY—PHOTOGRAPHY AND LIBEL—MR. LAKE PRICE'S "PHOTOGRAPHIC MANIPULATIONS"—ENLARGEMENTS AND PORTABLE FIELD APPARATUS—THE STEREOSCOPES.

It is very gratifying to all who care for the progress of permanent photography to see the increasing interest which prevails in the carbon process, both in the outside world and in special photographic circles. Since the publication of

Mr. Wharton Simpson's work on carbon printing, not many months ago, three others have been issued, of which I have seen copies: a translation into German, by Dr. Vogel, with a capital carbon print as illustration; another in German, a small compilation, by Dr. Liesegang; and an American edition, by Mr. Wilson, which, as stated, is chiefly based on Mr. Simpson's work (this also has a carbon print illustration). The argument I derive from the publication of these works is, that there is a demand for them, and that the process they describe is exciting wide-spread interest.

In France I see that various papers are communicated to the Society, chiefly on what are modifications of Swan's process; but as a rule I have not been able to perceive in what the modification consists. M. Jeanreudand's paper, for instance, appeared to be simply a statement of Mr. Swan's method. M. Marion has been working lately with praiseworthy energy in experimenting with carbon with his new pellicle (now acknowledged to be collodion, and not caoutchouc); but does not his method simply amount to the same thing as Mr. Swan's first method, when he prepared his tissue upon collodion instead of paper? The suggestion of Mr. Taylor, of Marseilles, for removing the yellow tint from the back of paper tissue, and so rendering printing through the tissue itself, appears to be a valuable suggestion for purposes in which extreme delicacy is required. If I remember aright, Mr. Swan once made a still better suggestion, which I have never heard of any one carrying out. I refer to the mode of making a tissue upon paper made transparent with oil or varnish, printing through the transparent paper, and when the operation of exposure, development, &c., were all complete, floating the print on a solvent of the oil or varnish to remove it, and so restore the paper upon which the print is formed to its opacity and whiteness, necessary to give it any value as a picture. Possibly, however, the now recognized method of carbon printing would give better results with less trouble.

The idea of the North London Society, of submitting the production of the presentation print to competition, is, I think, a very happy one. It gives an opportunity of bringing forward something specially good to all interested in securing honours, for it is an honour to supply the presentation prints to any society, especially when the selection must be made from the works of various competitors. And it will in all probability secure the members something more original than they might otherwise have secured, although, perhaps, it may be difficult to surpass, either in novelty or excellence, some of the pictures distributed within the last year or two to the members.

I am glad to see that a pirate cannot evade the payment of his fine by becoming bankrupt. If that had been found possible, the class of persons who systematically execute or vend piracies would, whenever heavy fines were inflicted, have found Basinghall Street a short cut from gaol. The fine inflicted is, as Lord Justice Wood has ruled, a punishment for criminal offence, and not an estimated amount of damage to be regarded as a debt to the person whose copyright is infringed. This decision may perchance press hardly upon the ignorant offender or the person led into the commission of an offence by the machinations of a spy or informer; but the fines can only be heavy where the transactions are large, and this can rarely be the case without the persons engaged in the guilty traffic having some notion of its illegality.

Photography of late years seems generally to take some part in the progress of almost all *causes celebres*, and I notice that photographs of documentary evidence were admitted in Court in the course of the action of Risk Allah against the *Daily Telegraph*. According to rumour, photography was to have entered more intimately into a succeeding case, which was, however, apparently withdrawn or compromised, as it did not come to trial. The Stereoscopic Company, it appears, exhibited during the trial, at Brussels, a portrait of Risk Allah, with a description appended, stating that he was

charged with the murder. The intended action was on the ground that the picture was exhibited with this description appended for some days after a verdict of acquittal was rendered. It is, perhaps, worth while for photographers to take a hint from this, and shun the risk involved, which might be so innocently and thoughtlessly incurred.

The issue of a new edition of Mr. Lake Price's "Photographic Manipulations" during the last few days is worth noting. The return of Mr. Price to an early love, after a long—not estrangement, but—pursuit of other interests, will be hailed with pleasure by photographers, and the advent of the new edition of his work, rewritten and enlarged, will be greeted with welcome, and I, for one, shall look forward to renewed triumphs in the phases of art-photography which were years ago adored by Mr. Price's works.

The question of producing small negatives with a view to the subsequent production of either an enlarged negative or enlarged prints—a question full of interest to the amateur photographer—has scarcely, I think, received sufficient attention yet amongst photographers. There are very few indeed, I fancy, who would not prefer to work the wet process to the dry process, if it were not for the serious difficulty imposed by carrying dark tents, manipulating boxes, &c. Now, if it were once determined that really good results could be obtained by the means of enlargement from small negatives, more than half the troubles of impedimenta might be made to vanish. Enlargements in portraiture in various manners have, of course, been tried, and found successful, especially when the work has been intended for retouching or colouring; but, as yet, the question of enlarging without the necessity of retouching, as applied to landscape photography, has not been very thoroughly or very fairly tried. I do not suppose that many of the schemes for producing negatives the size of postage stamps will ever receive serious attention; but I think that if negatives of about  $3\frac{1}{2}$  inches by  $2\frac{1}{2}$  inches were carefully produced, fine 12 by 10 pictures might be obtained from them. For such a purpose, the little apparatus referred to by Mr. Barrett in the *Photographic News* of last week, and described in a former volume, would be found by far the best of any contrivance hitherto proposed. Some years ago I had an opportunity, availing myself of Mr. Barrett's courtesy, of examining the equipment, and I was much struck with its ingenuity and convenience. A plate coated with collodion is immersed into the silver bath, and at once enveloped in a light-tight cover, from which it never emerges until it is a finished negative of about the size I have mentioned. The whole apparatus is scarcely larger than a man's hat; it is apparently very easy to work, and it certainly admits of the production of good results. How is it, I wonder, that such a piece of apparatus has never come into commerce?

The societies generally have brought their sittings to a close. Dr. Mann gave an interesting account of Professor Piazzi Smyth's operations in the Great Pyramid with an apparatus of a similar kind to Mr. Barrett's just mentioned; but in many respects not equal, I think, to the latter. Mr. Dunmore exhibited a tent which was undoubtedly convenient to work in; being intended for large plates, it was, however, necessarily a somewhat cumbersome affair to move about and erect. At the North London very little was done, except some society business. The South London Society had a capital meeting, at which, besides the election of officers, reading of a report, and transaction of the general business of an annual meeting, a suggestive and well-written paper was read by Mr. Pearce, and an interesting discussion followed. The proceedings terminated by an arrangement for an out-door meeting at Hampton Court, and an invitation to the members from the genial and large-hearted President to spend an evening at his house.

At the Manchester Society Mr. Mabley read some observations on print-washing apparatus, which originated an interesting discussion, in which short washing, with specific treatment, such as pressing, rubbing, &c., to remove

the hypo, was generally regarded as much more conducive to permanency than any mode in which merely prolonged soaking was relied on. At Oldham a pleasant out-door meeting was held, which gave general satisfaction to the members.

## Foreign Miscellanea.

FOLLOWING the example set by the Duc de Luynes, M. Frederich von Voigtländer has recently placed at the disposal of the Viennese Photographic Society the sum of four thousand five hundred florins (about £450), to be employed in encouraging the working out of improvements in the art of photography. According to the conditions drawn up to regulate the manner in which this sum of money is to be used, it is stated that the interest of the capital only will be expended, the principal being invested in the Austrian funds. A jury or prize committee is to be formed, composed of members of the society, and these will adjudge prizes, consisting either of medals or grants of money, to the more deserving candidates at a competitive meeting to be held annually. All works sent in to compete are not to bear the name of the artist, but must be marked with a symbol or device and accompanied by a sealed letter from the sender bearing on the outside a similar design; the candidates must be members of the Photographic Society of Vienna, but need not be resident in that city. In the case of the society ceasing to exist the money will revert to the donor or his successors.

In the *Mittheilungen* M. Grasshoff contributes a very clever paper on photographic backgrounds. He complains loudly of the manner in which some of the cabinet pictures are overloaded with accessories, stating that it sometimes appears quite wonderful how the sitter could have threaded himself through the mass of furniture and nicknaws with which he is surrounded, and which encumber and hem him in on all sides; the majority of backgrounds are, likewise, too highly coloured, and the perspective details generally too distinctly marked to appear natural. Scenic effects which give good results in one studio are sometimes found to be quite unserviceable in others, owing to the different lighting arrangements; and M. Grasshoff recommends, therefore, a final touching up and modification of the background when in position. To render portions of the background more brilliant, and to light up any dull points, a little powdered chalk will be found very efficacious; and, on the contrary, a glaring surface may be subdued by treating it with dry powdered ochre or umber.

In reference to the photographic establishment of M. Braun, of Dornach, the beauty of whose carbon printing is so well known, the *Photographisches Archiv* states that as many as seventy employes are engaged on the premises. The grinding and mixing of the pigments, as, likewise, the sensitizing and rolling of the carbon material, is performed by machinery, a six-horse power steam-engine being used for the purpose, and the benzole vapour from the transferred prints is dissipated by means of a windmill which makes twelve hundred revolutions in a minute. As many as four hundred 20 by 15-inch pictures are turned out every day, and this number will shortly be increased to five or six hundred. The *Archiv* states that the quality of the work performed is, on the whole, very good, but it is of opinion that the pictures produced by Swan, at Newcastle, are more brilliant and of a finer and better tone than those turned out at the Braun establishment; at the same time it should be remembered that M. Braun has had less experience in the process, and that he works on a very large scale.

A new process, says the *Archiv*, has been elaborated by M. Woithly, consisting in the use of urano-nickel collodion. The pictures produced by it are perfect as regards definition and clearness, and their tone is excellent. The details of the process have not yet been published by M. Woithly.

M. Tessié du Motay, a gentleman well known as a photographer and photo-lithographer, has discovered an easy and cheap method of obtaining oxygen, which is now being employed for furnishing gas for some oxy-hydrogen lime lights now under trial at Paris. Four candelabra have been erected upon the square in front of the Hotel de Ville for the purpose of thoroughly testing this mode of illumination. M. du Motay produces his oxygen at the rate of sevenpence per cubic yard; by passing a current of hot air over manganate of potash he converts that material into permanganate, from which the oxygen is readily generated by treatment with super heated steam.

M. Geymet recently calls attention in the *Moniteur de la Photographie* to the fact that he is able to prepare for commercial purposes the transparent sensitive film upon which, as he some time ago stated, photographic impressions may be printed, and afterwards transferred to a suitable support. The mode employed appeared to be a modification of the collodio-chloride process. The latter may consist of coloured paper, or of a leaf of metal—as, for instance, of gold or silver; and inasmuch as the photograph itself is perfectly transparent, even in the deepest shadows, a very pleasing result may thus be obtained, provided the nature or colour of the support is in keeping with the character of the picture.

M. A. de Constant writes to the *Archiv* in warm praise of Steinheil's new aplanatic lens for groups and landscape pictures. He has been able by its means to secure good results with coffee dry plates, with an exposure of from 12 to 15 seconds only, the plates being at the time a week or ten days old; the soft outlines of mountains twelve miles distant, as likewise the details of the foreground, are equally well rendered by the lens.

M. Dnbost, of Düsseldorf, has been very successful in the production of excellent negatives by the coffee process; they are both brilliant and harmonious, and developed by means of an acid solution, made up according to the following formula:—

No. 1.—Water	...	...	...	100 parts
Pyrogallie acid	...	...	...	1 part
Citric acid	...	...	...	$\frac{1}{4}$ "
No. 2.—Water	...	...	...	100 parts
Nitrate of silver...	...	...	...	6 "
Citric acid	...	...	...	6 "

The solutions are mixed together for use.

## PICTORIAL EFFECT IN PHOTOGRAPHY ;

BEING LESSONS IN  
COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

### CHAPTER XXIII.

"Fit it with such furniture as suits

The greatness of his person."

*Shakespeare.*

"It shall be so my care

To have you royally appointed, as if

The scene you play were mine."

*Shakespeare.*

### BACKGROUNDS AND ACCESSORIES.

PERHAPS in no other one part of their art have photographers so outraged nature as in the choice of accessories and the make-up of their pictures.

Let me turn over the leaves of an album, and describe one or two of the pictures contained therein.

No. 1. A portrait of a lady in an evening dress, walking on the sea-shore; in consideration of her thin shoes, that part of the sands on which she is standing is carpeted.

No. 2 represents a veteran photographer standing on a terrace. The terrace is carpeted, and on it stand a pedestal and column, round which is festooned a curtain elaborately tied up in various places with cord and enormous tassels. The distant landscape is delicately and well done, but adds force to the absurdity of the curtain in the open air.

No. 3. A gentleman standing before a profile balustrade and pillar, with landscape behind representing distant mountains. The light on the figure is from the right, that on the balustrade from the left. The shadow of the column falls on the distant mountains, which are much more clearly defined than the head of the figure.

No. 4. A lady reading at a window, but the light comes from the opposite direction. The shadow of the window-curtain falls on the sky.

No. 5 represents a gentleman with a gas chandelier, globes and all, sprouting out of the top of his head.

There are one hundred pictures in the book, many of them from the most popular studios. There is a column or balustrade in seventy-eight of these cartes. And yet photographers accurately represent nature!

A curtain is allowable because it is possible, but the use of the column is open to very grave doubt, and the two together are so exceedingly improbable as to be almost absurd. It is true, the employment of these accessories as a background is to be found in the pictures of some great painters, but the tricks of one art may not be applicable to another. The column and curtain are conventional. Now conventionalities may be right in an art like painting, where a good deal of license has been allowed, and has become sanctioned by custom, but photography is a new art, the results of which are taken direct from nature, and is without precedents. It is an art in which departure from truth becomes absurd. We, the workers in the first quarter century of its existence, are the makers of precedents: let us be careful, then, that they are not misleading and dangerous ones.

Photography is the most imitative of all the arts, and photographers the greatest imitators, as they have shown by the way they have followed and adopted much that is bad in painters; and perhaps the worst of these imitations has been this column-and-curtain conventionality for most of their sitters, when it is probable that few under the rank of those who dwell in palaces ever naturally have the opportunity of being in the neighbourhood of such accessories. In painted pictures the column is shown with some chance of possibility, but the way it has been used in photography has been ridiculous and absurd, it generally being placed on a carpet. Now everybody must be open to the conviction that marble or stone pillars are not built on carpets or oil-cloth for a foundation. But there was a lower depth. Wooden columns were not bad enough, nor cheap enough, so recourse was had to imitations of these sham pillars manufactured out of flat boards and canvas, and painted in perspective that looked every way for the point of sight without being ever able to discover it; if any of the lines were right, it was on the principle that makes a clock that does not go, right at one second of the day at least. The violent light is often represented as coming from the opposite direction to that which illuminated the figure. Then, by a stroke of genius, somebody extended the application of these profile slips to the representation of other objects, such as chairs, on which, being flat, it was impossible to sit down, pianofortes, fireplaces, French windows, and everything that was capable of being caricatured in this manner. But the "crowning glory" of this kind of sham furniture was the *multum in parvo*, or "universal," that Protean construction which was at one minute a pianoforte and at another a bookcase—a sort of economical houseful of furniture in one piece. This was certainly an improvement on the slips, and if manufacturers would only add a little taste to their cabinet work, suppress the rococo ornamentation, and make them much plainer, they may be of use where the very best work is not necessary.

But if the photographer has any pride in his art, if he desires to do the best that can be done, he must eschew imitations, and have nothing in his studio but genuine furniture of the best kind, and of good design and character. When the photographer is furnishing, he would find it a good plan to fit up, not only his studio, but his reception rooms also, with chairs of different patterns—a "Harlequin Set,"

as collectors of old china would call it—so that he may be able to make a constant variety in his pictures. He would do well to avoid the elaborately carved, high-backed chairs, so constantly seen in photography and seldom anywhere else, the high back often sticking out round the head like a Gothic glory: if this chair is used at all, it should be so arranged that the head of the sitter is quite clear of it. Dining-room and library chairs are always useful, so also is that kind of chair to which the name of *Prie-Dieu* is given, especially for standing figures. It is very difficult to meet with a good arm-chair suitable for photographic purposes. The chairs of the present day are made more for comfort than appearance, and are so low that the sitter is dwarfed and foreshortened. It would pay manufacturers to employ a good designer to supply them with patterns and make them for the profession.

After chairs naturally follow tables. It is scarcely necessary to say anything against the little round table, about twelve or fourteen inches in diameter, to be seen in many early photographic portraits, the use of which is now gone out, except in the smallest and lowest glass sheds. The furniture in a picture should give an idea that there is space in the room; this is not done when a small table is employed, obviously because there is no room for a larger one. A long, oval table, about 3 feet 6 inches by 1 foot 6 inches, is a very useful size and shape; it should be made light and upon large castors, that it may be easily moved. This should be provided with one or two good covers of a quiet pattern. In a table-cover, as in the covers of chairs and cushions, violent and "noisy" designs should be avoided. As a change from the plain table, a more elaborate carved oak table may be admitted for occasional use, and so may a judiciously selected cabinet, but it must be always remembered, in introducing these necessities, that it is the portrait of the sitter that is required, and which must be most prominent, and not the magnificence of the fittings of the studio, which may be "richly suited, but unsuitable."

Some photographers employ a table which can be raised or lowered, to suit the stature of the sitter, by means of rackwork. This, in the hands of a photographer of great judgment, may be a very useful accessory, but it is a power that should be employed very sparingly and within very narrow limits. If it were raised too high it would dwarf the figure by comparison, or, in the reverse case, by screwing it down too low, it would transform the sitter into a giant, reminding us of the *carte-de-visite* of the short man whom *Punch* represented as having his portrait taken surrounded by toy furniture. The same principle has also been applied to the pedestal and column.

The great idea of many photographers, in taking standing figures, seems to have been that they must have something to lean upon (could the idea have originated in the supposition that some support was necessary after the toilsome ascent to their studios in the sky parlours?), and, therefore, the want was supplied by a pedestal that outraged nature, as I have already said, most abominably. It is not necessary to an easy and graceful effect that the figure should appear to be too tired to stand on its own feet. Lounging is no more graceful than is a lisping and insipid manner of speaking gracious, but tends more to what Sir Joshua Reynolds called the most hateful of all hateful qualities, affectation. If people look well in a standing position at all (which some certainly do not, and should never be taken so), they will be found to do so without the aid of a prop; but still, for the sake of variety, and because some people have been so often taken with a support that it has become a custom with them from which they do not like to depart, it is as well to have something of the sort at hand. The best piece of furniture of the kind is a cabinet. A low bookcase is not objectionable, neither would be a well-designed what-not, but the ugly, meaningless pedestal should never be used. I should consider I was doing a great service to the art progress of photography if I could induce all photographers who have columns and pedestals

to burn them at once. Don't send them to the broker; he may sell them again to do further mischief.

A few low ottomans and footstools should always form part of the furniture of the studio. They are especially useful in grouping children. The carpet of the room should be of a small, neat pattern, and contain no great contrasts of dark and light.

A great deal can be done and very beautiful pictures made by the mixture of the real and artificial in a picture. Although, for choice, I should prefer everything in a photograph being from nature, I admit a picture to be right when the "effect" is natural, however obtained.\* It is not the truth of reality that is required, but the truth of imitation that constitutes a veracious picture. Cultivated minds do not require to believe that they are deceived and that they look on actual nature when they behold a pictorial representation of it. An educated observer does not, like that Moor to whom Bruce, the African traveller, gave the picture of a fish, believe that the artist had made a reality, and say: "If this fish at the last day should rise against you and say, 'Thou hast given me a body, but not a living soul,'—what should you reply?" Art is not the science of deception, but that of giving pleasure, the word pleasure being used in its purest and loftiest sense. For this purpose—that is, the mixture of the real with the artificial—the accessories of the studio should receive the addition of picturesque or ivy-covered logs of wood, ferns, tufts of grass, &c., either growing in low pots or gathered fresh. It will be found easy to make up picturesque foregrounds with these materials, behind which a painted view or sky may be placed. If the background be well painted it will be found to unite very naturally with the foreground. Care must be taken that linear perspective be avoided, and that the light fall on the figures in the same direction as it does on the painted screen.

## PHOTO-ZINCOGRAPHY IN PRACTICE.†

BY J. WATERHOUSE, R.A.

### PREPARATION OF THE ZINC PLATES FOR RECEIVING TRANSFERS.

THE zinc used for this purpose comes from Silesia. It is supplied in rolled sheets of different sizes and thicknesses; the price is about two shillings a square foot, varying slightly according to the gauge. The gauges in general use for photo-zincography are from 7 to 11 Birmingham wire gauge, or 3-tenths to 1-eighth of an inch. Plates of any size are supplied by Messrs. Hughes and Kimber, at 2s. a square foot, ready for graining, or grained at 2s. 9d. the square foot. It will be most convenient for the amateur to purchase his plates ready grained; but as some may prefer buying them in a rough state, I will describe the whole process of preparing the plates. The zinc plates, when received from the makers, are rough and full of hollows and other blemishes, which render the plates unfit for use till one side has been made perfectly smooth and has received an even graining with fine sand, which covers the surface with sharp, fine, uniform grains or asperities, and thus increases its affinity for the greasy ink or crayon, and renders the surface as capable of retaining moisture as the lithographic stone.

The first operation is to take off the sharp edges of the plates. The plate is fixed down by weights or clamps to a table, the edges are scraped down in succession with a tool resembling a spoke-shave; when the sharpness has been taken off all round the plate on both sides, the edges are smoothed with a rasp, and the corners of the plate are rounded off. It should now be examined on both sides, and the best side marked; it is then heated in the sun or before a fire, to render the metal more pliable, and passed three or four times through the copper-plate press, under full pressure. During this process the plate becomes bent, and care must be taken to roll the plate the last time with the best

\* For other reasons why, see chap. xii.

† Continued from p. 307.

side downwards. The plate is then placed, face upwards, on a table, and the surface is scraped with a razor-blade inserted in a groove in one end of a flat wooden handle. To make this tool, take an ordinary razor, break off the tang, and fix the blade into the groove in the handle; sharpen it by grinding it vertically on an oil-stone; by this means the blade receives two scraping edges, both of which may be used before re-sharpening. This tool is held with both hands, thumbs in front, pointing up. The plate is scraped evenly all over in parallel lines till all the inequalities have been taken off and the surface appears tolerably smooth and bright all over. It is then examined for holes and other serious flaws, which must be hammered out. The position of the hole is marked on the back of the plate by means of a pair of callipers, which may be made of a strip of hoop-iron with a hole at each end, and doubled so that the hole corresponds exactly one over the other. One hole is placed over the flaw, and a mark made on the back of the plate through the other hole. The plate is then laid, face downwards, on a very smooth steel anvil, and the back of the plate is hammered at the spot indicated by the pencil-mark till the face is perfectly smooth and the flaw removed. The hammer-head has a flat face at one end, and is round at the other; the anvil is of steel, about 4 inches in diameter, and is fixed into a strong wooden block. They are to be obtained at the tool shops where engravers' tools are sold.

The scraping is continued till the surface is uniform. The plate is then removed to the graining-trough and rubbed with pumice-stone lengthwise and crosswise in parallel lines till it is perfectly smooth. The pumice should not be too hard, or it will cut deep scratches in the plate, which will be removed with difficulty. The softer it is the better; if it works gritty, which can easily be felt, the plate should be washed and the pumice cleaned with water. When the plate is quite smooth, and all furrows and markings have disappeared, it is smoothed with Water-of-Ayrstone, or, as it is commonly called, snake-stone. This is worked in the same way as the pumice-stone, the plate being occasionally washed with water. When the plate is quite smooth, bright, and free from scratches, it is fit for graining, which is done by sprinkling fine graining-sand upon the plate, with enough water to moisten it, and working it with a zinc muller round and round with a slow, consecutive, rotary motion, in *small circles*, up and down and across the plate in every direction, till the surface appears of an uniform dark grey tint. The sand used for this purpose is the soft, yellow, loamy sand called brassfounders' moulding sand. Silver sand is not suitable for this purpose; it is too hard, and liable to scratch the plate. Before use it should be carefully sifted through brass-wire sieves varying in fineness according to the effect required: for common work sieves containing from 80 to 120 holes to the linear inch may be used; for close, fine work, 140 holes; and for half-tones, where a very fine grain is required, 160 holes. It can be bought ready sifted, of different degrees of fineness, and may be preserved in bottles with a small hole in the cork. The mullers are of different shapes, but it is essential that the sharp edges should be rounded off with a file. There are three kinds of mullers in use, as shown in the annexed diagrams. Fig. 1 is a solid,

conical mass of zinc, with a base of about 4 inches diameter; fig. 2 is a disc of zinc 4 inches diameter, 2 inches thick, fastened to a wooden or iron handle. To cast them, a mould is made in sand, the iron handle is suspended over the centre of the mould with a piece of string, the melted zinc is then poured in, and, when cold, is faced and turned in a lathe.

No. 3 is a simple and cheap form; it consists of a large bung, on the base of which a square piece of sheet zinc is laid, the sides turned over and pressed towards the circumference of the bung. The corners are cut away and turned up. Owing to slight inequalities there frequently remain strips or patches on the plate which are not granulated; these should be worked with small mullers, as fig. 4. While graining the greatest care must be taken to avoid getting any grit on the plate. The mullers should be carefully washed before use, and while in use should not be put down on their faces or where any grit or dirt may attach itself to them. When the sand first applied has become too fine, and is of a dark slate colour, it should be washed off, and fresh sand applied. In the course of from half an hour to two hours the plate should appear of an uniform grey colour, finely granulated, and may be considered ready for use; it is well washed with water and a soft flannel kept for the purpose, till all traces of the sand are removed, and then turned up on its edge to drain. Hot water is then poured over the back of the plate, so that the face may dry as quickly and evenly as possible. The plate is then carefully stowed away in a dry place till required for use. The greatest care must be taken not to touch grained plates with the fingers, and to keep them from anything greasy. A plate is in its best condition when first prepared; by keeping it gradually deteriorates, and should not be used after it has been kept a fortnight.

#### TREATMENT OF ZINC PLATES WHICH HAVE RECEIVED TRANSFERS.

The zinc plates can be regained, and used over and over again, without any sensible diminution of thickness. The regaining is a very simple operation, and not so troublesome as the first preparation of the plates. If the plate to be regained is "gummed up"—that is, covered with gum to preserve it—wash off the gum, remove the ink with turpentine, wash clean with water, and apply the

#### Alkaline Solution.

Potash	...	...	...	...	4 pounds
Quicklime	...	...	...	...	4 "
Water	...	...	...	...	6 gallons

A strong solution of common potash will answer. The object of this is to destroy the greasiness in the ink. Wash well with water, and with a flannel rubber apply an acid solution:—

Water	...	...	...	...	2 ounces
Sulphuric acid	...	...	...	...	2 drachms
Muriatic acid	...	...	...	...	2 "

Let this remain for a few minutes, and then wash well with water. This should be done in the open air, as the fumes arising are very unpleasant. The plate is then treated and grained as before described.

(To be continued.)

#### MR. PIERCY'S PATENT METHOD OF ARTISTIC PRINTING.

WE recently noticed some very fine examples of artistic printing by Mr. Frederic Piercy, a gentleman well known in art circles as a skilful painter. We subjoin the specification of the method whereby the results are obtained. The application of lithography to photographs, as our readers know, is not new; the novelty here consists in the mode of regulating the tint, and giving it a certain amount of pictorial gradation, by removing portions from the stone or plate before printing; in the mode of obtaining texture and modelling by manipulating on the applied tint with bread or india-rubber; and of obtaining sharp lights by burnishing at the back of the tracing or print placed on the inked stone previous to printing the tint on the photograph to be treated.

The effect obtained by working on and graduating the delicate grey ink which is applied to the photograph gene-

rally is singularly pleasing, producing a quality of texture we have not seen produced by other means, and in large pictures is exceedingly valuable. The specification is as follows:—

My invention relates to a process whereby new effects in portrait, landscape, and other subjects are attained which may be used in connection with and as an aid to photography, lithography, plate and wood block printing, and in some cases alone, or to give permanence to photographs.

The process by which these effects are obtained is as follows:—An outline of the photograph, drawing, or print to be treated is traced on the back thereof, or on a sheet of paper. The picture and paper are placed together on a lithographic stone, wood block, copper, or other plate having on its surface or in the mezzotint, aquatint, machine tint, or other ground, the colour the whole or portion of which it is desired to transfer to the picture; said picture is placed with its face downwards, having the sheet of paper intervening between it and the stone or plate, then, by rubbing, pressure, and burnishing those parts in the tracing corresponding to the parts required to be left light in the picture, the colour on the stone, block, or plate will be transferred to the sheet of paper intervening between the picture and the stone or plate wherever the pressure or burnishing is applied. If the traced outline has been made on the sheet of intervening paper the picture must be removed, and registering points used or held so that it can be returned to the exact position it first occupied, the rubbing and burnishing process being applied to the tracing as before, but to the sheet of paper instead of to the back of the picture: for example, if the general colour of a face or sky is required lighter than the rest of the picture, the surface occupied by the tracing of the face or sky is rubbed or stumped so that a portion of the colour on the stone or plate corresponding to the tracing may be transferred to the sheet of paper. The high and secondary lights are obtained by burnishing those parts of the tracing which represent the proper position of the required lights, removing the colour from the stone, plate, or block in those parts. By a careful use of the burnisher or pencil used, lights may be obtained of varied character, either graduated or sudden and sharp. Sheets of paper, cloth, or other fabric to which the colour is transferred, may be used of different textures for different parts of the same picture according to the effects required. In certain cases I prefer to protect the photograph or other subject by means of gum or chalk to serve as the intervening material on those parts which I wish to be light, the protecting substance or substances being removed by washing or friction after the operation of printing. When as much of the colour is removed from the stone as desired, the sheet of paper is taken away, leaving the stone exposed, when the colour may be still further removed by means of bread or otherwise. The picture is then laid, face downwards, in its proper position on the stone, and passed through the press; when the picture is removed from the press, and while the ink is still wet and manageable, the effect is heightened and refined by means of bread, or an effect may be wholly obtained by the application of bread to wet or partially dry printing ink. When the photograph is printed on albuminized paper it will be found useful to use a knife or mezzotint scraper to obtain sharp and other lights, and this without disturbing the surface of the paper or albumen. This process may be repeated as often as required, various colours and shades of colour being added at will; as, for instance, the colour of the hair or face may be printed on the picture, for if the stone or plate be charged with a flesh tint, and the colour transferred to the intervening paper or cloth in those parts where it is not required, the picture will consequently, when printed, be left uncoloured in those parts. In colouring photographs I may also use a tint engraved on a plate or block, the parts to be coloured being indicated by tracing on the plate, when the appropriate colour is filled into those parts of the engraved tint, which may then be printed on the photograph with an engraved surface; the effect on photographs may be further modified by "wiping close" those parts required light in the photograph. In order to colour numerous copies of the same picture without the repeated use of the sheet of transferring paper, the colour may be permanently removed by scraping out or biting away by means of acid the light parts on the stone, or by burnishing and scraping when a plate is employed, which effects are then to be completed by the application of bread to the wet or partially wet ink.

My invention further consists in the use of a glass plate, the

surface of which is finely ground to receive a tint similar to that obtained in lithographic printing; or the glass plate may be machine-ruled to receive a tint, when, by placing the picture behind the glass, the effects before described may be obtained with increased facility, and printed on the picture from the glass plate.

My invention also consists in transmitting rays through a lens from the object to be coloured on to a lithographic or engraved tint, or on to the paper covering that tint, by which I am enabled to place in proper position on the stone or plate the colours which are to be printed on the picture, or to remove colour in those parts required light when printed. In the case of photographs the rays would be transmitted through the lens from the negative. By the application of oil colour to photographic and other pictures their permanence is increased, the coating of oil colour forming a protection against atmospheric and other injurious influences. When applied to photographs the soda used in fixing the prints is neutralized and fixed by the coating of oil colour. A ground may also be obtained with oil colour upon which to work with pencil, chalk, and crayons, or to paint with oil or water colours, and this ground I print on the paper either before or after printing the photograph. If the ground is printed before the photograph the high lights and gradations must be obtained as before described, and the tint used must be one which will not be injuriously affected by the chemicals employed in photographic printing; as, for instance, the combination of black, indian red, and ultramarine, will produce such a tint. Where a carbon printed photograph is to be transferred to a ground work, and effect produced by my process, this, of course, is not essential. Pencil and other sketches may also be let by my process, and have lights and skies readily introduced. Pictures on porcelain may either be wholly or partially printed by my process, and then burnt in as usual. It will also be found useful to charge albuminized or other paper with printing ink, and to obtain effects by the means already described, and then, by the use of a press, or by burnishing, to transfer the colour to the photograph or other work of art, by which means various colours may be applied, and a very delicate effect produced. In photography a print the reverse of the one to be treated may be used, when all the parts may be tinted in this way at leisure and with the greatest precision, while the application of bread to the wet ink will be found to give effects of the greatest value.

Having described the nature of my invention, and the manner of performing the same, I declare that what I claim as my invention to be protected by the herein-before in part recited letters patent is,—

First. Tinting or colouring photographs, engravings, water colour and other drawings, or porcelain, by the several means and processes herein described.

Secondly. I claim the use in the above processes of an intervening material or materials upon which is to be transferred, by means of pressure, rubbing, and burnishing, portions of colour not required in the finished work of art, as and for the purposes herein-before described.

Thirdly. I also claim obtaining an entirely novel effect in the process of tinting or colouring of my invention by the employment of bread in the manner and for the purpose described.

#### M. CARRIER'S SENSITIVE PAPER.

The Commission nominated by the Photographie Society of Marseilles, and consisting of MM. Gobert, Jeanrenaud, Paul Gaillard, and Civiale, have just made their report upon the keeping qualities, &c., of a new sensitive paper prepared by M. Carrier. The mode of preparing it is not stated, but it is believed to be a modification of the collodio-chloride process. The report is signed by M. Gobert on behalf of his *confrères*, and is as follows:—

"At a meeting of the Society held on the 7th February last, M. Carrier submitted to the inspection of the members an unalterable sensitive paper, suitable for the production of positive prints, of which he presented to the Society several specimens. We have now to report the result of experiments we have made with this paper.

"The prepared paper has been preserved in a sealed packet, in the chest of the Society, from the 11th February until the 27th April (75 days), care being taken to keep

it protected from the light. On opening the packet the paper was found perfectly intact, white, and presenting not the least sign of alteration, as may be seen from the two specimens annexed to this report.

"M. Carrier went through the process of printing in our presence, in the studio of M. Davanne, the negatives selected being of different descriptions, so as to offer a variety of subjects of different intensity. The printing was most successful. Without entering into any details with regard to toning and fixing, we may say that the manipulations with this paper required about the same time as with ordinary albuminized paper. It is necessary, however, to mention that M. Carrier employs a toning bath specially prepared for the purpose, and composed of—

Water...	1,000 centim. cubes
Sulphocyanide of ammonium	100 grammes
Chloride of gold and potassium	1 gramme

The toning is effected very promptly, the paper assuming an agreeable tint and rich tone. The prints are subsequently washed with some rapidity, and then plunged into a solution of hyposulphite of soda at a temperature of 20 degrees Cent., to complete the fixing of the prints, which has partially taken place in the toning bath. Finally, the prints are well washed in water as in the usual manner.

"We have the honour to submit to your inspection the pictures obtained in our experiments, and we hope that the Society will be of the same opinion as ourselves, that the advantages claimed by M. Carrier for his paper have been fully established by our experiments."

#### THE COFFEE PROCESS.

BY M. A. DE CONSTANT.\*

PROFESSOR TOWLER has recently published in one of the American journals an article upon the different dry plate processes, and in it he makes some mention of the coffee process, a method of which I have had some considerable experience. In making a statement of the comparative value of the different processes, that gentleman states that, although at first the coffee dry plates are found to give superior results to those prepared by other methods, still, after the first day of their preparation, their sensitiveness becomes impaired, and the longer they are kept the greater is the exposure required; according to Professor Towler they lose their sensitiveness altogether in a few days.

As this statement stands in direct contradiction to the representations made by the discoverer of the process and his many disciples, and is likewise quite the reverse of what I have written, after experiments which have certainly been more complete than those instituted by Professor Towler, it is impossible for me to allow that gentleman's article to go forth unchallenged. I still stand by every word that I have said in regard to the great keeping qualities possessed by the coffee plates; at the same time I admit that the secret of their preservation is in a great measure due to the care with which the plates are dried. Rapid dessication by artificial heat and preservation in a dry locality are the conditions laid down by M. Baratti. This mode of proceeding is to employ a metal case with a false bottom in which water is placed and brought up to the boiling point by means of a spirit flame, and the plates are laid upon this water bath until they become so hot that it is impossible to touch them. Plates prepared in this manner will, after twelve months, or even two years, yield excellent negatives, and need not be exposed longer than four times the period that would be required if the plates had been freshly prepared. I have used coffee plates six months old which were over-exposed after a period of four minutes; during the first month of their preparation, when using a good apparatus, I never exceed an exposure of two minutes.

If Professor Towler had carefully studied the instructions given by M. Baratti for the preparation and preservation of

coffee plates he would not have come to the conclusion that their valuable properties are due merely to the moisture they contain, for it is precisely the damp that causes them the greatest injury. The plates owe their superior qualities to the special properties of the coffee, and in no way to their hygroscopic condition, as Professor Towler believes. This, in fact, explains the ill-success attending that gentleman's experiments, for coffee plates which have been imperfectly dried, or preserved in a damp locality, would, under no conditions, be equal to plates prepared and stored in a proper manner. I lay particular stress on the proper storage of the plates, as, in like manner with other dry plates, they become covered with a light deposit of moisture whenever they are exposed to a damp atmosphere or any change of temperature: if this moisture is not dissipated before the plate is put into the dark frame, it is almost certain that the film will be found to have become insensitive and useless. In winter there is a difference of three or four degrees between the locality in which I preserve my dry plates and the inside of my camera, and the manner in which the deposit of moisture takes place upon the plate is perfectly visible; it is only by the application of warmth that the plate again assumes its glossy appearance, and recovers its precious qualities.

It has been my intention for some time past to call the attention of photographers to this point, for it is a matter of some difficulty to maintain the dark-room, the plate-box, and the camera at an equal temperature. M. Baratti preserves his coffee plates in a box with fused chloride of calcium, but the great liability of this substance to become changed by moisture is a great drawback to its use.

If the bromide of silver collodion process of M. Carey Lea fulfils all that it promises, many of our present manipulations will be simplified, and failures from the effects of moisture will be avoided; for the dry plates of Mr. Lea, prepared without any preservative film, are so hard that it is almost impossible to moisten them, and a damp atmosphere would therefore probably have no effect upon them. During the last month I have been experimenting with this process, and the results obtained lead me to hope for excellent things from it. By the aid of certain preparations which I have been using, I have been enabled to work faster with plates two days old than with moist plates, and the pictures thus produced left nothing to be desired, either as regards beauty, softness, or detail. At the same time the uniform preparation of the bromide of silver collodion appears to be not unattended by difficulty. Mr. Lea at first advised that it should be allowed to stand for the period of a week, but now he prefers to leave it for a month.

#### ON THE REPRODUCTION OF ENGRAVINGS AND LINE DRAWINGS.\*

BY F. FINK.

THE publication of the following remarks on the copying of engravings by means of photography has been decided upon by myself, less in the hope of making known new data in connection with such a proceeding, as for the purpose of pointing out certain reliable facts which may be serviceable to photographers engaged upon this description of work. Those who have experimented at all in this direction know that a collodion which gives excellent results in portraiture will yield but a poor, weak negative when used for the reproduction of an engraving or a line drawing. The reason of this is very simple: the iodizing of the collodion has been insufficient to produce the necessary vigour required in a picture made up solely of fine lines. To produce a good negative of this description it is necessary that a somewhat strongly iodized material be used, as, for instance, a collodion containing one-third more of the iodizer than would be required for portraiture work; such a col-

\* Photographisches Archiv.

\* Read before the Photographic Society of Vienna.

lodon that is condemned by the portrait photographer because it is over iodized and gives hard pictures is most suited to the purpose.

A negative of an engraving taken with collodion of this description, if sensitized in a slightly acid bath and exposed for a suitable period, should exhibit perfectly clear, transparent lines on an opaque, inky black ground. The exposure should be, if anything, rather too short than too long, for a full exposure, so necessary to the production of an artistic portrait, is fatal to the existence of fine lines in a negative of this kind. Over intensification of the negative must likewise be avoided, as the more delicate lines are easily destroyed by carrying this part of the process too far.

The intensifying solution I would recommend is a developer prepared according to either of the following formulæ:—

No. 1.—Water ... ..	20 ounces
Sulphate of iron ... ..	1 ounce
Nitrate of potash ... ..	$\frac{1}{2}$ "
Alcohol ... ..	2 ounces
Sulphuric acid ... ..	$\frac{1}{4}$ ounce.
No. 2.—Water ... ..	10 lbs.
Citric acid ... ..	$3\frac{1}{4}$ ounces
Sulphate of iron ... ..	2 "
Alcohol ... ..	6 "

After the picture has been completely developed, the image is intensified by adding a few drops of a 20 per cent. solution of nitrate of silver, the treatment being carried on as long as the fine lines remain visible. After fixing, the plate should be well washed, and then again intensified with a concentrated solution of bichloride of mercury, the treatment with the latter material being repeated as often as may be thought necessary—say from one to four times. With No. 2 solution the subsequent intensifying with bichloride of mercury may sometimes be dispensed with.

The picture to be copied should, if possible, be lighted from the front, direct sun rays falling at an angle of from 50 to 80 degrees, yielding the best illumination; if the sun is higher and the rays fall at an angle of 10 to 30 degrees, shadows are cast by the texture of the paper, and the negative produced presents a rough, mealy appearance, which will be found to be in the highest degree objectionable when an enlargement of the original is prepared.

## DETECTION OF HYPOSULPHITE.

BY M. CAREY LEA.\*

THE subject of the examination of liquids for traces of hyposulphite of soda has assumed so much interest of late years, that, although the subject has been already well handled, a few more remarks may not be unacceptable.

Having recently had occasion to make some delicate testing in this direction, I tried all the methods usually recommended, submitting each to a rigorous examination upon solutions of hyposulphite made expressly, and of a known strength, and came to the following conclusions:—

*Nitrate of Silver* has been unduly condemned, for want of using it in the right way. I find it a very useful test when it is boiled with the suspected solution. The liquid to be tested is placed in a test-tube, a small crystal of nitrate of silver is dropped into it, and the solution is boiled. If any hyposulphite be present, the liquid presently turns brown.

It is to be observed that certain organic substances have the same tendency to turn brown a solution of nitrate of silver when boiled with it. To discriminate, drop in a single drop of nitric acid, and boil again. The liquid presently clears up and becomes colourless. Not that the sulphate of silver has dissolved, but has separated. It will be found at the bottom of the test-tube in the form of

minute black shining scales. By this test I have been able to detect the presence of one hundred-thousandth of hyposulphite; beyond this the indications cannot be relied on. This test, though delicate, is therefore surpassed by the following (it should be remarked, that when the hyposulphite is present in so small a proportion as one hundred-thousandth, the black scales just mentioned are not visible).

*Iodide of Starch.*—This reaction is more delicate than the preceding. The best course is that recommended by Dr. Vogel: to use two tubes, and place a piece of white paper behind them, the better to judge of the colour. The following is the method which I employ for preparing and using the iodide of starch:—Place about a quarter of an ounce of water in a test-tube, take up a bit of fine starch, grind it between the finger and thumb, letting the powder fall into the water (half a grain is sufficient); boil till the liquid is clear, and let fall in a single drop of tincture of iodine, agitate well, and let cool. Of this dark blue solution, allow a drop or two to fall into each of two test-tubes, an exactly equal quantity in each, then fill the test-tubes half full, one with distilled water, the other with the liquid to be tested. The colour of the blue should be just perceptible in the tube with common water; if, then, the blue disappears in the other, it is an indication of the presence of hyposulphite. This test is more delicate than the preceding. I obtain indications with one-millionth of hyposulphite, in this result agreeing with Dr. Vogel.

It is to be observed that the great difficulty in removing hyposulphite lies in the fact that photographic paper is sized, and, consequently, very difficult of penetration by fluids. I called attention, some years ago, to the fact that as most photographic paper contains a starch sizing, this affords a ready basis for testing. It is only necessary to draw a brush containing a very weak solution of iodine over a white portion of the paper. If the print is clear of hyposulphite, a blue mark will be produced; if traces of hypo are present, no dark result will follow. It is to be remembered that in using this method it is necessary to have ascertained beforehand, once for all, that the photographic paper in use contains starch, which, of course, is done by applying a little weak iodine solution to the paper before sensitizing. This should be done on the back, not the albuminized side. A blue mark indicates starch, and such paper is then known to be suitable for the application of this test. So far as I remember, this suggestion of mine was the first application of iodide of starch for detecting hyposulphite in photography, though such application was too obvious to be overlooked. Of course, the solution of iodine must be very weak, otherwise one portion of the iodine may destroy the trace of hyposulphite, and the remainder may bring out the blue reaction. This should never be forgotten in employing this test in all its shapes.

This mode of testing is decidedly surpassed by the following:—

*Zinc and Sulphuric Acid.*—It has been ingeniously proposed to convert the sulphur in the hyposulphite into sulphuric acid, and detect the latter by lead.

Much as has been said of this test, it has scarcely been done justice to. It has every advantage: ease, certainty, and wonderful delicacy. It has the great advantage that, if pure materials be used, there is no possible ambiguity in the result. Other substances, in the first method spoken of, may be browned by silver nitrate; and in the second, other reducing agents may decolorize iodide of starch. But, in the method here under consideration, nothing but a sulphur compound can produce the characteristic reaction with lead.

The liquid to be tested is to be placed in a narrow, deep beaker; a fragment broken off from a stick of pure distilled zinc, which, with a few drops of pure sulphuric acid, is to be dropped into the beaker. It is immediately covered with a piece of Swedish filtering-paper, twisted under the lip of the beaker. The wet stopper of an acetate of lead

\* Philadelphia Photographer.

solution bottle is then to be touched in several places upon the paper cover. This last, being twisted under the lip of the beaker as just directed, confines the gases generated, to some extent, and gives them opportunity to act upon the solution with which the paper is imbued. The whole is then set in a warm place. If much hyposulphite be present the lead solution turns black; with less the effect diminishes. With such quantities a brown stain is produced.

By operating in the above manner, I have been able to obtain distinct indications from one two-millionth of hyposulphite, a faint but distinct stain appearing. I enclose the paper for inspection; on the underside a light brown colouration will be observed.

That this stain came from the infinitesimal quantity of hypo just spoken of does not admit of doubt, for in another beaker inside it were placed the same materials, but with water only—the same water that had been used for the hypo solution. The two, therefore, differed only in the presence of the one two-millionth of hypo: in the one the stain appeared, whilst the other remained white.

Whilst this is the best of all tests for hyposulphite of soda in solution, it must be remembered that any saline substance is but gradually removed from the interior of sized paper, so that, consequently, testing wash-water may lead to serious mistakes, unless the prints have remained in it sufficiently long for it to adequately represent their condition—some hours, I should say. I therefore think that, for practical purposes, in ordinary photographic operations, I should prefer the use of solution of iodine applied with a brush in the manner I indicated in 1864. The precautions which I then mentioned were, not to use the iodine solution too strong, but to prepare it by adding a few drops of tincture of iodine to several ounces of water; to assure one's self that the paper be one sized, in whole or in part, with starch; by observing that the iodine solution will strike a blue colour with it before it has sensitized; and finally, if the iodine solution gave the blue colour on the printing, to consider it as a proof that, with a little more washing, the print would be safe.

But, if the highest accuracy is desired, crush up one of the prints into a beaker with water enough to cover it, place a capsule or watch-glass over, and set it aside till next day. Then, touching the paper only with a spatula or glass-rod, squeeze out the water, and subject it to trial with zinc and sulphuric acid.

I am in the habit of using paper exclusively for drying glass-plates after cleaning them; and I believe it to be a needful precaution to ascertain that no trace of either hyposulphite or of chlorine is present. I find the best plan to be, to take out a trial sheet or two and test them. I test for hyposulphite with the zinc used; and the absence of chlorine and of hypochlorites is ascertained by observing whether a strip of litmus paper left in the beaker with the paper previos to applying the zinc test is bleached or not. In this way litmus paper is very useful, affording a treble indication, being turned red by acids, blue by alkalis, and bleached by chlorine and hypochlorites. (A strip of litmus paper should always be blue at one end and red at the other, to afford the double indication.) Ordinary cheap blotting-paper is apt to be faintly alkaline, perhaps from the presence of lime added with the hypochlorite of lime used for bleaching, which is always largely mixed with it, and of which some may be left behind when the hypochlorite is removed. Even if the lime has become carbonated by exposure to the atmosphere, this would not prevent its acting upon test-paper, as carbonate of lime has a slightly alkaline reaction upon test carbonates. Lime, of course, could not act very seriously; indeed, it is largely employed in the shape of whiting for cleaning plates. The object of using paper instead of a cloth is that it gives a brighter surface and is less apt to leave a pluff behind it. If a glass, just before collodionizing, be breathed upon and then be rubbed dry with clean bibulous

paper, it has a better chance than if brushed over with camel's-hair brush, for the latter, in certain states of the atmosphere, may leave marks behind it; but paper to be used for photographic glass must not be left about exposed to fumes of a laboratory.

I inclose a piece of Swedish paper, with a brownish stain obtained from a two-millionth solution of hyposulphite.

## Recent Patents.

### PORTABLE PHOTOGRAPHIC LABORATORY.

BY HIPPOLYTE ROCHAT.

The following plan for a portable laboratory was only provisionally specified:—

This apparatus is composed of a rectangular wooden case hermetically joined, the dimensions of which are regulated by those of the basins and frame intended for the operations. The normal or ordinary plate requires interiorly from about 20 to 22 inches in length by about 14 inches in breadth, and an equal height. The top or lid opens from the front backwards to a width of about 10 inches, and from the back forwards in a breadth of a little over 2 inches. The middle part remains fixed. These two openings are provided with yellow glasses lighting the interior. A moveable covering intended to prevent the reflection of the light on the surface of the glasses when it is raised, and to preserve these from contact with exterior objects when it is lowered, is joined by means of hinges to the fixed part of the lid; the sides or overlaps of this shade slide on the exterior of the sides of the case, covering the openings of these sides, and are fixed by the operator at the desired height by means of an adjusting screw. The two sides and the front of the apparatus are pierced about  $1\frac{1}{2}$  to  $1\frac{3}{4}$  inches above their centres with a round opening of from 5 to 6 inches in diameter, to which is fitted a sleeve of a thick black fabric about 8 inches long, and terminating in an elastic wristband. A groove intended to receive the frame, hollow or projecting, according to the construction of this latter, is placed at the bottom of the case at the end, and at the height of the basins; it serves to give to this frame the necessary slope or inclination for preventing the fall of the glass plates into the interior of the apparatus. A small spiral spring presses against the frame when the opening by which it has been introduced is closed, it keeps it in its position, and adds to the facility of seizing the glass plate, as both hands may be employed. Lastly, four sliding feet placed at the angles permit the raising of the laboratory and placing it horizontally on any ground. The dimensions of this apparatus, according to the sizes to be obtained, may be determined in the following manner:—

**Length.**—The breadth of the two basins suffices, as the blotting-paper may be placed even more commodiously on the side of the covering of the basins which presents itself when the basin with the silver bath is uncovered.

**Breadth.**—The length of the basins, plus the distance from the groove intended to receive the frame to the back of the case, calculated according to the inclination which it is desired to give to this frame.

**Height.**—That of the frame starting from this groove.

**Method of Operating.**—The photographer changes nothing in his ordinary manipulations. Arrived on the spot for his operations, the case is set horizontally, two basins of equal dimensions are placed in the interior one beside the other, the sensitizing bath is poured into the one and the developing bath into the other, at the choice of the operator. A small flap fixed to this latter by hinges permits their being alternately covered to prevent splashes from one bath into the other. The glass plate, collodionized in the full light, is placed in the frame; this latter is introduced into the dark chamber by the back opening, which is reclosed; the hands, passed into the sleeves, take the glass plate in this frame (which must not open from the bottom upward); it is immersed in the silver bath, drained on the blotting-paper, replaced in the frame, brought back in the apparatus after the pose, and the development made in the second basin. It is afterwards withdrawn by the large opening in front, washed, fixed, and even strengthened, if necessary, in the usual manner. It is very useful, in order to prevent the chafing of the edges of photographs enclosed damp or unvarnished in the special boxes, that the grooves of these latter

should not be square and about the thickness of the glass plate; but triangular, so that the edges of the plate have no point of contact with them but by their extreme angles. The operations ended, the object glass, the dark chamber, the basins, flasks, and so on, are placed in the apparatus, which thus serves as a packing case, and is no encumbrance.

### EXPERIMENTS WITH FILTERING PAPERS.

The *American Journal of Pharmacy* contains an interesting account of a series of experiments by Mr. C. E. Avery, undertaken to test the relative value of various forms of paper-filters. Some condensed extracts from the article may be useful to many of our readers.

"The filter most commonly employed in analytical laboratories is a circular piece of paper folded twice upon itself into the form of a quadrant, and supported on a glass funnel with straight sides. This filter, though commendable in so far as it is capable of supporting the weight of a considerable column of liquid without breaking, is objectionable, inasmuch as liquids cannot pass through it so rapidly as is desirable. Since at almost every point the paper is in close contact with the glass, but little of the liquid can flow off between the filter and the sides of the funnel.

"Several schemes have at various times been proposed for opening water-ways between the glass and the paper; the interposition of straws, glass rods, and splinters of wood between filter and funnel, as well as fluted funnels and plated filters, are all devices looking to this end.

"The advantages of the plated filter are so great that some chemists prefer to use it, even in quantitative analysis, instead of the common form, in spite of its greater liability to break, and the difficulty of washing the precipitate.

"Another excellent method of increasing the speed of filtration, suggested by the German chemist, Fleitmann, consists in placing one plain filter within another of coarser fibre; for instance, a fine, plain filter of Swedish paper may be placed within another plain filter of coarse German paper, supported, as usual, on a funnel.

"In experimenting upon these various forms of filters, it occurred to me to fold the plain qualitative filter in two operations instead of one. In place of folding the filter doubled upon itself down the middle in the usual way, I proposed to turn down on each side of the paper a fold equal to one-quarter of the semi-circle, and then to fold the sectors of 45° arc thus formed back upon themselves.

"The filter is then opened without disturbing the folded portions, and placed upon the funnel. In this form the triple side of the plain filter is broken up, and the folded portions keep open passages, instead of hindering filtration.

This filter, as tried against the plain form, gave, 1st, 133 : 100; 2nd, 111 + : 100; 3rd, 205 + : 100.

"Two plain filters ran equally in several trials; each was changed into the other's funnel, and No. 1 ran 33 per cent. less than No. 2. No. 1 was dried and folded into my form; remaining in the same funnel, it ran 32 per cent. faster than the other. Both filters were then opened, and showed no tear or weakness when held against the light.

"As these filters gave different results in different funnels, I thought I would ascertain the cause. The water seemed to be retarded in its passage by the attraction of the glass; therefore, those funnels having the greater portion of the paper free from the glass would be the best; that is, a broad-throated funnel, other things being equal, will filter faster than a narrow-throated funnel.

"To test this point I selected two large funnels; No. 1 had three times as broad a throat as No. 2. With the first filters they ran:—

117 : 100    123 : 100    133 : 100    118 : 100

"The reason for this low difference was found in a thin spot near the point of No. 2.

"I understood the idea of the Fleitmann filter to be this: that, likening a plain filter to a peat bed resting upon an impermeable sub-soil, it might be compared to a porous

substratum interpolated between the swamp and the clay bottom.

"To test this idea a Fleitmann filter was made and wetted, carefully patting down and smoothing out any irregularities. It was tried against a plain filter which was placed in a funnel with but two-thirds as wide a throat as that of the Fleitmann. It ran 114 : 100; that is, the passages kept open by the elasticity of the paper, the creases and abutting edges liken this filter to tile drainage.

"To increase the size and number of passages I tried putting the inner filter into a plated filter of coarse paper. Changing the filters after each trial, I found this form gave the following results as compared with the plain filter, calling the latter one hundred:—

1st trial	184 : 100	4th trial	166 : 100
2nd "	201 : 100	5th "	170 : 100
3rd "	250 : 100		

"I afterwards found a thin spot in the plain filter of the fourth trial.

"I thought, since the adhesion of the water to the glass is the cause of slow filtration, I might increase the flow by coating the funnels on the inside with paraffin, to which water does not adhere. No. 1 being coated, No. 2 left clean, I got—

1st trial	200 : 100	3rd trial	100 : 100
2nd "	184 : 100	4th "	137 : 100

"The filters in the third and fourth trials were the same, but the funnels were changed about."

### Correspondence.

#### CARBONATE OF LIME IN TONING.

SIR,—Mr. Bovey, in the last of his interesting papers upon Printing and Toning, has kindly promised to answer the questions of his readers.

As far as I can see, his objection to the use of carbonate or acetate of soda in the toning bath would not apply to the pure carbonate of lime, which, while it would neutralize any excess of hydrochloric or nitric acid which might be present in the chloride of gold, being itself insoluble in water except with the assistance of carbonic acid, would probably be unable to act upon the neutral chloride of gold.

I have been in the habit of using precipitated chalk and chloride of lime in preparing a toning bath, and have been very successful with it, and have seen first-rate tones produced by it in the hands of my friends. Probably Mr. Bovey would object to the use of chloride of lime, on account of the free chlorine; but as the prints are immersed in the toning bath without any preliminary washing, it is neutralized at once by the free nitrate of silver in them.

If Mr. Bovey will give his opinion upon these points, I shall be much obliged.—Your obedient servant, AMATEUR.  
Brighton, June 30, 1868.

### Talk in the Studio.

ROYAL PHOTOGRAPHERS.—The *Censor* is somewhat hard upon photographers, or else upon their royal sitters. In a column of things "Wanted," and "Not Wanted," it has the following:—"Not Wanted—any more of those dull, ordinary, common-looking photographs of the royal family. N.B.—Photographers have done more to destroy the ideal of royalty than all the republicans in the world; the Briton, as he passes a shop, or stumbles over H. M. Q. V. in an album, involuntarily quoting Pater Pindar—What's that, the Queen? what, that thing there?"

MEMORIAL CARD MOUNTS.—Mr. S. B. Beal has submitted to our notice a very neat form of card mount intended for the portraits of deceased friends. A good design in black is printed on a delicate grey or lavender tint. Interwoven in the design are various scrolls to be filled in with any inscriptions chosen, the centre being an oval for reception of the portrait.

**INTENSE NEGATIVES.**—A correspondent of *Humphrey's Journal* says:—"No doubt some of your readers, as well as myself, are sometimes annoyed with negatives getting too intense after a number of prints have been made from them. Several remedies have been suggested. Some recommended floating the paper (after sensitizing) on pure water, in order to have less free nitrate on the surface; but I think it is always best to have the negative of the proper printing qualities. My mode is as follows: Take equal parts of liquid ammonia and alcohol; then wet the varnished surface of the negative with water; then flow the solution over one plate, and allow it to remain on only long enough to soften the varnish, not to remove it; rinse well with water. If the negative has been strengthened with mercury, flow first with cyanide solution; should you still wish more reduction, rinse well, and flow with bichloride of mercury, and then again with the cyanide solution. This can be repeated as often as necessary, and the strongest negative can be so modified as to give beautiful prints. The above operation will only reduce the intense parts of the negative, leaving all the half tones undisturbed; and it does not take as long as it does to write the above. If there are any who doubt it, let them make a trial with some old discarded negative that has become too intense; and if they like it as well as I do, they will adopt it until some brother photographer introduces something better."

**THE SPECTRUM RECONSTRUCTED.**—Prof. Listing, of Göttingen, considers the solar spectrum as made up of nine colours, in the following order: brown, red, orange, yellow, green, blue, indigo, violet, and lavender. He has also calculated the number of vibrations of each, and has found that their numbers constitute an arithmetical progression; the interval between one colour and the next always being 48,524 billions of vibrations per second. The number of vibrations constituting the two extreme colours are represented by 364 trillions for the brown, and 801 trillions for the lavender.—*Scientific American*.

**TO MAKE PLASTER OF PARIS HARDER.**—With one exception, all admixtures impair the hardness of the plaster. The exception is iron filings. When these are mixed with plaster they rapidly oxidize, and the coherent mass of oxide of iron formed adds its own strength to that of the plaster, making a very firm mass, which has also the advantage of strongly uniting itself to surfaces of iron. I have not observed what proportion of the filings is best, but suppose they should form about one-fifth the whole weight.—*Ibid*.

## To Correspondents.

**M. D. L.**—It is probable that your collodion will be improved by the addition of more pyroxyline. We find the sample you have forwarded gives a thin limpid collodion with 6 grains to the ounce of solvents; if, therefore, you have used only 4 grains the collodion will be too thin. You may also, without impropriety, add 1 grain more per ounce of iodide and  $\frac{1}{2}$  grain of bromide. The formula you quote is doubtless a very old one. The newness of the collodion has also, you must remember, tendency generally to cause it to yield thin images. 2. The addition of a little gelatine or sugar to the developer will doubtless aid you in securing more intensity.

**J. F. B.**—In attempting an operation like making your own chloride of gold you should, unless tolerably well versed in chemistry, take some carefully stated formula and follow it accurately. After dissolving your gold in aqua regia you should, if you wished to employ the chloride of gold formed with certain specific formulae, have got rid of the acids by evaporation. Neutralizing the acids by adding chalk does not remove them. You form nitrate of lime, chloride of calcium, and when phosphate of soda is added to the solution phosphate of lime will be formed, which, being insoluble, is precipitated as you describe. Gold is not soluble in sulphuric acid, but after forming the precipitate from such a solution as you describe nitric acid would be present, and gold in a fine state of subdivision is, in some degree, soluble in a mixture of sulphuric and nitric acids. 2. Dilute sulphuric acid will dissolve the zinc and leave the silver intact.

**C. E. F.**—We find that toning solutions prepared by different formulae give distinctly different results; some tending to black tones, others to warm tones; some bleaching a little and increasing brilliancy, and others toning without altering the character and depth of the print. We cannot very well tell you which we recommend, therefore, without knowing the kind of result you require. We sometimes use the acetate, sometimes the lime formula; but that we most commonly employ—because it is simple, effective, and readily prepared—consists in the addition of a few grains of chalk to the standard solution of chloride of gold (1 grain of the salt in

1 drachm of alcohol), and pouring sufficient hot water upon it to make the desired strength, generally 5 or 6 ounces to the grain. By the time this solution is cold it is fit for use, and gives good results. 2. The object of adding spirits of wine to the paper sensitizing bath is to reduce its tendency to dissolve the albumen and get discoloured. This it does very efficiently. The chief object of adding sugar to the bath is to enable the paper to be kept longer without issuing in discoloured prints. Very little will serve; about a drachm of sugar to a quart of solution. Read Mr. Bovey's article in our last YEAR-BOOK, and his article on toning in last two numbers of the NEWS. Also see our YEAR-BOOK for various toning formulae.

**JAMES STODDARD.**—The conditions of success in producing good copies of a pen-and-ink drawing are somewhat different to those required in portraiture. In the latter you want softness and gradation, with no approach to pure white or deep black except in minute points; in the copy of the pen-and-ink drawing, like that enclosed, you require a large space of pure white, and such blacks as there are very intense. Presuming that the drawing is on pure white paper, you need have no difficulty. Use an old ripe collodion of good body, and develop with a gelatine-iron developer, and take care not to dash the developer over the plate, so as to drive all the free silver off the film. If, after fixation, the white portions are not quite opaque, wash the film well, and intensify with pyro and silver, first treating the film with a dilute solution of iodine, washing it again, of course, before applying the intensifying solution; or you may, if you are familiar with the results, employ any of the mercury intensifying processes, or the solution of Schlippe's salt, or of permanganate of potash. Any of these will increase the intensity of the finished print. Try again, and let us know the result.

**W. J. A. G.**—We are not familiar with the exact form of stereo camera of which you send us cardboard model; but the working of it seems tolerably clear to us. The operations will be very similar to those of the Latimer Clark camera, which we described last week. If you focus with the pointer placed opposite *a*, and then move the bar with the pointer opposite the 2 at either side, the image should still occupy the same place on the ground glass and be quite sharp, in one case a little more of the right side of the subject being taken, and in the other a little more of the left. To work the camera after focussing with the pointer at *a*, and seeing that the images come right when it is moved to either side, move the point to the right-hand 2, and proceed as we last week described. By moving the camera nearer to or further from the pointer end of the bar, you increase or decrease the distance between the points at which each picture is taken. 2. The design on the back of your card is very good, and the hint to exacting friends neatly conveyed. 3. The tone and general quality of the print are good; but the negative is just a little under-exposed.

**J. STUART.**—It seems probable, from a general examination, that the spots are due to imperfect fixing and washing, the result having been finally brought about by the damp; but we will examine the matter more carefully, testing both prints and cards, and then report.

**GARNIER.**—Thanks for the interesting photographs of Victor Hugo. Messrs. Marion and Co., Soho Square, or the London Stereoscopic Company, Cheapside, may probably find customers for such pictures.

**ONLY AN AMATEUR.**—The instructions given in the printed paper were not definite. The portion of bichromate supplied was to be dissolved in *some* water. If you wish to try such a mode of printing you may dissolve an ounce in a pint of water. Various formulae for bichromate printing processes have appeared in our pages. 2. A good intensifying solution of pyrogallie acid may be made as follows: 3 grains pyrogallie acid, 2 grains citric acid, 1 ounce water, with a few drops of a fresh 20-grain solution of nitrate of silver added just before use. After developing with your iron solution, wash thoroughly and intensify with the above; or you may intensify after fixing with the above, if you wish.

**MAGNESIUM.**—The time required for fixing depends somewhat upon the quality of the paper used. Thick paper requires a longer time than thin paper. If your enlargements are produced upon drawing paper thirty minutes will not be too long; for a stout photographic paper about twenty minutes will suffice. Wash the print very thoroughly after development before immersion in the fixing bath. The object of the acetic acid in the nitrate bath for the printing by development process is to restrain reduction and prevent discolouration of the whites.

**E. GREGSON.**—The person whom you mention has made a composition with his creditors, and is, we believe, retiring from photographic business. Possibly your letter has been accidentally overlooked.

**ERRATA.**—In Mr. Waterhouse's article on Photo-zincography, p. 294, para. 3, line 4, for "cemented" read "connected." In corresponding line of next column, for "glycerino" read "glycocine." In last week's issue, p. 310, in the heading of Mr. Gaffield's letter on the Transmission of Actinism, for "light" read "glass."

Several Correspondents in our next.

### PORTRAITS WITH LANDSCAPE BACKGROUNDS —DOUBLE NEGATIVES.

SINCE we called attention some months ago to the charming card pictures of Mr. Edge, in which a landscape taken from nature is introduced as a background to the portrait, many ingenious suggestions for modes of double printing\* and for the production of double negatives have been communicated to our pages. We have now to introduce to our readers a mode of producing a double negative by which the figure and landscape background can be printed successfully at one operation. The method we are about to describe is due to Mr. Burgess, of Norwich, and is, we venture to think, so simple and efficient as to leave nothing further to desire in this direction. By the use of ordinary skill, care, and taste, double negatives with various effects can be produced, and the printing is conducted in the ordinary manner without extra care or trouble. The examples which Mr. Burgess brought under our attention some weeks ago, when he favoured us with a visit, were described as merely experimental essays, but their excellence afforded sufficient warranty of the capability of the process, and we apprehend that the beauty of the results, so far as the background can influence it, need only be limited by the art skill of the photographer.

The plan devised by Mr. Burgess consists in a new use of our collodio-chloride process. A negative is taken, as usual, in the studio, with such foreground effects as may be suited to the finished result; the background screen must, however, be a dark one, either black or as nearly so as the darkest part of the landscape. When the negative is completed it requires a protective coating, which prevents the film from being dissolved or injured by the next coating, which consists of collodio-chloride. Mr. Burgess at first used india-rubber-solution, but has since found that albumen answered better, and the latter will doubtless aid in securing vigour in the image. When the protective varnish of india-rubber or albumen is dry, it receives a coat of collodio-chloride of silver, and when this is dry the figure and foreground are carefully painted out upon it with indian ink applied with a camel's-hair pencil. This done, the sensitive collodio-chloride film is exposed under a transparent positive obtained from any suitable landscape or other negative which may be chosen, and a negative image so produced. It is then fixed and washed in the usual manner. Toning, it will be observed, is unnecessary, as the brown tint of hypo fixing is most suitable for printing purposes. The indian ink which masked the figure is washed off in the course of the fixing and washing, and

the figure and foreground remain as in the original negative.

We subjoin Mr. Burgess's communication, received since we saw him, in its integrity:—

"My dear sir,—I have pleasure in sending you my promised communication on 'double printing,' or rather *double negatives*, but my time has been too much occupied to permit me to experiment with it so far as I should have liked. However, the specimens I send herewith are sufficient to show that it can be done satisfactorily. When used with taste and skill, I think the method will give great power to the photographer, as it is possible to make the background harmonise and blend with the figure; and this being done on the negative, of course the printing proceeds with no more than the usual trouble. I quite appreciate *good printing*, but, I think, as a rule, we do not spend sufficient time and care in producing negatives of a superior quality.

"The admirable little pictures by Mr. Edge first induced me to give my attention to double printing more closely than I had hitherto done, although I had frequently printed in skies and made use of the *dodge* in other ways without any scruple as to its legitimacy. I did not until then fully realise the additional power which is thus gained by the photographer. At first I took the figure and foreground with a light background, graduated to dark grey at the bottom. A print having been taken from this, I painted out the figure and foreground with indian-ink (this is easily done by any one who can draw moderately well, even with a profile), and laid the print upon the background negative. When the print is washed, prior to toning, the indian ink is carefully removed, a little friction with a brush being sometimes necessary. The advantage in this plan lies in the fact of its being possible to follow very intricate outline without any fear of the mask slipping. Another plan is to paint a mask on 'vitrified' sheet india-rubber, or talc. This is laid over the print and gummed in its place. I have made the 'sheet india-rubber' by coating a glass alternately with collodion and india-rubber until of sufficient thickness.

"But it is the plan of making a double negative which I think is most useful, and I will proceed to describe my method of doing this. I take the negative of figure and foreground with quite a dark, plain background, and, whilst still wet, after fixing, flow over albumen and water mixed in equal parts. When dry, I coat the plate with collodio-chloride of silver, and when this is again dry paint out with indian-ink all the figure and foreground. I then proceed to print from a transparent positive of the background on the collodio-chloride of silver, which will, of course, produce a negative of the background at the back of the figure.

"I have also tried coating the negative of figure, &c., with india-rubber, and preparing as a dry plate, but found

\* We may here remark that Mr. Robinson has recently reduced double printing to a system of great simplicity, arranging the negatives for combination in a picture so that they may be worked by his ordinary printers by a system of registration, in which care to follow instructions alone is necessary to success. We shall have something to say on this subject shortly.

it more unmanageable than the plan described above.—  
I am sir, yours very truly, J. M. BURGESS.  
"Norwich, July 3rd, 1868."

The method referred to in the last paragraph of Mr. Burgess's communication had also been proposed to us by Mr. Cherrill as a means of securing a double negative. The chief objection to it is the risk to the first negative involved in its re-immersion in the nitrate bath, and the prolonged operations involved. Probably the dry collodion tissue, as prepared by Mr. Woodbury on a basis of leather collodion, might be found useful in some cases, with the advantage of being detached from the negative at will; but none of these plans seem so simple and efficient as that proposed and carried out by Mr. Burgess.

There is another facility presented by this mode of securing double negatives which should not be overlooked. Whilst it is proposed as a means of introducing landscape backgrounds to figures, it is obvious that this is not the only purpose for which it is available: the production of groups from various negatives taken at different times, or the introduction of objects or accessories—in short, any combination difficult or impossible to be gained on one plate with one exposure—may, by the exercise of skill, be brought together in one negative, and printed at one operation.

#### LAKE PRICE ON PORTRAITURE.

THERE is no department of photography upon which Mr. Lake Price will be heard with more profit to the student than that which treats of portraiture and the rendering of figures generally; and, as we have before stated, his new work contains very much on this subject which will be read with eager interest by the professional portraitist. We propose here to lay before our readers, in extracts or epitome, some of his instructions in this department of the art.

Whilst dimension is stated to be an element of great importance in photographic portraiture, Mr. Price points out the great difficulties necessarily involved in attempting large direct exposure. A lady whose huge photographic portraits have been much praised in *delectante* art circles, claims it as a merit that they are taken direct, and admits that very long exposures are required—so long, in fact, that we heard it once facetiously remarked that it was quite admissible for the sitter, wearied with the long exposure, to stretch his legs by a turn round the studio during the exposure. Mr. Price, deprecating especially protracted sittings, says: "The sitter's countenance, which, had it been taken rapidly, would have been life-like, sparkling, and intelligent—no matter what his good looks or otherwise—becomes leaden, rapid, and, indeed, loses its resemblance to the original; for the soft and mobile parts of the face, round the mouth—which is the chief seat of expression—have so drooped that their very form is altered during the sitting." "Thus," he continues, "photographs which have been attempted, approaching *life size*, have been most abortive and disagreeable, and heads of three and four inches have not yet been obtained, with the *figure and hands* in the picture in fair focus and drawing, and when the *head alone* has been given, the operator has been obliged, in order to obtain any degree of rapidity, to use too large an aperture, and the *line* of correct focus traversing the face is, on both sides, in immediate contact with distorted forms. When it is desired to take heads *of this size* it is useless to attempt the hands and figures; the face must occupy the *central* portion of the lens, and, thus treated, heads of study, &c., can be obtained up to four inches or so. It is at these dimensions especially and those approximating to them, either larger or smaller, that the new portrait lens of Dallmeyer shows its superior capabilities, and becomes most valuable to the photographer; giving a general fleshy softness to the features in lieu of the metallic hard appearance, and by increasing the depth of perfect focus."

The largest size at which he considers a portrait can be

undertaken to include the person and hands, giving a three-quarter length, may have the head about 2 inches in length. Suitable lenses for such work may vary from 4½ inches to 6 inches in diameter, and from 15 to 24 inches in focal length. Groups in which the figures must be smaller may be on 20-inch plates; but for single figures he recommends 12 by 10. His remarks on card portraits we give at length. He says:—

The "carte-de-visite" is the smallest size it will be necessary to notice. The great popularity it for so long a period enjoyed shows that the qualities it possessed must have largely satisfied the taste of the public. The time of exposure, depth of focus, completion, delicacy, and rotundity of the image it possesses, are qualities which are only obtained with the greatest difficulty and under the most favourable circumstances in larger works. The damaging condition was this—that from the extreme facility of their execution they became extremely commonplace, and that when the photographer had the talent of arrangement necessary to compose a *picture*, the time so occupied would not be repaid by the small charge customary, whilst the public, entirely ignorant—as a mass—of art principles, was equally delighted to find itself depicted as abiding in Cockney Gothic interiors of a cathedral character! bought by the square foot of some dauber, with vulgar and absurd accessories—as it would have been with a higher grade of representation. Many very charming works may be selected from the mass—"vari nantes"—in the ocean of mediocrity, which show that "small sizes" are, as a rule, the thing to attempt photographically. The *carte-de-visite* may be divided into four distinct classes—the head only, of about one and a quarter inch in size; the half-length; three quarters; and full. The first, unless executed by a very first-rate operator, is apt to look distorted, coarse, and exaggerated, but has the advantage of giving details of the countenance—sometimes too much so, indeed—of interesting individuals. The instrument proper to take such pictures is a 3½ double lens, 10-inch focus; they are often taken with less diameter, but suffer in consequence, as the lens has to be approached too near the sitter and is "strained." The next size appears to the writer to offer the greatest advantages; the head is as large as in the so-called "cabinet" size, the hands can be included without distortion, and sufficient of the body to give interest—for six and eight inch focus lenses are the proper ones to employ, and of the best makers—considerable rapidity is gained over the ten inch focal length.

The full-length size is executed with lenses of two-inch to three and a quarter-inch short focus in diameter; according to the space at the command of the operator to withdraw his camera further and further from the sitter. It is in all cases better to do so, to the extent the lens will allow; to properly fill up the dimension, rather than attempt to take sizes above the power of the instrument by approaching too near the model. Generally speaking, an extreme definition, approaching the steel, has apparently been more valued and attempted than artistic qualities, and the hacknied positions and commonplace accessories have done much to wear out the subject. The dimension being so small, the utmost *finesse* and delicacy—not wiryness of execution—is necessary in these works. Development by iron should alone be practised, and the whole scale of light and shade, from bare glass in velvets, &c., to opaque white, in *small quantities*, be utilised in the subject, thereby giving relief, sparkling brilliancy, and effect.

The cabinet portrait Mr. Price admires, but considers that they will require more skill in the photographer. Possibly that is the reason for their tardy progress in popularity in this country. He says:—

The "cabinet" size portrait is the last form which appears as a candidate for public suffrage. It has many advantages; its increased dimension permits a "closer acquaintance with the original," without his being absolutely put to the microscopical examination of injudiciously treated larger sizes; the enlarged scale showing them better, renders it more worth while to pay additional attention to the accessories and chiaroscuro, but at the same time, as it shows their excellencies better—when they exist—it most certainly equally emphasises defects; and full-lengths, male sitters especially, cannot be rattled off with the indiscriminating facility of the "carte," if absurd want of aplomb or other damaging shortcomings are not to obtrude themselves on the beholder. In fact, the "cabinet" will be found much more difficult to bring to an *equally* satisfactory result.

Although himself a skilful artist, and not opposed to the occasional retouching or doctoring of either negative or print if required, Mr. Price does not believe that any skill in retouching can produce pictures equalling the best results of pure photography, and would never dream, when he met with prints of unusual excellence, that they must necessarily be retouched. He says:—

No "*skilfully retouched*" (?) picture could for one moment compete with the qualities displayed in the large vignette heads of T. R. Williams, or other successful photographs. Modifications of the

above manipulation are applicable to larger portions of the picture; namely, weakening by cyanide the too dense deposit on portions of background, accessories, &c., thereby "keeping them down," or by a general "tint," of greater or less opacity, lightening portions or masses, thus giving "breadth of effect." These latter treatments, equally applicable to landscapes, interiors, &c., &c., as they do not interfere with the *drawing or definition given by the lens*, are, if skillfully managed, unobjectionable; in many cases, even desirable, improving light and shade, massing too minute detail, giving "breadth of effect," and artistic qualities.

A pregnant hint on the study of art is conveyed in the following paragraph:—

In portraiture the student should refer to prints from the works of Velasquez, Titian, Vandyke, Rembrandt, Rubens, our own Gainsborough, and Sir Joshua Reynolds, eschewing the affectations of the periwig school of Mignard and Lely. If he really can do anything, this study will surely bear fruit and make itself felt in his works. It has lately been matter of observation how much the study of art principles has enabled M. Adam-Salomon to prove the fallacy of the idea that the photographic representation is a mere mechanism, dependent upon the lens and the box it is mounted in, whereas in this department of it, and in all that is arranged and composed from the human figure, the will, intention, and idiosyncrasy of the producer makes itself felt as completely as though he were at work with palette and brushes.

But whilst Mr. Price holds that there is no result which is given by perfectly successful untouched photography, he is not opposed to the employment of any aid which may compensate for the occasional shortcomings of photography. If we remember rightly, he was the earliest authority who recommended securing a control over the development of certain parts of the negative by using a glass syringe to displace a little developer in some small part of the negative where diminished intensity might be desired; or to add a drop of nitrate of silver on some portion of the image where augmented vigour would be useful. On retouching the negative, he says:—

In a variety of ways, however, the necessity will arise for touching upon the negative; the following are the most general causes: light grey or blue eyes. Besides *profile* treatment, which is the most judicious for such subjects, the pupil of the eye should be *most carefully* and skillfully touched with a small sable brush just dipped in a solution of cyanide. This must of course be done before the negative is varnished, and it must be *carefully* washed afterwards; no scraping can equal this treatment. The high light may now be added in black varnish or vermilion, zinc white, &c. Under-exposed negatives, or harsh lines on the sitter's countenance, may be worked over very extensively, using a *magnifying glass*, with either of the following: Take a piece of glass with a coarsely-ground surface, rub it on a "Paber's" black-lead pencil, add spirits of turpentine, thoroughly mix, better *grind* under a glass "muller," stipple, and soften the asperities. Another method: remove old films from glasses in water, as directed, page 91; recover them by percolation through linen; *when dry*, treat them as above in every particular. A successful portraitist at Vienna is said to be very clever at this "touching up;" but, however skillfully all this sort of thing may be done, the result shows the means employed, and, to those competent to judge, is, as before stated, merely an expedient which, whenever possible, should, by proper treatment, be rendered quite unnecessary.

We must for the present conclude our extracts, promising to recur to the subject again on an early occasion.

## Critical Notices.

THE PRINCIPLES AND PRACTICE OF PHOTOGRAPHY FAMILIARLY EXPLAINED; Being a Manual for Beginners and Reference Book for Expert Photographers. By JABEZ HUGHES. Eighth Edition. (London: 379, Oxford Street.)

It is an opinion which has been entertained by many that the depression which has for some time prevailed in professional photography has been chiefly due to the large number of persons who have acquired and practised the art. If the dictum were accepted as true, we know of no one who would be so largely responsible for that depression as Mr. Jabez Hughes, who has, we believe, contributed by the Manual before us to make more photographers than any contemporary instructor. If, however, on the other hand, it be

held, as we contend it ought to be, that the cause of the depression has been more due to the number of bad photographers entering the profession and initiating a race for cheapness instead of a struggle for excellence, then Mr. Hughes must be entirely exculpated, for no one has more contributed to make good photographers than he.

Every edition of the manual, of which the eighth lies before us, contains some addition and improvement, the result of a most intimate practical acquaintance with every important branch of the art, and of a rarely conscientious desire to omit nothing which either student or advanced practitioner of the art ought to know. As the work is so well known, it would be superfluous to enter into a detailed description of the plan upon which it is written, combining rigid accuracy of instruction with a singularly pleasant familiarity, simplicity, and lucidity of style; but the point which will interest our readers most to know is, that all the regularly worked processes of photography as described here are given with the latest modifications which trustworthy authorities have accepted as improvements, and that the work may be safely accepted as a *vade mecum* by skilled photographers as well as studied as a primer by those who have only just approached the threshold of the art. Our space does not permit us to give any extracts at present, but we shall seek early occasion to quote some important matter from the pages of the new edition.

THE PHOTOGRAPHER'S REFERENCE TABLE, for Studio and Field Work. By L. G. BENSA. (London: Carter and Piper, Gough Square.)

THE object of this Reference Table is to enable the photographer to ascertain without troublesome calculation four specific things, the necessity for a knowledge of which is constantly arising: *first*, the distance between camera and object with a given size of subject to be taken and image required, and a lens of a certain focus; *second*, what the equivalent focus of the lens should be when size of subject and image and distance of the camera are already determined; *third*, what size the image on the focussing screen will be at a given distance from the subject of a certain size and with a certain lens; and *fourth*, the amount of angle included when the image is of a given size with a lens of given equivalent focus. The photographer is here presented with the means of obtaining this information by certain simple rules and reference to a table provided. An "Angle Tape" is provided, by which and a two-foot rule the photographer may ascertain the amount of angle included in any given view by a very simple process of measurement. The Photographer's Reference Table will doubtless find its way into the studios of all photographers, who will thankfully avail themselves of the facilities Mr. Bensa has placed before them for ascertaining accurately and easily facts which many of them have only guessed at or groped after.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURA FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XXIV.

"The satirical rogue."—*Shakespeare*.

SOME OLD NOTIONS TOUCHING PORTRAITURE.

HAVING concluded my task as far as relates to the composition of lines, and having touched upon photographic portraiture and all concerning it, before I commence what I have to say on chiaroscuro I feel tempted to interpolate a chapter culled from a rare old quarto, a translation of which was published in the last century, and which, from the quaintness of its manner, will be interesting and readable, as well as for the down-right good sense and sound teaching it contains. Much of what I have extracted will be found of great value to the portrait photographer.

The title of the book is "The Art of Painting in all its Branches, Methodically Demonstrated by Discourses and Plates, and Exemplified by Remarks on the Paintings of the Best Masters, and their Perfections and Oversights Laid Open. By Gerald de Lairese. Translated by John Frederick Fritsch, Painter." This book was written long before Reynolds, Gainsborough, and those famous painters who revived the art of portraiture became known to the world. This is what the translator says of his author and his book; he might have been talking satirically of photographic art teaching in our own day:—"The author's known abilities and great reputation in Holland have justly recommended him to the esteem of the most knowing there, I thought it very proper to make him speak English; and the rather (to use his own reason) for that, though many excellent authors have written on painting, yet, in bulk, they seem rather to cry up the art and the artist than lay down solid rules for attainment. To which I may add, that those authors are mostly useless to an Englishman, and few or none copious enough to answer general purpose; nor at best are of general service in England, where fresh and fair nature is preferred before the brown and warm colouring of some other countries, especially Italy, where the best books have been written on the subject. But principally for that I think nothing has been published here so learned, full, and complete, and so well explained by plates and examples as the author will be found to be; nor, perhaps, wherein portraiture (a branch which England mightily affects, surpassing in this particular their mural decorations, which, in the judgment of the judicious, would better have been left blank walls) is so copiously handled."

Passing by some hundreds of pages on pencilling, beauty, ordonnance or composition, colouring, landscapes, &c., let us extract some sentences from Book vii. "Of Portraiture." the subject we have in hand.

Since we meet with no precedence in the art, nor pretend to insist on ceremonies, we shall treat of things as they occur to us, and as clearly and profitably as possibly.

As in music and singing, a good ear is requisite, so in portraiture it is impossible to excel without a good eye; such an one, I mean, as is governed by sedate and sober sensation, and not by self-love and passion. Next, we must be thoroughly judicious in the graceful choice of light, and the place where the person is to sit, that the face may appear to the best advantage; and then the body is to be disposed to the most natural and becoming posture. As for the choice of light, in order to apply it most advantageously for the benefit of either sex, it is certainly a matter of great moment, since the fair sex commonly partake of more delicacy and grace than men, so they must have a light as beautiful and agreeable as their persons.

But our author is heterodox here. He says: "I think those masters have made the best pieces who have chosen a front-light." He should have been painter to Queen Elizabeth. In continuation of the subject of light and shade he mentions some things that should be avoided by those who imitate M. Adam-Salomon.

We see that many, without difference, be the figure in full proportion or in little, give the touches under the nose so black and dark that it seems as if a black beetle were proceeding thence; whereas it is certain, and nature teaches it, that when the light falls strong on the nose, the nostrils and their ground-shades can never appear so black; and yet some think they have done great feats in using force and strength, and will do it even in a fair and tender face, and no bigger than the palm of the hand, although the deepest black should not have force enough to shade the other objects of a darker colour, such as hair, a cloak, or other garment: by which sort of management the face seems to jump out of the frame, and to desert the wig, hair, and garment. We must not so understand when we teach that the face must have the main light; we mean only that all ought to keep due order, that it may look natural.

On dress, accessories, and the management of the sitter, we have the following capital remarks, which are as applicable to photography as to painting. There will be noticed a curious vein of satire throughout. He is rather hard on the ladies.

Self-conceit and self-love seem natural to all, but especially to the female sex, who, whether their pictures are drawn on their own accounts or through the desire of others, imagine they deserve much homage; nor stops it here, for although they may possess a tolerable

share of beauty, yet that is not satisfactory enough, they must be flattered, and their pictures painted in the most beautiful light; and unhappy is the painter who abates but half a drachm of such a beauty.

For these reasons the master is obliged to have a principal regard to light and shade; but to the light chiefly, since it is well known that nothing gives greater offence to ignorant people than shades, and still more when they are strong and broad; they believe they speak to the purpose in objecting: 'Well, how can it be possible that my neck and cheek should have such large shades, when I daily consult my glass and find my skin all of a colour and white?' and then the painter is blamed. But are not such reasons weak and absurd?

It is evident that backgrounds contribute very much to the charming grace of objects; nay, I dare say, that the decorum mostly depends thereon; and though many imagine that a black or dark ground always becomes a portrait, yet it is no rule, since, as before has been said, each individual object requires a particular background; besides, if such things were to be taken for rules, the art would smell too much of an humdrum.

It may not be foreign to our main design to put the artist in mind of the application and right use of such materials as may enrich a portrait and make it look the more noble. This is so great a point in portraiture that when well known we need never be at a stand through the mishap or defects we often meet with in the disposition of a portrait, and which sometimes must not be hid, since we have often means enough for obviating them with seeming reason, and without forcing nature; as a long and narrow face may be helped by a hood or other head-dress; a thick and too round a face by the contrary; a figure too lonesome may be embellished by such things as are proper to it, which serve not only for ornament and grandeur, but also to express the sitter's lustre and virtue; but care must be taken that the figure of the sitter, as the principal object of the piece, fill up the major part of it, either by a spreading away of the posture, or by the addition of some proper by-work, by which means it will have a good effect.

Some persons may be too long and sharp-nosed, or too hollow-eyed; for such, a low light is most proper; but when it is otherwise, an high light. In this manner a judicious master ought to help the defects of nature, without adding to or taking anything from them; yet, to the sorrow of impartial masters, the contrary is too often seen, for with many portrait painters their work is better known by their particular manner than the sitter by his picture.

I think, also, that the common and useful dress of a person is a great addition to likeness; for no sooner is the dress altered but the look does the same, and shows itself either more or less pleasing and agreeable. Some painters keep in their room for the use of all their sitters, be it he or she, without discrimination, certain pieces of cloth and velvet, by which they imitate the Roman manner; but thereby the persons represented become more or less unknown.

#### The following is capital advice:—

The painter should likewise discover and know, as much as possible, the nature and temper of the person sitting, and in what circumstance lies his favourite pleasure; that he may, when sitting, be entertained with talk pleasing to him, and his air thereby kept steady and serene, and his posture natural and easy; avoiding everything tending towards sorrow or frightful relations; for these are apt to ruffle the mind and so to decompose the face that it cannot easily be got right again; but if the sitter himself do, by his talk, discover his own bent, the painter ought to humour him to the last, whether it be jocose or moderate, without exaggeration or diminution, yet with such a variety as not to prove tiresome and make the face alter.

But to return to the original matter: I must warn the artists not to give in too much to what is common, or humour ignorant people so much as not to reserve to themselves some liberty of doing what they think proper for the sake of reputation. Surely this cannot be strange advice; for a master who prefers money before art has no more dangerous rock to split on, since the ignorant multitude usually insist to be drawn according to their own whims. One says to a good master: 'Draw me thus, or thus; let me have one hand on my breast, and the other on a table;' another must have a flower in his hand, or a flower pot must be by him; another must have a dog, or other creature, in his lap; another will have his face turned this or that way; and some who would be drawn in the Roman manner must be set off by a globe or cloak on the table, whether such ornaments be proper or not. On mentioning the Roman manner, I find that it signifies a loose airy undress, somewhat savouring of the mode, but in no wise agreeing with the ancient Roman habit.

This is admirable and true. The fine gird at the "Roman" manner is capital. In the author's day it was the custom to have portraits and statues habited in classical costume, with, perhaps, the addition of the immense "Duvilliers" wigs of the period, an absurdity that West, greatly daring and against the advice of his brother artists, broke through for the first time in his "Death of Wolfe." This manner of trying to make the sitter look a much finer fellow than he

really is has its counterpart at the present time, even in our own art, and is followed by photographers who will defy nature and stick to precedent. As our author says:—

Some painters will keep to the old road, because it is difficult to correct a rooted evil; they do as the old woman did, who, being exhorted in her last sickness to embrace the true faith, answered, 'She would follow the steps of her forefathers, were they all gone to the devil.'

There is a pernicious custom among some inferior photographers of collecting together a set of poses and fitting their sitters to them, or of allowing their customers to select their own, no matter how incongruous the thing may be, so that it is paid for. This is a detestable practice. Photographers should learn the principles of their art, and then invent poses for themselves, instead of cowering in borrowed plumes. The effect is peculiarly ridiculous when the feathers are too fine for the bird, and he endeavours to make a maid-servant look like a duchess. Here would be a time to introduce your column and curtain, if you like! *Laissezse*, with the instinct of a true artist, is very severe on a similar practice.

I have discovered a great oversight in some artists, which is, that when the face is finished, they had no further regard to the life, but chose a posture at pleasure out of drawings and prints, without considering whether it suited the person, and whether the figure was proper to the condition and countenance of the sitter; nay, whether the head matched the body; certainly a great heedlessness. If things be done without making distinction of persons and their conditions, the artist will work to his dishonour. He who steals thus may not indeed call the work his own without reproach. Some will object, as Michael Angelo did once to a painter who practised it with success: '*What will become of your pictures at Doomsday, when the parts shall return to their own wholes, seeing your works are made up of stolen pieces?*'

In another place the writer complains of those who take the designs of others, and, by transforming them, make them their own.

What one artist uses in the distance (he says) the other, that it may not be known, brings forward; and what he has represented in the open air, the other contrives in a dark room. A poor method of concealment, but it is such men's misfortune to be, in this particular, most out of the way when they think they do best; for, wanting the great master's wit, judgment, and apprehension, they have no true notion of his conduct, and therefore are easily misled, and, like *Æsop's* raven, exposed to censure.

I have only given a slight skimming of the contents of this rare old book, but I am overrunning my space, and shall conclude with a bit that might have been written anent the doings of some who write on photography and art at the present time.

We find many artists never pleased with other men's works, but, being full of themselves, despise everything they see, and this, perhaps, on no better bottom than a pique against the artist's conversation, talk, dress, or money, or else because of his greater fame; and yet if ten persons happen to applaud a fine picture of this eye-sore master, they will at that juncture chime in with them, to screen their prejudice. And, on the contrary, if but a single person afterwards find fault, they immediately turn the tables against ten others. Again, if a piece of their friend be brought on the carpet, though never so faulty, they will applaud and justify it at any rate, though against their own convictions of conscience, if they have any. But this partial and prejudiced humour is most prevalent in those who know least.

## ON THE PRINCIPLES OF LIGHTING AND OF CONSTRUCTING STUDIOS.

BY DR. H. VOGEL.

THERE is nothing of more importance for the professional portraitist than a judicious arrangement of his studio and lighting arrangements. Innumerable faults have already been committed in this matter; enormous sums have been dissipated in curious constructions, which have proved to be impractical in working, and which were found impossible to alter without great loss of money, if possible at all; and notwithstanding these experiences, different opinions still prevail as to the best construction and arrangement of the glass room. "What is the best form, a high skylight or a low one?" is still constantly asked. Art photographers of great influ-

ence utter opinions which are quite opposite to one another "What kind of light has it?" is the first question asked regarding a glass house; and this stereotyped phrase indicates the chief point to be considered in constructing skylights. I shall try to explain the principles of illumination in studios according to physical rules, and, at the same time, I shall review the actual construction of studios generally.

Suppose a room which is enclosed on all sides by walls, and which receives its light through one single window, illuminated only by the light of the clear blue sky. Experience teaches that the brightness of light is different on different spots of such a chamber: the further a point is removed from the illuminating window the darker it will appear; and the nearer it is situated to that window the brighter it will appear. But not only the distance of a point from the window, but also its situation in reference to the window, is of importance. A spot near the wall in which the window is placed will be much darker than a point situated at the same distance from, but quite opposite to, the window.

First of all we must endeavour to explain this. Direct sunlight, being kept out, it is the blue sky alone which affords light to the chamber. A certain point in this room will therefore be the brighter in proportion to the greater portion of the skylight sending its rays upon it. Suppose, for instance, a certain point *a* (fig. 1), opposite to a round window,

Fig. 1.

it will be the top of a bundle of rays, the diameter of which will be appropriate to the aperture of the window. Suppose a second point, *a'*, at a greater distance from the window: this is illuminated only by the cone of rays *b a' c*, which is much more narrow than the first. The cone of rays which illuminate the point *e*, situated at the side of the window, is still smaller, whence it follows that *a* must be brighter than *a'*, and this brighter than *e*. In consequence of this, the aperture of the cone of rays—that is to say, the angle—formed by the lines which we may draw from the illuminated point to the edges of the window, affords a criterion of the intensity of light for the point referred to. I beg to term this angle the angle of light. If the supposed point be situated within the wall the window is in, that angle of light would only form a straight line, and therefore such a point would be quite dark if it did not receive some light by reflection from the light walls. But it is obvious that not only the dark wall of the window, but also every other point of the chamber, receives such light reflected from the walls, ceiling, and floor. Therefore, every point within the chamber, except the wall with the window in it, will receive

its light from two different sources. It will be illuminated (1) by the direct light of the blue sky, the amount of which is the greater the greater part of the skylight sends light upon the point; (2) by the light reflected from walls, &c., which is of a very complicated nature. Let us for a moment leave out the reflected light, in order to examine the effect of direct light alone. The brightness which this latter affords to a point may be briefly termed direct brightness.\*

The direct brightness of a point within a room depends, as already stated above, first of all, upon its position in reference to the window, and consequently on the extent of the latter. In order to examine these points more exactly, we shall start from the most simple hypothesis, and treat at first on the brightness of a point situated directly opposite to a narrow round window. The greater the aperture of the window the greater is the angle of light. If the angle of light be only small, the brightness of a point will be proportionate to the superficial extent of the aperture.

Now, the superficial contents of analogous figures are to one another as the squares of homologous lines; therefore, the intensity of light will be in the proportion of the squares of the window diameters. We mathematically may prove this as follows:—

Suppose that the quantity of light afforded by a certain piece of the blue skylight be proportionate to its area, then the bright-

Fig. 2.

ness of the points  $a' a''$  (fig. 2), situated directly opposite to a round window, is fixed by the area of the spherical part of

Fig. 4.

veiled with curtains. Half the angle of light is here,  $a$ ; the aperture being successively made twice, thrice, and four times as great ( $cb' cb'' cb'''$ ); the angle of light is only enlarged by the pieces  $a' a'' a'''$ , which, as may be seen in our diagram, do not increase so rapidly as the aperture. We

the calotte, enclosed by the cone of light which is formed by the rays. The area  $J$  of a calotte is the radius of the basis of the segment, being  $= a$ , the height  $= h$ , equal to  $\pi (a^2 + h^2)$  (fig. 2). The angle of light being  $2a$ , it follows—

$$h = r (1 - \cos a).$$

For very small angles we can set—

$$1 - \cos a = 0,$$

whence follows

$$J = \pi a^2;$$

that is to say, the area of a calotte are equal to the basis, while the radius  $= a$ , if the angle of light is small. Therefore, the

Fig. 3.

brightness of different points,  $a' a''$  are in the proportion of—

$$\pi a^2 : \pi a'^2 : \pi a''^2,$$

$a^2$  being  $= \sin^2 a$  (fig. 2) the amounts of light of the points  $a' a''$  are to one another in the proportion

$$\sin^2 a : \sin^2 a' : \sin^2 a'';$$

or, since for small angles the sinus are to one another in the same proportion as the tangents; as

$$\pi \tan^2 a : \pi \tan^2 a' : \pi \tan^2 a''.$$

The tangents are found by dividing  $F$ , the radius of the aperture by  $E$ , the distance of one of the points  $a' a''$ ; therefore, the amount of light at  $a' a''$  are in the proportion—

$$\frac{F^2}{E^2} : \frac{F^2}{E'^2} : \frac{F^2}{E''^2};$$

that is to say, the intensity of light decreases as the squares of the distances increase; and increase in the same proportion as the squares of the radius of the apertures do.

A round or square window of the double extents will therefore afford four times as much light to the same point, and thrice as great window nine times as much light. With larger windows the amount of light increases not so rapidly if the aperture is enlarged. Suppose, for instance, a point  $a$  (fig 4), opposite to the aperture  $cb$ , in a glass house entirely

\* I confess that this is a very bad name, but I do not know another at this moment, and I think it is reasonable.—DR. V.

instantly may apply this to practice (fig. 5). In a studio of 32' of length, place a person,  $a$ , at a distance of 5' from the glass wall and 4' from the background, the curtains being closed between  $g$  and  $h$ . By constructing the angle of light,  $h a g$ , we receive a criterion of the amount of light at  $a$ . The piece cut out from the skylight by the angle  $h a g$  determines the intensity of light at  $a$ . If our studio had a

length of only 24' instead of 32', would therefore  $i$  be the end, the intensity of light would be determined by the angle  $i a g$ , all other circumstances being the same. Already, in the diagram, we see that the two angles  $i a g$  and  $h a g$  are

Fig. 5.

not very different from each other, whence follows that, in this case, it would not be of great use to add a piece of eight feet ( $i h$ ) to the glazed wall, especially as a great deal of the rays, falling upon the glazed wall under very great angles, are reflected by the glass.

(To be continued.)

#### TONING AND FIXING IN ONE BATH.

In a recent interview we had with Dr. Liesegang, referring to Dr. Towler's suggestion to give the mixed toning and fixing bath another trial, he mentioned a formula which he had recently been trying which yielded fine rich, warm, black tones, with somewhat rosy half. He had, he informed us, produced a large number of prints which were now undergoing tests for permanency, the result of which he will duly communicate to us. The formula stands thus:—

Water ... ..	2 ounces
Sulphocyanide of ammonium...	50 grains
Hyposulphite of soda ... ..	240 "
Acetate of soda ... ..	15 "
Chloride of gold ... ..	1 grain.

Dissolve the gold in a small quantity of water, and add it to the other solution.

The bath may be used immediately after preparing. The prints are not washed before putting them into the bath. They become yellow at first, but afterwards recover their force. The toning and fixing takes about ten or fifteen minutes, but can be continued for some hours.

The acetate may be substituted by the beuzoate, the phosphate, borate, citrate, or any other such salt, for the purpose of modifying the tint desired.

#### COLLODION WITHOUT BROMIDES.

Mr. R. Waitz, of Boston, sends the following formula to the *Philadelphia Photographer*, as giving results equal to collodion containing bromide:—

Iodide of ammonium ... ..	4 grains
Iodide of cadmium... ..	3 "
Chloride of calcium ... ..	1 grain
Collodion (plain) ... ..	1 ounce.
40 to 50 grains nitrate bath.	

#### DEVELOPER.

Protosulphate of iron ... ..	1 ounce
Water ... ..	12 ounces
Alcohol ... ..	1½ "
Acetic acid... ..	1½ "

Mr. Waitz is now using this process in his daily practice. He finds it to work very quickly, as he is able to secure excellent negatives of children in two seconds, requiring no re-developing. We have inspected several of Mr. Waitz's negatives, the editor of our contemporary remarks, and find them to excel those made by him with bromized collodion.

Mr. J. W. Black is also using the same formula, entirely discarding the use of bromized collodion in his dark room. We saw him make a number of exquisite negatives as large as 11 by 14, full of charming gradation and softness, and fully equal to anything we have ever seen.

It is so simple and so cheap that it will come into general use, doubtless, bromide patent extended or not.

#### ON A NEW AND SIMPLE METHOD OF RECOVERING METALLIC GOLD AND SILVER FROM RESIDUES.

BY VICTOR G. BLOEDE, CHEMIST.\*

*To Treat Developer Residues.*—The black, muddy mass remaining in the developing sink, or obtained by precipitating with common salt (the precipitate obtained by sulphide of potash will not answer), may be treated by amalgamation, with even better results than can be obtained by the smelting process. To treat this somewhat troublesome compound, proceed as follows: Thoroughly dry the muddy black mass, whether it be from pyro or iron development, and when all moisture is driven off, place it in an iron mortar, and thoroughly pulverize and triturate it; then pass it through a brass-cloth sieve (having meshes about half as large as a fine flour sieve) and place the resulting black powder into a narrow-neck glass-stoppered bottle, adding to each pound of the powder at least half a pound of mercury. Then pour on a sufficient amount of boiling water to make the whole of the consistency of thin cream, and shake the bottle and contents for several minutes. Let the mass remain in the bottle for an hour or two, shaking briskly occasionally, so as to bring the black powder in immediate contact with the mercury. Finally, empty the whole contents of the bottle into a pint evaporating dish, allowing the black solution, which is of no value, to flow off, but taking care not to spill over or lose any of the mercury. To clean the mercury of all the adhering black precipitate, place the dish under a tap of flowing water, and, by careful management, the entire impurities can be quickly washed away. When the mercury has been perfectly cleaned in this manner, filter off the remaining water, place the quicksilver in a piece of buckskin, and proceed precisely as directed in the last.

Another method, which is very much simpler and easier than this, is to place the wet muddy mass, just as it comes from the tank, into a coarse damp cloth, and to subject it to pressure between the hands. By these means all impurities may be removed as readily as by drying and sieving, thus economizing much time and labour. The cleaned black mass may then be treated precisely like the former.

*Amalgamation of Paper Ashes, &c.*—Paper and filter, as well as cloth ashes may be very successfully treated by amalgamation, providing that they are very thoroughly burnt and reduced. The paper, in saving, should be kept free of all impurities, especially pins and other metallic

\* Continued from p. 307.

substances. Place the paper clippings, &c., into a clean wooden box, and thoroughly sprinkle and impregnate them with the following solution :—

Protosulphate of iron	...	...	2 ounces
Nitrate of potash (saltpetre)	...	...	2 "
Water	...	...	2 quarts

When the paper has been well moistened all through, spread it out, let it dry thoroughly, and finally burn it in a stove having a good draft.

The paper should be added very slowly by the handful, so that the reduction may be complete, which will not be if the flame is at all smothered.

By using the sulphate of iron, any undecomposed nitrate that may exist in the paper, as well as portions of chloride of silver, are reduced to the metallic state.

The ashes should be removed from the stove and spread out upon an iron plate, so that the air has free access to them, and that they can glimmer out. When cold, throw them upon a fine flour-sieve, and separate the fine dust. Any impurities may then be picked out. It is advisable to grind the ashes in a mortar before sifting. When the ashes are very rich, large spangles of silver are frequently found upon the sieve; these should be picked out and added to the fine powder. Place the fine ashes in a bottle and dilute to the consistency of cream with boiling water. Four ounces of mercury should now be added for each half pound of ashes, and the mixture then thoroughly shaken at intervals for about an hour. Finally, empty the contents of the bottle into a small evaporating dish, and wash off the powder as directed in the last case. The clean mercury receives the same treatment as in the two preceding processes. The yield of silver by this process is very large, if the paper has been properly burnt, but any large lumps of chloride of silver in the filters should be removed, as such do not get enough heat to be reduced to the metallic state, and are, consequently, not taken up by the mercury. A large quantity, as ashes, may be readily reduced by this method with but very little trouble and expense.

*Reduction of Chloride of Silver.*—To properly treat the chloride of silver in the manner I am about to describe it is essential that it be freshly precipitated, or at least, it must not have been dried. Place the pasty mass in an evaporating dish of proper capacity, and add to each half pound about 2 ounces of tacks or other small bits of iron, then dilute until the chloride is of the consistency of thick cream, and add sulphuric acid (oil of vitriol) until a lively effervescence ensues. Allow the mixture to remain at rest for two or three days, after which time the white chloride will have changed to a dark grey mass, consisting of metallic silver and iron. Should all the iron have disappeared at the lapse of this time it is advisable to add a little more, and repeat the process, otherwise dilute or wash the grey powder carefully with water to remove the superfluous acid, and, finally, thoroughly dry the powder and sift it. If any impurities were contained in the chloride they will be upon the sieve, and may be removed. To further purify the silver obtained, place the fine powder in a clean bottle, and pour on enough mercury to dissolve it. The mercury is squeezed through the buckskin as in former cases, and a solid amalgam remains behind.

*Another Method.*—Another method, which is somewhat simpler than the foregoing, is the following :—Place the newly-precipitated chloride in an evaporating dish, and pour upon each ounce of the chloride from 2 to 4 ounces of ordinary developer, minus the acetic acid, and perhaps a little stronger in iron, and place the dish upon a stove and let it simmer gently, with continual stirring. A very marked change rapidly takes place in the precipitate, from white to black. The dish and contents may then be placed in a light place, and allowed to remain at rest for several days. The superfluous solution should then be poured off, the grain silver washed with water, and the resulting grey powder, after the addition of some hot water, treated with 1 ounce of

mercury to each 2 ounces of silver, well shaken, and finally finished as before directed.

*Treatment of Toning Precipitate.*—The black precipitate obtained from old toning baths by means of protosulphate of iron solution, and consisting of metallic gold with a large amount of iron, while still wet, must be placed in a coarse cloth previously damped and pressed, to separate any impurities; it is then put in a clean white glass bottle and diluted with boiling water to the consistency of cream, and to each pint of this solution 2 to 4 ounces of mercury added. The mixture should be shaken occasionally, and allowed to remain in the bottle for several hours. After this time the contents of the bottle may be poured into an evaporating dish, and all the black powder (which is now of no use) washed away by a stream of water under the tap. A small amount of amalgam only will remain in the buckskin after pressing, but this is equal to at least ten times the quantity of silver amalgam. It should be carefully preserved and treated in the manner I shall presently describe.

I have thus given in detail a process which, in my hands, has always been an eminently successful one, and which I commend for trial to the profession. With a little experience, the ashes, developer, and toning residue especially, may be reduced with but very little expense, and incomparably less labour than by the furnace and smelting method. Having treated the various residues as I have directed, the next and last step is to drive off the mercury, and thus obtain the precious metals in their pure state.

*How to Treat the Amalgam.*—Place the buttons of brittle amalgam upon a shallow dish of sheet iron, or upon an ordinary coal shovel, and expose them to a low red heat on a lively coal fire. Great care should be exercised that the cover of the stove fits tightly, and that the dampers are all open, otherwise the very deleterious mercurial vapour will pass off into the room. When the dish containing the amalgam has been at a dull red heat for about five or ten minutes, it may be removed. A button of pure gold or silver, as the case may be, is the result. The high heat in a few minutes volatilizes the entire mercury. When the button of amalgam is large it should be heated for about fifteen minutes, merely for the sake of certainty, as at a full red heat the process is completed in a much less time. When a considerable amount of amalgam is worked up, an iron retort must be made use of to volatilize the mercury, as it is both safer and more economical. It consists of a sort of iron cup or pot, having a closely-fitting cover, from which extends a small piece of bent iron tube. When in operation, the tube is dipped to the depth of about one-eighth of an inch in a basin of cold water, and the iron body, in which the amalgam has been previously placed, is put into a lively coal fire. The mercury is volatilized, and its vapour, coming in contact with the cold water, is re-condensed, and gathers in drops on the bottom of the dish.

## PIRACY AND INFORMERS.

SOME time ago we pointed out the dangers which attended a system in which hired spies were engaged to entrap the unwary into acts of piracy; and, whilst strongly condemning photographic piracy, we deprecated the systematic employment of informers whose only object is to secure a conviction and penalties by fair means or foul. A case has just been tried in Dublin in which the unscrupulous conduct of these informers called for the condemnation of the judge, and issued in a verdict for the defendants. A correspondent sends the following cutting from a Dublin paper :—

COURT OF QUEEN'S BENCH, July 4.  
(Before Mr. Justice Fitzgerald and a Special Jury.)

*Graves v. Mercer.*

This was an action by an eminent London publisher of engravings against a photographer resident at Belgrave Square, Rathmines, for damages, for having, as alleged, infringed of the law of Copyright, by selling a copy of an engraving called "Broken Vows," of which the

plaintiff possessed the copyright. It appeared that, in consequence of numerous piracies, the plaintiff employed persons to detect forbidden sales of his engravings throughout the empire, for the purpose of prosecution. Some time ago a person of gentlemanly appearance, named King, an agent employed by the plaintiff for this purpose, called upon the defendant, and pretended to be a hawker of pictures, and to want to buy some from him, to sell again. He gave a reference to some person in the trade, and the defendant desired him to call again, and in the mean time waited upon his "reference" to make inquiries, it being the custom, according to the defendant's statement, for persons in that line of business not to deal at once with strangers, because there were persons who were in the habit of endeavouring to gain access to print-selling establishments for the purpose of prosecuting the owners. When King called again, the defendant told him that his reference was satisfactory, and he accordingly entered into negotiations with him. Several interviews took place. King handed him a list of engravings which he wanted to purchase. These were all copyright. The defendant said, "Do you think any man in his senses would sell you these?" King said he could get them very easily in England. At length he consented to take others, and the defendant gave him a large collection to select from, which he asserted contained no copyrights. While King was selecting, he was called out of the room, and was absent for some time—for five minutes, according to King's evidence; according to the defendant's, for twenty minutes or half an hour. When he returned King pointed to a lot, which he said he had selected from the general collection he was desired to choose from. The defendant, in his evidence, stated that on counting those which King had selected, he discovered that there were several pictures amongst them which he had always considered copyright of late, and which he took to be dangerous to sell. "How is this?" said he; "I find several copyright pictures here." "They were," said King, "in the list that you told me to select from." "I doubt it very much," said the defendant, and asked him whether he had not been looking over some of the others lying in other parts of the room. King said he had not. The defendant said, "Well, in any case, wherever you got them, you cannot have them;" and he accordingly removed them from the lot. Defendant said he sold King four dozen photographs of non-copyright pictures at 18s. per dozen, but denied that at any time he sold him a copy of "Broken Vows." In reply to his counsel, he stated that any "Broken Vows" he had were smaller in size than the one produced on the part of the plaintiff, and alleged to have been purchased from him. He also stated that he had ceased the business of photographing engravings, and now confined himself exclusively to portraiture and landscape work.

The defendant, in reply to further questions, said that on the first occasion when King showed him the list of pictures he wanted, he said, "By the way, there are some of these that I have not got, and others that I have discontinued to sell since the difficulty about copyright arose." He added that he had not sold any copyright pictures during the last year and a-half or two years.

King stated in the most positive manner that he purchased several copies of "Broken Vows," one of which was that produced, from the defendant himself; that he did not steal any of them; that the defendant was present when he selected them; that the defendant saw what they were; that on the occasion when the defendant was absent he was only absent five minutes; and when he returned he only counted the photographs by the corners; and that no such scene took place as that deposed to by the defendant about finding copyright pictures in the lot selected by him, and refusing to let him have them.

A witness named Cattermole deposed that he went with King on one of those occasions, and remained for him outside, and when he came out he saw with him in the bundle he had purchased copies of "Broken Vows," and that when King was going in he (Cattermole) saw that he had none with him, in order that he might swear to that fact.

Mr. Justice Fitzgerald, in the course of his charge to the jury, said he could not commend the stratagem employed by the plaintiff's agent. It was one which no just mind could approve, and he was sure that Mr. Graves himself, now he had heard the facts, disapproved of it. The sole question for the jury, which altogether depended on the credit they gave to the witness, was whether or not Mercer sold to King a copy of "Broken Vows."

The jury returned a verdict for the defendant.

## MIXTURE FOR RETOUCHING NEGATIVES.

BY WILLIAM BELL.\*

THE exquisite effects of softness and half-tone portrayed in many of the French and German photographs recently imported into this country are secured by skillfully retouching the negatives. One or two processes have been described in your journal, but after considerable experiment I find the

\* Philadelphia Photographer.

following an excellent and practical method of preparing the material or pigment for use in retouching the negatives.

As alcohol and oil of lavender are both solvents of most negative varnishes, permit me to caution the experimenter that a rough, hard, or continuous stroke will cut though the negative, unless protected by a coating of albumen before varnishing. I proceed, therefore, as follows:—

After the negative is fixed and washed, flow with a mixture of—

Albumen ...	...	...	3 ounces
Water ...	...	...	3 "
Liquor ammonia...	...	...	1 drachm.

Dry, varnish, and retouch with the following described pigment. All shades can be produced with it so strong that no light can penetrate it; so fine that it will offer but little obstruction to light; and, after drying, cannot be removed except by strong alcohol and oil of lavender mixed. In fact, it becomes incorporated with the negative.

To make the pigment,—

No. 1.—Pyrogallie acid ...	...	...	20 grains
Water ...	...	...	30 ounces.
No. 2.—Nitrate of silver ...	...	...	240 grains
Water ...	...	...	20 ounces.

Add No. 1 to No. 2. Let it rest for two hours. Collect the reduced silver on a filter; wash and dry. When dry, take very thick negative varnish, and make a paste with it and the dried reduced silver. Again dry.

To use the above, take of—

Alcohol ...	...	...	$\frac{1}{2}$ ounce
Oil of lavender ...	...	...	$\frac{1}{2}$ ounce,

and mix them together. Dip the brush in the mixed oil of lavender and alcohol, and moisten the dried pigment. When the touches are put on with artistic judgment, the print from the negative will look like a retouched photograph that has been finely stippled with india-ink.

## MORE PIRACY OF ENGRAVINGS.

MR. JOHN HALL, a hawker of photographs, who has before been convicted of piracy, was last week charged before Mr. Tyrwhitt, at Marlborough Street, with selling a photographic copy of "My First Sermon," and some other pictures, the copyrights of which were the property of Mr. Graves.

Mr. George Lewis, Jun., appeared for the prosecution, and said that Mr. Graves's object was not so much to punish the prisoner as to discover the originators of this fraudulent system. One person who had infringed the Copyright Act had been sent to prison for nine months by Mr. Woolrych, and the judges had upheld the decision. He had to ask that the prisoner be kept in custody until Monday, as Mr. Graves wished, if possible, to find out with whom the prisoner was acting, the fraud having been carried on to a large scale. He had been for some time looking after the prisoner, and had advertised for him in the *Times* and *Photographic News*.

Mr. Tyrwhitt said it appeared to him there must be a large profit made out of this business.

Mr. Lewis stated that Mr. Graves had already spent £1,000 in tracing out this affair.

Mr. Graves having identified the prisoner, and said that he had been twice convicted at Bow Street, and each time fined £50, the prisoner was remanded until yesterday (Monday).

Mr. George Lewis, Jun., appeared for the prosecution; and Mr. Pullen for the prisoner.

Mr. Sutton, of Harrow, said, on the 27th of December last he was at Portsmouth, and saw the prisoner at North's Hotel, High Street. He had some conversation with the prisoner, in the course of which the prisoner offered him some photographs for sale, recommending them as cheap and good. He purchased one copy of "Morning Before the Battle," and a second of "Evening after the Battle." The prisoner told him he did not mind selling them to him, as he was a gentleman. On the 29th he purchased a copy of "Finding the Text," and of the "Good Shepherd." Afterwards he purchased a copy of "Waiting for the Verdict" and "The Acquittal," also "My First Sermon," "My Second Sermon," "Ordered on Foreign

Service," and "The Lost Piece of Money." The purchases he now produced; they were photographs of engravings and works the property of Messrs. Graves and Co. The prisoner travelled through the country selling these kind of photographs.

John Cattermole, in the employ of Mr. Henry Graves, said he was at Portsmouth on the 25th November, when the prisoner told him that he was the Mr. Hall who had lately been fined £75. He asked the prisoner to sell him some photographs, and the prisoner told him he could have them through Mr. Sutton.

Mr. Boydell Graves produced the certificates of the registration of the pictures above-named, and stated that, either directly or indirectly, the photographs produced were copies of the originals. The prisoner sold the photographs at about one-third the price of a genuine copy.

In reply to Mr. Pullen, Mr. Graves said he could not produce the assignments from the artists, in consequence of their destruction by the fire in the Haymarket.

Mr. Pullen took a legal objection on this point, but it was overruled.

Mr. Trywhitt could have no hesitation in ordering the prisoner to pay the penalty of £5 for each spurious copy sold by him, or a month in each case if default occurred. The trade of pirating copies appeared to be a very profitable one to some persons, and he had no doubt the prisoner would not be inconvenienced by the penalties he was now called upon to pay.

The penalties and costs, amounting to £51 2s., not being paid, the prisoner was locked up.

### SEPARATING GOLD FROM SILVER.

THE *Scientific American* gives the following description of the method employed in separating gold from silver in the United States Assay Office:—

The mixture of gold and silver is melted, and poured into water, by which it is granulated. The granules are placed in porcelain jars containing nitric acid. Heat is then applied, and as the acid boils, the yellow fumes, which our readers have doubtless so often seen proceeding from the chimney of the Assay Office, are given off. This process goes on for about twenty-four hours, when the jars are emptied, and in the bottom is found a brown substance resembling mud or anything else upon earth rather than "gold—glittering gold." It is, in fact, however, pure gold, or, at least, very nearly so. The silver has been dissolved by the nitric acid, and is in solution. It is carefully put aside for future treatment, for in the Assay Office nothing must be lost or wasted. The brown substance found at the bottom of the jars is placed in large wooden tubs and washed by percolation in warm water until all traces of acid have disappeared, and it is said to be "sweet."

The gold is then of .940 fineness. Formerly it was subjected to a second boiling in nitric acid, which left it about .993 fineness, but by the process at present in vogue it is treated with sulphuric acid, by which a fineness of .998 is attained. This is termed pure gold, although it is not actually so; but to deprive it of the two parts of alloy it now contains would involve an expenditure of time, money, and trouble altogether useless. After its treatment with sulphuric acid, the gold, which still looks more like red mud than a precious metal, is again washed until "sweet." It has now a reddish yellow line. After being dried, it is taken to a hydraulic press, where it is made into "cheeses," so called from the colour and shape. The cheese made in the Assay Office is richer far than the most fertile vales of Gloucester ever produced. Each "cheese" is about thirteen inches in diameter, but it is worth about 20,000 dollars. These cheeses are baked in an oven heated by steam until all remaining moisture is expelled, when they are remelted, cast into bars or bricks, assayed, and stamped with the weight, fineness, and value. And now they look like gold indeed.

The reader will remember that the nitric acid poured

over the gold and silver granules, in the porcelain jars, and now containing a large quantity of silver in solution, has yet to be disposed of. A solution of chloride of sodium—common salt—is first added to the solution, and a deposit of white powder is the result. This powder is chloride of silver. The next process is to free the chlorine from the silver, and this is done by placing it in vats with granules of zinc. The chlorine and zinc readily combine, and the silver is set free in the form of a light grey powder. This, like the gold, is washed, pressed, and formed into "cheeses" worth 800 dollars each. These are melted, weighed, stamped, and ready to be disposed of as occasion may require. The silver obtained by the above process contains but one part of alloy in 1,000. Some silver is so pure that it requires no "parting," and, after being assayed, is sent at once to the Mint.

The Assay Office was established in this city in October, 1854, and since that time over 160,000,000 dollars have passed through the hands of its officers.

## Correspondence.

### CARRIAGE OF PHOTOGRAPHIC GOODS ABROAD.

DEAR SIR,—Finding it impossible to forward collodion or any liquid, however innocent, by the Overland Routes to India and the Australian Colonies, through the false fear as to its liability to explosion, &c., existent in the minds of the directors of the companies who work these routes, and it being a great inconvenience to my customers to have their goods forwarded by sailing vessel round the Cape, I think it quite time some steps were adopted to abate the nuisance. Knowing thoroughly well the properties of collodion, you will, I think, agree with me, that when packed securely in tins, and, in addition to this, enclosed in a tin-lined case, no possible harm to other goods could ensue from contact on board ship. May I therefore ask the benefit of your valuable assistance in this matter, as it not only concerns me and other dealers in photographic requisites, but is of great moment to those who practise photography abroad?—I am, sir, your obedient servant, J. SOLOMON.

London, June 26th, 1868.

[The inconvenience involved by this determination on the part of the overland carriers is undoubted. With careful packing no serious risk need be involved; but the only remedy we can suggest is combination between the manufacturers and dealers to make such representations and place such pressure on P. and O. Company as shall induce them to relax the stringent rules in question.—ED.]

### PANORAMIC CAMERA.

DEAR SIR,—Will you allow me, through the medium of the NEWS, to give a description of a panoramic camera which anyone with a little ingenuity can construct for himself.

It consists in using a dark slide belonging to a Latimer Clarke's stereo camera, fitted on to the end of a quarter plate camera, and focussing the right-hand side of the intended view, and taking it on the left-hand end of a stereo plate; then turning round the camera to embrace the left-hand of the view, and taking this on the right-hand end of the same plate. You have a panoramic view about 6 by 3, only it has the disadvantage of showing a slight line down the centre of the view: but I am in hopes this can be remedied, and if I should succeed in doing it, I will send you full particulars and a print or two.

By blocking out the sky the join is very little seen, and altogether it is better than taking a view on two negatives and joining the prints.—Yours truly, THOMAS GULLIVER.

18, Union Street, Swansea, July 7th, 1868.

[The plan suggested by our correspondent, to whom photographers are indebted for many ingenious suggestions, has before been applied. Mr. Penny, of Cheltenham, some years ago sent us an example in which no traces of the junction of the two halves of the image is perceptible. Mr. Woodbury also, some years ago, sent an example from Java to the Manchester Society.

## Talk in the Studio.

**POISONING BY NITRATE OF SILVER.**—The *Union de la Sarthe* relates the following:—"The Abbé Salvy, vicar of Senonches, had been appointed to the Church of Saint-Denis-des-Fuits, in the Canton of La Loupe. Three inhabitants at the latter place arrived at Senonches to remove his furniture. The Abbé placed some bottles of cider in a corner of one of the waggons to refresh the men on the journey, and with them he brought a smaller bottle, well covered and tied up, which he told them they must not touch or permit any one to touch. The day being very hot, one of the men said, 'That must be right good stuff which the curé told us not to touch.' 'No doubt,' replied another, 'it must be far better than the cider.' 'Let us try it,' said all three. The bottle was produced. The man who took a good sup said it was not good. 'See,' said he, handing it to one of his companions. The second tried, and pronounced a still more unfavourable opinion. 'As it is so bad,' said the third, 'I shall not have any; let us put back the bottle.' Scarcely was this done than the two who partook of the liquid fell on the ground writhing in dreadful agony. In a short time both were dead. They drank a solution of nitrate of silver, which the abbé used for photographic purposes." In case of the accidental swallowing of nitrate of silver solution it should be remembered that a strong solution of common salt is the immediate remedy. The nitrate is by its aid converted into insoluble chloride, and is generally in this state got rid of by vomiting.

**MONUMENT TO FARADAY.**—The Royal Society has memorialised Her Majesty's Government in favour of the erection of a monument in Westminster Abbey to the memory of Faraday, at the public expense.

**MOULDS FOR THE GALVANOPLASTIC PROCESS.**—When the objects to be gilt, silvered, or coppered are of large dimensions, gutta-percha cannot be employed for moulds without much difficulty. Herr Kness recommends in this case the use of an artificial mixture which is obtained by melting together 6 parts of white wax, 2 parts of asphalt, 2 parts of stearine, and 1 part of suet. When the mixture has become perfectly homogeneous, lampblack is added, until the mass takes a fine black colour; finally, to give more body to the compound, and to prevent it adhering to the object, a small quantity of finely-pulverised plaster of Paris is added. The models must be previously covered with a thin layer of oil. The above mixture is then run on to them at a moderate temperature. If the latter is too high, the mixture adheres to the model. When cold, the composition is easily detached from the original.—*Scientific Review.*

**CRYSTALLINE PAPER.**—Puscher's process for ornamenting paper with silky crystals is to mix the gum made by heating commercial starch to 320° Fahrenheit, known as British gum, with equal parts of Epsom salts and of water, to which is added a small quantity of glycerine. After being brought to the boiling state the mixture is immediately strained. While yet coated with a thin solution of glue or gelatine. The paper, on warm it is spread with a camel's hair brush upon paper previously being dried, presents a beautiful crystalline surface. The size of the crystals may be varied by altering the strength of the solution, and by drying the paper more or less rapidly. Crystals of different tints may be made by mixing aniline colours with the solution, and preparing the paper with the white of eggs instead of gelatine.—*Ibid.*

**A NEW OPTICAL TOY.**—A new optical toy, called the kine-scope, is being made in Paris. It is a microscopic reproduction of the zoetrope, so well known with us. Its most remarkable feature is, that the objects in motion appear solid. This is obtained by making use of microscopic photographs encased in a little apparatus something like a Stanhope lens, and destined to be worn attached to the watch chain as an ornament. The effect of motion is produced by the rapid change of position of two images only. The little instrument, or ornament, forms an elliptical medallion, and the two photo-microscopic cylinders occupy the centre, being perpendicular to the thickness of the medallion. They represent the same object in two positions. The effect is produced by a very simple mechanism. The two photo-microscopic cylinders are encased in a guide surrounded by a caoutchouc membrane, on which is placed a vertical rod terminating in a button, which is outside the medallion. On

looking through the central aperture of the medallion one of the images only is seen; but in pressing the button with the finger, which pressure is communicated to the caoutchouc membrane, the relative position of the two cylinders is changed, and the second image succeeds the first before the latter has ceased to affect the retina.—*Ibid.*

**CRYOLITE GLASS.**—By melting 1 part of the mineral cryolite with 2 to 4 parts of pure silica, a beautiful kind of glass is formed; we believe it is the same to which the Americans have applied the term cast porcelain. The product is susceptible of being cast in a mould, it will take a fine polish, and can be manufactured into a great variety of useful and ornamental articles.—*Ibid.*

**A HANDSOME STUDIO.**—The *Liverpool Daily Courier* gives a long and interesting account of a new photographic studio recently opened by Messrs. Vandyke and Brown, in Liverpool. An extract from the description will interest many of our readers. The general style of the arrangement and decorations is described in "form and colouring as Pompeian, but there is an intermixture of Egyptian ideas in the lotus symbol on the staircase walls; of ancient Greek decoration in the key pattern of the borders and some of the stained glass designs. and of modern Greek ecclesiastical ornament in the very effective gas standard at the foot of the stairs. No violent anomaly, however, is apparent: the whole harmonizes and the general effect of the 'grand Pompeian entrance-hall,' as it is termed, is decidedly agreeable. Of the luxurious appearance of the general reception-room, and of the ladies' boudoir attached, we can only speak superlatively, and say that, in the latter apartment especially, there is an air of magnificence which is only not regal because of the evidences of 'business' which lie scattered about, in the shape of exquisitely finished portraits in every style, from the tiny medallion to the enlarged cabinet picture for display after the manner of the old orthodox family portrait in oil. The operating-room, or studio, is said to be the largest in England; it is fitted with every known improvement in the various matters already indicated, and the numerous other workrooms for finishing and mounting are on the same complete scale."

## To Correspondents.

**REDCAP.**—A great variety of materials may be used for a curtain in a photographic studio, each of which will yield a good result, so that it is quite impossible to say which is best. It depends entirely upon circumstances, upon the effect you want, upon the character of the other accessories, and upon the kind of light in the studio. Tabaret is a good material, so is repp; perhaps nothing is better than velvet; cotton velvet answers well, and is cheap. The colour may be green, dark blue, maroon, or a sober tint which does not come out too light. You will doubtless be able to get the proper article from a local draper.

**ENAMEL.**—From a hasty examination of the cards we do not think that they contain anything injurious to the photograph. More time and careful examination would be necessary for a decided statement.

**A. B.**—Some samples of paper are undoubtedly more prone to meanness than others; but the actual cause is generally the state of the toning bath. If your acetate bath tones slowly, it is probably due to the use of an impure sample of acetate of soda. You will at least be free from the meanness when the toning is slow. Try the addition of a few drops of a fresh solution of gold if you wish to accelerate the toning. The brown precipitate you describe is the result of something having been introduced into the bath which should not, either by want of cleanliness or in some other way. Are you quite certain that your fingers had not touched hyposulphite and then touched the toning solution? or that the dishes had not been used for washing prints? Hard water is *not* pure water, and when water is very hard it usually contains a variety of lime salts; what it is impossible for us to say. Use for your toning bath distilled water. By chalk we mean carbonate of lime. You had better procure it of a chemist. A bath made with it will usually keep, if placed in the dark. Strengthen by adding fresh concentrated gold solution and a little hot water. Read Mr. Bovey's recent article on toning.

**YOUNGSTER.**—An orange or deep yellow is best. If the light be quite non-actinic you may have plenty of it without danger. The use of light yellow calico or glass gives an admixture of white light which is dangerous. 2. Do not paint, but varnish, the wooden trough. 3. It is the practice of photographic colourists of the

present day to use albuminized prints for colouring; but, to a person more familiar with ordinary water-colour drawing than photographic colouring, plain salted paper will present the least number of difficulties.

**JOHN HILLEY.**—There will be an agent, we believe, for M. Carrier's paper in this country, which will doubtless be duly announced. We cannot say at present whether any greater permanence is promised by his process. 2. We do not know of any practicable carbon process besides Swan's. The method proposed by M. Marion would be, we believe, an infringement of Mr. Swan's patent. Mr. Blair has worked with praiseworthy perseverance at carbon printing, but we do not know of any practicable process he has proposed which might be used as a substitute for Swan's. 3. The patent rests chiefly, we should say, on the use of a distinct tissue which permits printing on one side and washing away on the other, and on the modes of transfer employed. We do not know of any one who touches carbon printing.

**E. MORGAN.**—You will find the formulae you require in any good manual of photography or in any of our YEAR-BOOKS. The cause of the discolouration of your toning bath is probably contact with dirty fingers, especially with fingers which have touched hypo; or possibly the use for the toning bath of a dish in which prints have been washed, to which some trace of hypo may cling. Our engagements do not permit us to answer questions of this kind privately.

**T. P.** (or some similar initials very carelessly written).—The prints enclosed are pretty good, and the negatives are not bad, but a little under-exposed. We cannot give you any idea of what salary you might obtain or be worth.

**AN ENQUIRER.**—The construction of your studio will doubtless have to be subject to the control, in certain respects, of the local authorities. Different towns are under different forms of local government, and all public buildings must conform to certain conditions laid down by such government. In your case it is probable the Board of Health will possess such power. As a rule, wooden buildings are not permitted, because of their liability to fire.

**B. N. P.**—The strength of the ethereal solution of wax is not important, the chief object being to obtain on the plate an almost imperceptible film of wax, which, being a neutral substance, prevents chemical action from any dirt on the glass. The use of wax for such a purpose is an old idea, but how old we cannot with certainty say. About four years ago it was proposed by Mr. Wenderoth to be applied to the glass to aid in transferring operations. Mr. Henry Cooper at that time called especial attention to its value in giving immunity from the influence of dirt. Its subsequent recommendation for use on dry plates of course was not original. The remarks and the ignorance to which you refer were alike characteristic, but are not worth comment.

**VERITAS.**—The lighting of the figures is pretty good; in Nos. 1 and 3 the negatives have been over-intensified. In all, the tone is good of its kind, but is blacker than we like. We cannot give you much information as to the chances of obtaining a situation, such questions being somewhat out of our province.

**THOMAS STOTHARD.**—The deposit of silver on the sides of the bottle holding the printing solution is due to the presence of organic matter, such as albumen, which has a tendency to reduce silver, especially if white light has reached the bottle.

**DR. STANTHURPE.**—It is important to remember that the only light which is of any real value in illuminating the sitter is that which falls directly upon him from the sky. To ascertain how much of this reaches the model in your studio place yourself in his position and note the amount of the sky which you can see. We fear, from the diagram, that much of the light which enters your studio does not reach the sitter directly. The top-light is not sufficiently in advance of the sitter, but is directly over-head; and the still more important side-light will scarcely reach him at all, being cut off by the projecting portions of wall belonging to the folding doors. If these could be removed, and the side windows extended laterally on the north side, and also taken quite to the eaves, you would gain much additional light of great value in illuminating the figure; or, failing that, if you could extend the north window at E an advantage would be gained.

**J. C.**—Pinholes may proceed from a variety of causes, of which the most common is the excess of iodide of silver present. We cannot from any general description of results indicate the precise cause. The only mode in which a defect can be traced home to its cause consists in a series of exhaustive experiments, beginning with the most simple and probable sources of error. Read the chapter devoted to the subject in our YEAR-BOOK. Especially try the plan of keeping the bath cool by placing it in cold water, or tying a wet cloth round it.

**FOURTH VOLUME.**—The task of copying coloured drawings on old discoloured parchment is rather a difficult one, and probably several essays will have to be made before succeeding. Use a collodion containing a full proportion of bromide, expose well in as good a light as possible, and develop with a weak iron solution.

**C. A. S.**—The affinity between gold and chlorine is very slight, and

the slightest excess of heat will drive off the chlorine and leave metallic gold. From your description it appears that a portion of the gold is converted into protochloride of gold, which is insoluble in water, and is often decomposed by its throwing down metallic gold. Take care in evaporating to preserve a low temperature, and before the evaporation is complete be content with a slightly acid solution, and neutralize with carbonate of lime. 2. Mr. McLachlan resides at Manchester. The sample of nitrate of silver he prefers was found on examination to be pure nitrate of silver. 3. You can obtain nitrate of magnesia of your London dealer; or you may make it by neutralizing nitric acid with carbonate of magnesia. 4. We cannot decipher your question as to citric acid.

**W. J. A. G.**—Matt silver stains are of various kinds, and spring from various causes. The character and form of the stain afford some clue to the cause; but you do not describe the exact character. If they run from the edge of the plate it is probable that they arise from contact between the nitrate of silver and the inner frame of the dark slide, and that is a more common cause than is suspected. We can only counsel you to read the various articles which have appeared on the subject in our last two or three volumes. Be careful to wash the inner frame very thoroughly; let the plate rest on blotting-paper; use a somewhat weak bath; and avoid the use of a horny, repellent collodion. We shall have something more to say on the subject in an article next week. We prefer 2, 4, or 5 of the collodions named.

**SILEX.**—We are obliged by the sample of carbon printing you have forwarded, and we shall examine the matter carefully. So far as we have had time to give to the matter at present, we find your description quite correct; but it also appears to us that the edge of the white card on which the discoloured portion is mounted has become somewhat yellow, indicating that the same cause has acted on the card which has tarnished the purity of the print. 2. The damaged collodio-chloride print is a charming picture. The cause of the film splitting and leaving the paper is partly due to the use of unprepared paper, but still more to the use of an unsuitable sample of collodion. It gives a film of the horny contractile kind, which readily splits. A more powdery, adherent sample should be used. The high glaze of this sample at once indicates the horny character of the film. A more powdery sample would give a surface with more of the matt character. We have met with splitting films, but it is a difficulty we have removed at once by using a suitable collodion. We shall have pleasure in seeing a perfect print from the same negative. Thanks for the paragraph, which we shall have pleasure in using.

**J. H. BRUCE.**—Thanks.

**THE DEFENDANT.**—A report of the matter was in type when your communication reached us. It shall have our attention.

The continuation of Lieut. Waterhouse's Articles on "Photozincography," and several other articles in type, are compelled, from the pressure on our space, to stand over.

Several Correspondents in our next.

## PREVENTION OF STAINS ON NEGATIVES IN HOT WEATHER.

THE recent hot weather has brought into operation the train of summer difficulties with which photographers are familiar. Matt silver stains and other markings—the result of the silver solution drying or concentrating on the film if the plate be kept more than a few minutes before developing—pinholes, and similar troubles, have been prevalent, as we learn from the letters of many correspondents. We do not intend here to enter into a re-discussion of the various remedies which have been proposed and tried with more or less of success. For information on almost every form of the defects in question, and for details of the various remedies, we must refer our readers to many articles published in our previous volumes.

We wish now to call attention to the practical working of one of the remedies for matt silver and other stains, which we recently saw in very efficient operation in the establishment of Mr. Hughes, at Ryde. The remedy in question consisted in washing the excited plate in distilled water as soon as it was removed from the nitrate bath. This, it will be said, is not new; and the observation will be unquestionably true. The novelty and the especial efficiency consist in a very small item in the operations. When a plate has been washed in this way it is necessary to restore the free nitrate which has been removed to aid in the operation of developing. Two or three modes of effecting this have been tried. One method consisted in adding a little free nitrate to the developer. The disadvantage of this method was a tendency to irregular and patchy development; and unless the plate had received considerably longer exposure than it would have required when unwashed, a hard, under-exposed negative has been the result. A more even development has been secured when the plate has been covered with a little of the nitrate solution previous to applying the developer, and a better result still when the plate has received a momentary redip in the nitrate bath prior to development. But still it has been found that an unusually prolonged exposure was necessary to secure a good negative, and an impression has prevailed that a washed plate was less sensitive than a wet plate in its normal condition. That this impression is erroneous we have recently had opportunity of proving satisfactorily. The whole secret of success depends on the time the plate is permitted to remain in the bath on redipping: sufficient time is necessary to permit the film to become thoroughly permeated again by the nitrate solution. It seems that each atom of impressed bromo-iodide of silver requires the contact of free nitrate of silver in order that the proper reduction may be completed by the developer. The plate which, receiving only a momentary redip sufficient to cover its surface with the silver solution, would yield a thin, hard, under-

exposed image, will, when left sufficient time in the bath in redipping, yield a fully-exposed, detailed, and vigorous negative, always exquisitely clean, uniform, and free from defect. The time which the plate should be left in the bath in redipping in order to secure these results is from forty to sixty seconds. The first plate so treated in our presence was of large size (14 inches by 10 inches), and was kept upwards of an hour on an excessively hot day; but it developed satisfactorily, giving a clean, detailed, and vigorous negative. Any tendency to drying of the film is, of course, unimportant, as the whole becomes uniformly saturated again with the nitrate solution.

Many photographers will not care to undertake this extra labour, except in cases where, from any cause, long keeping of the plate between exciting and developing is necessary; but it may be used, nevertheless, without much trouble, by all who suffer from matt silver and other stains in hot weather. The operation is simple: it consists in the use of a dipping bath of distilled water, into which the plate is plunged as soon as it has acquired a creamy film in the nitrate bath. Immersion for a minute or two in the distilled water, with agitation of the plate, gives the film sufficient washing, and the same bath of distilled water may be without disadvantage kept in use all day, and, if necessary, used for two or three dozen plates.

Practically, it would follow that the plates immersed in the bath which had already washed a few dozen plates are in reality placed in a dilute nitrate bath, another mode of securing immunity from many of the troubles of hot weather. Some years ago we recommended the use of a second new uniodized nitrate bath as a means of getting rid of pinholes and stains. We found, in the course of the experiments made at that time, that after exciting the plate in the usual way, immersing it in an uniodized 10-grain nitrate bath secured immunity from many difficulties, and yielded on development a perfectly good negative, without redipping, the weak silver solution serving every purpose necessarily in the operation of development, having, perhaps, a tendency to give more detail and less density than when a stronger solution was present. During the prevalence of the extremely hot weather we recommend the attention of these suggestions to any of our readers who are troubled with stains and other defects which are brought about by high temperature.

## SENSITIVE ALBUMINIZED PAPER PRESERVED READY FOR USE.

WE were favoured a few days ago by a visit from M. Romain Talbot, who introduced to our attention some samples of M. Carrier's preserved sensitive albuminized paper, which is stated to keep indefinitely without deterioration, and without requiring any especial care in its

storage beyond the matter-of-course necessity of darkness. It is stated to be unalterable at all temperatures, and to be quite unaffected by humidity in the atmosphere.

Time will be a necessary element in presenting our readers with the results of our own experience with the sample of paper left in our hands, but we may briefly mention such facts as are before us. The paper is apparently *Saxe*, and possesses a good albuminized surface. We are informed that it has been sensitized some months, and it is perfectly purely white without the slightest indication of discolouration, or tint of any kind. Some prints which have been printed some months, but not toned or fixed, are equally unsullied and pure in the whites. The colour of the image is of a mauve or lavender tint, and on proceeding to print upon the paper we obtained an image of similar tint. The time of exposure was, as nearly as we could estimate, about the same as for ordinary albuminized paper. A special toning bath is recommended, which as yet we have not tried. It consists of—

Common water	...	...	...	1 litre
Chloride of gold, or, better still, the double chloride of gold and potassium	...	...	...	1 gramme
Chloride of cadmium	...	...	4 to 10 grammes	
Sulphocyanide of ammonium	...	...	100 "	

This, in round numbers, gives 1 grain of chloride of gold, 10 grains of chloride of cadmium, and 100 grammes of sulphocyanide of ammonium in a little more than 2 ounces of water. The prints are to be fixed and washed as usual. The prints we tried in an old toning bath we had ready gave a variety of good tones, the whites of which remained very pure and brilliant in all cases. So far as we can judge from the hasty experiments already made, the paper is better suited to vigorous negatives than soft ones, rendering, with much delicacy, all the gradations in negatives usually yielding hard pictures: with a soft negative the prints we have tried lacked vigour. There is clearly no free nitrate present; but whether any other salt, except chloride and albuminate of silver, we have not yet ascertained. We shall test the paper from time to time, and report on its continued keeping properties.

The convenience, especially for amateurs, of possessing sensitive paper which will keep good indefinitely, and is always ready for use, is doubtless very great. The price is a little more than double that of ordinary albuminized paper. A preserved sensitive matt paper at a still higher price is mentioned, but we have not seen it nor any pictures produced upon it.

#### RECOVERY FROM CYANIDE POISONING.

A CASE of violent poisoning by cyanide of potassium or prussic acid was treated with great success on a recent occasion at King's College Hospital. A little boy about six years of age, the son of Mr. Spooner, a hatter in Holborn, was brought to the hospital in a comatose state, with rigid spasms of the muscles of the jaw, so that the mouth was closed and the teeth firmly clenched. It appeared that he had been drinking from a bottle containing a fluid labelled "Warranted not poisonous," which, on analysis, however, was found to contain a large quantity of the poison in question. The child was admitted to the hospital within ten minutes of its having swallowed the liquid, and its mouth was at once forced open, by means of a spatula, sufficiently wide to allow of an emetic of mustard and water being administered; the patient's throat was likewise tickled with a feather, but neither treatment was sufficient to produce vomiting. The house-physician then reluctantly had recourse to the stomach-pump, forcing the mouth wide open by means of an instrument, in order to introduce the apparatus. The stomach was well washed out, and all the poison contained therein removed, so that the object yet to be attained was to keep the patient alive until such of the

poison as had already been imbibed by the system was eliminated by the lungs, &c. As the child was evidently sinking, the limbs becoming quite rigid and blue, it was quickly undressed and placed alternately in a hot and cold bath, which had the desired effect of partially rousing the patient. After treatment in this manner for about twenty minutes, the child again began to succumb, and artificial respiration was then tried, in conjunction with constant friction of the body towards the heart, to keep up the circulation. This was continued for some time, and afterwards a galvanic battery was placed in connection with the limbs, and a current of some intensity administered. By this means the patient was just kept alive, and while still in a very precarious state it was put to bed with mustard poultices applied to the feet. After a period of five hours from the time of its being taken ill, the child began to show signs of consciousness, crying out from the pain caused by the poultices; and in a few hours more all effects of the poison had totally disappeared.

#### THE COFFEE DRY PROCESS.

We printed a short time ago an account of some comparative experiments with dry processes by Dr. Towler, in which he found, contrary to the experience of many others, that coffee plates did not keep well. Col. Baratti, the originator of the process, points out, however, in our Philadelphia contemporary, that the coffee process described by Dr. Towler essentially differs from the process of the inventor. He says:—

"Dr. Towler takes—

Water	...	...	...	5 ounces
Coffee, roasted and ground	...	...	...	6 drachms
Loaf sugar	...	...	...	3 "

Boil the mixture for five minutes, then allow to settle, &c.; coat the plates, and finally let them dry. That is all.

"My process is much more complex:—

"*Collodion—Silver Bath—Developer*.—Everything is combined together, and all should be carried on with the greatest precision to obtain the result which I infallibly arrive at. Even the preservative of Dr. Towler is not according to my formula, for we read in the *Camera Oscura*:—

#### "PRESERVATIVE SOLUTION.

Water	...	...	...	300 grammes
Ground coffee	...	...	...	30 "
Refined sugar	...	...	...	15 "

Put the ground coffee and sugar into a bottle, then pour in boiling water, and cork up. When cool, filter.

"Why did the Professor boil the coffee five minutes? And the developer? He uses—

Double sulphate of iron and ammonia	...	...	...	3 drachms
Water	...	...	...	4 ounces
Nitro-gelatine	...	...	...	40 minims
Alcohol	...	...	...	40 "

"I, on the contrary, have directed—

Distilled water	...	...	...	300 grammes
Double sulphate of iron and ammonia	...	...	...	7-50 "
Crystallized sugar	...	...	...	7-50 "
Sulphate of copper	...	...	...	7-50 "
Citric acid	...	...	...	15 "

"Is it not probable that all these changes enter for something in the final result? But even more than this, I recommend, as a condition, *sine qua non*, to dry the plates over the fire after having treated them with the preserving liquid. For this purpose I use a tin box filled with very hot sand or boiling water, kept at the highest possible temperature by means of a spirit-lamp; and after that I put them in a box with chloride of calcium on the bottom, so that the collodionized surface takes the appearance of a very brilliant varnish, contrary to the conclusion of the learned

Professor. The least trace of dampness, which at times is condensed on the plate in passing from one ambient to another, is an infallible cause of non-success; and it has sometimes happened that I could not produce the least shadow of an image, even after an exposure of ten minutes, whilst, with my ordinary method, plates prepared twenty-two months back gave me excellent negatives after ten seconds of exposure; and after twenty-four hours I guarantee the instantaneity, provided that there are no deviations made from my prescriptions.

"Besides, my process is much used in Italy and elsewhere, and every one is satisfied. It would not be so if, as Dr. Towler affirms, the sensitiveness of the plates lasted only one or two days. Many professional photographers make use of it for portraits; and the Signor Chevalier Marini, of Genoa, wrote to me a year ago: 'Since I tried your process I always prepare my plates at night, and the next day I make use of them for portraits, as the customers arrive. What an economy of time for me, and a saving of annoyance for them!'

"Now I have introduced radical modifications in my process; it is even more simple, more sure. On one hundred plates exposed, if the sitting is good, not one will fail. I have proposed to the French Photographic Society to send one dozen plates, so that they could be tried at different times. I will give them the time of sitting for each difference, and I am sure that the result that I have indicated beforehand will be reached. I have so much confidence in the coffee preserver, and I have always obtained such fine results, that I should like to see it tried by all landscape photographers; but exactly according to my formula, otherwise I can promise nothing, and new experiments would have to be made."

Mr. Jex Bardwell, in the same journal, states that his experiments with coffee plates has been much more satisfactory than that of Dr. Towler. Speaking of the first batch of plates he tried, he says:—

"I found them everything I could wish, they being much less trouble to prepare than by any dry process that I have found at all satisfactory; very clean, free from streaks or fog, full of detail, and very sensitive, and, I must say, a good keeping plate, for the last one I tried, being within a few days of four months old, gave me a good result with thirty seconds' exposure. The plate was every way good, clean, free from fog, and intensified as free as a new plate. The coffee plates are eminently free from that hardness so often seen in a dry plate. I have had considerable experience as a dry-plate worker, and have none to suit me so well. I even use dry plates for solar landscape negatives. I cannot say too much in favour of the coffee process, and can assure the dry-plate worker that it is one every way worthy of his confidence. I look on pyrogallic acid as the proper developer for a dry plate, and if the Professor will but try the coffee plates on their own merits, and not in testing an iron developer, he will come to different conclusions."

In our friend Dr. Towler's experiments, aiming at the uniform treatment in development, and estimating results under such treatment, is, perhaps, scarcely a fair mode of judging the value of a process, since almost every kind of dry plate requires its own special development to secure the best results.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XXV.

"The exclusive power of chiaroscuro is to give substance to form, place to figure, and to create space. It may be considered as legitimate or spurious; it is legitimate when, as the immediate offspring of the subject, its disposition, extent, strength, and sweetness are subservient to form expression and invigorate or illustrate character, by heightening the primary actor or actors

and subordinating the secondary; it is spurious when, from an assistant aspiring to the rights of a principal, it becomes a substitute for indispensable or more essential demands."—*Fuseli*.

#### CHIAROSCURO.

The natural and simple effect of light, with its attendant shadow on objects, is given with greater truth by good photography than by any other method of delineation, although in ignorant hands it may degenerate into weakness, or, as is more often the case, take the form of patches of black and white unconnected by gradation. However, in these chapters I assume that the student is a good manipulator, and has a sufficient technical knowledge to render it unnecessary for me to say anything on that part of the subject; I shall therefore confine myself to a consideration of how best light and shade may be arranged so as to produce the most beautiful and striking pictorial effect. A knowledge of how to mass light and shade, with its intermediate gradations, connecting one with another, to which the name of chiaroscuro has been given, is most necessary for the student to attain, and can only be thoroughly learnt by careful observation of nature and the study of the works of those masters who have excelled in this important branch of the art; there are a few simple rules, however, a knowledge of which will assist the student in his further studies in this direction. It is to these rules that I now propose to call his attention.

Chiaroscuro not only lends a "something more exquisite still" to the most perfect outline, but clothes an inferior design with a beauty it would not otherwise possess. This is notably the case in the pictures of Rembrandt, often ill-drawn, always vulgar in choice of form, but of priceless value for their marvellous chiaroscuro, the alchemy of his art transforming dross into pure gold.

That which, as a mere sketch, was flat and monotonous, when clothed in cleverly managed light and shade stands forth as a reality. It gives depth and roundness and space; it also contributes infinitely to expression and sentiment; likeness even can be altered by the way in which this great power is managed. If it be remembered that by the minute modifications in the place, form, and depth of shadows, the whole of the infinite range of expression of the human face is determined, the importance of judicious lighting and skilful disposal of shadows will be pretty well appreciated. Many of my readers will remember the marvellous exhibition of Herr Schultz, at the Egyptian Hall, who exhibited every ethnological type on his own face, principally by the aid of lights and shadows skilfully cast from different directions. The magic of light and shade has become a proverb.

The word chiaroscuro, derived from the Italian, and literally meaning light-dark, by no means clearly conveys the idea of what it is intended to express. Usage has, however, reconciled us to the use of the term to express, not only the means of representing light and shadow, but the arrangement and distribution of lights and darks of every gradation in masses in a picture so as to produce pictorial effect—just as the word composition is used to express the arrangement of lines.

The objects of chiaroscuro are, first, to give a pleasing general effect to the whole picture, by dividing the space into masses of light and shade, giving breadth of effect, and preventing that confusion and perplexity incident to the eye being attracted by numerous parts of equal importance at the same time. Secondly, to place before the spectator at once the principal object represented, so that the eye may first see it, and be gradually and insensibly led to examine the whole picture; to keep parts in obscurity, and to relieve others according to their pictorial value. And, thirdly, to aid the sentiment and expression of the picture.

It will be seen that I have omitted relief as one of the objects of chiaroscuro. There is no doubt that a certain amount of relief is of advantage to a picture, but to strive too much for this quality would be sacrificing a much greater advantage—breadth—for the sake of an effect which could not, in a picture, be made to compete with the perfect manner in which it is given in a toy—the stereoscope. Relief is not the object of the picture. If it were, the artist

would have to first see the place where it was to be hung, that he may see the direction in which the light would fall upon it, and his chief consideration would be that the objects in the picture should be lighted by the window of the room, his chief aim to produce an illusion, perhaps the most vulgar thing in art. Twining, in his "Philosophy of Painting," says on this subject, "Although relief may be considered as an additional advantage, and deserves attention as long as other points are not sacrificed to it, the artist would decidedly take a false view of the calling of art who would set it up as a goal, directing towards it all his exertions; and, fortunately, to strive, as some have done, for this kind of eminence, generally involves the neglect of other attainments which ought to have stood foremost. We cannot expect to see those powers which, like projection and relief, may be termed practical, imitated in perfection, with those which, like expression and beauty, are fruits of the imagination and sentiment; our physical nature is opposed to it. But in the picture, *chiaroscuro*, or light and shade, has other purposes to fulfil than those which in nature serve to mark the rotundity and projection of form. A happy distribution of the lights and shades becomes of itself a source of pleasing effect and beauty; at times, by concentrating the effect, and consequently the impressions of the observer, towards a given point; at times by extending the interest, with the dispersing of the lights, over a wider scene. It is towards the attainment of effect that the varied resources of light and shade are thus chiefly directed. Without this enlivening principle the eye of the observer, satisfied with a first glance at a picture, would immediately seek for recreation and amusement elsewhere, so necessary it is that favour and attention should be won in the first place by the external appearance, in order that those more hidden perfections which are the result of profound thought and assiduous study may in turn receive their due consideration."

I may quote a much greater authority to the same effect. Sir Joshua Reynolds says:—"This favourite quality of giving objects relief, and which De Piles and all the critics have considered as a requisite of the greatest importance, was not one of those objects which much engaged the attention of Titian. Painters of inferior rank have far exceeded him in producing this effect. This was a great object of attention when art was in its infant state, as it is at present with the vulgar and ignorant, who feel the highest satisfaction in seeing a figure which, as they say, looks as if they could walk round it. But however low I may rate this pleasure of deception, I should not oppose it did it not oppose itself to a quality of a much higher kind, by counteracting entirely that fulness of manner which is so difficult to express in words, but which is found in perfection in the best works of Correggio, and, we may add, of Rembrandt."

It is admitted by all writers on the subject that mere natural light and shade, however separately and individually true, is not always legitimate *chiaroscuro* in art. In nature generally light is shed indiscriminately on all objects, subordinate objects may be brought prominently forward, and important features may be cast into the shade. It is not so with art. Art must select and arrange, or it is no longer art. But although separate truth may not be true art, true art requires that there should be no absence of truth; but the truth must be represented as a whole. Hence arises the indispensable necessity of judicious selection in the subject and treatment of a picture, so that art may be observed and truth preserved. In no part of art is judicious selection of more consequence than in the choice of light and shade, because light and shade so governs and contracts the effect of a picture that a subject may be either beautiful or the reverse, according to the way in which it is clothed in light and shade. Photograph a landscape with the sun shining at the back of the camera, and the effect will be flat, tame, and uninteresting; take the same view with the light coming at the side, and the difference will be evident; the magic of *chiaroscuro* will be at once felt. Barry, speaking of the scenes about Hyde Park, Richmond, Windsor, &c.,

says: "The difference between a meridian and evening light, the repose of extensive shadow, the half lights and catching splendours that those scenes sometimes exhibit, compared with their ordinary appearance, do abundantly show how much is gained by seizing upon those transitory moments of fascination when nature appears with such accumulated advantage. If this selection be so necessary respecting objects intrinsically beautiful, how much more studiously ought it to be endeavoured at when we are obliged to take up matters of less consequence. How many of the deservedly esteemed productions of the Flemish and Dutch schools would be thrown aside, as intolerable and disgusting, were it not for the beautiful effects of their judicious distribution of lights and shades. Art is selection; it is perfect when this selection is pursued throughout the whole, and it is even so valuable, when extended to a part only, as to become a passport for the rest."

It is interesting to note here, incidentally, that Barry does not say that art consists in the manner of holding a pencil, or laying on colour, or handling a modelling tool; he does not even say that it consists in the embodiment of the imagination by means of these implements, but he distinctly states what has been denied by some modern critics when dealing with photography, that *art is selection*, and is most perfect when the selection is the most judicious.

It is the same with portraiture as with landscape photography: beauty will depend in a great measure on treatment. Take a beautiful face, place it fronting the light, and photograph it; the result will be flat and even, in some cases ugly. The most amiable face may be made to look cross, and even savage, by excess of top light. It is strange that the effect of light on the face is not more studied on the stage, where facial expression is seriously interfered with by the unnatural effect of the light coming from below.

Light and shade are always at our command, in portraiture at least, and in some degree in landscape, to compensate for our inability to regulate the drawing to any great extent. I do not say we can, like the enamellers, make an ugly face "beautiful for ever," but we can make a beautiful picture out of ugly objects if we can throw over them the glamour and witchery of perfect *chiaroscuro*.

## PHOTO-ZINCOGRAPHY IN PRACTICE.\*

BY J. WATERHOUSE, R.A.

### TRANSFERRING TO ZINC.

THE transfers are trimmed with a pair of scissors, and all parts not required to transfer are cut away or stopped out with a composition of flour paste coloured with vermilion. Any faulty parts or corrections may be put in with a fine pen and the ordinary autographic ink used by lithographers. Several sheets of waste paper (spoiled prints, &c.) should be damped, and kept on a table under a board; a few damp sheets of clean demy paper will also be required.

The transfer is then placed between the sheets of damp paper, and allowed to remain for a short time, during which the zinc plate is placed on the press, wiped with a dry muslin rag, taking care not to touch the grained surface with the fingers; lay on it two or three sheets of clean paper, and pass it through the press once or twice till the pressure is regulated. Examine the transfer, which should not be very damp (experience is the only guide); if damp enough, take it out, lay it down carefully in the place it should occupy on the plate, over it lay a sheet of clean damp paper, and over this a sheet or two of dry paper. If the transfer is new, once passing through the press is sufficient. The effect may be examined by gently lifting one corner; if all the ink has not left the paper, turn the plate and pass it through the press again, slightly increasing the pressure. The transfers will be found closely adherent to the plate. Damp the back of it with sponge and water, and after a few

\* Continued from p. 335.

minutes, or as soon as the white parts appear loosened, gently remove the paper. If the operations have been properly carried out, the ink should have been almost entirely removed from the paper. The plate is now washed with water and a soft sponge, to remove all traces of paper and gelatine, and is fanned dry with a fan made of a stiff piece of cardboard inserted in a wooden handle. Should any corrections be required, they may be made with pen and transfer ink or with an etching point, as will be afterwards explained under the head of "Corrections." It is sometimes advisable, especially if the work is delicate, to let the plate remain a little time before etching, and also to warm it slightly, which causes the plate to absorb the greasy ink more perfectly, and strengthen the fine lines. The plate is now ready for etching; but before describing that operation I will give an account of the plan to be pursued in joining together several transfers on the same plate. If the work has been copied in sections, and it is desired to join all the transfers together, attention to the following directions will secure good results:—

1. A liberal margin must be allowed all round the sections.

2. All the sections must be copied under precisely the same conditions, so as to correspond exactly in size. The least shifting of the camera or plan-board will be sufficient to throw them out.

3. The transfer must be of the same age, otherwise some may transfer and some may not. To join the transfers, have ready a drawing-board, and two or three sheets of clean

paper, some pins, and some thick gelatine solution. Cut the black edges off the transfers, lay them down face upwards on the paper in their proper position, and select the best lines for cutting them, which should run as far as possible in blank spaces, crossing the work as little as possible.

Only one transfer is cut as a rule, but parts of the other one may be made available if desired. Now, with a pin, fasten down any two corresponding points on both transfers, and do so in as many points as may be required. When the work has been all fitted together, take some of the gelatine on a fine brush, and put a little between the transfer here and there, but not close to the edge of the join, or there is a danger of its spreading over the lines and spoiling the transfer; when this is dry take out the pins, gently turn the sheet over, cut away the paper of the under transfer to within half an inch or so of the joins, and pass the gelatine under the joins, and let it dry. The sheet may now be removed to the damping-book and treated as before. If the joins are too apparent on the zinc plate, any blank spaces may be filled in with a pen and transfer ink, or scratched in with a point, and any thickening of the lines may be reduced with the point of an eraser.

The plate must now be etched in order to fix the design on it and render the surface of the plate more capable of retaining moisture; this is done with a mixture of weak acid, tannin, and gum water. The theory of its action is not thoroughly understood, but it is supposed that the acid dissolves the oxide from the surface of the plate, and, by slightly corroding it, forms innumerable little hollows which retain moisture; the acid also decomposes the alkali con-

tained in the ink, and renders it insoluble. It is supposed that the gum and tannin combine with the surface zinc, and form an insoluble layer which preserves the zinc from the immediate contact of the water, and renders it more susceptible of receiving, without alteration, water and gummy liquids. The etching, also, draws off all dust and greasy stains, and increases the sharpness and vigour of the lines. The etching liquid is prepared as follows:—1 quart decoction of galls; 3 quarts gum water, about as thick as cream; 3 ounces phosphoric acid. The decoction of galls is prepared by soaking 4 ounces of bruised Aleppo galls in 3 quarts of cold water for twenty-four hours; the water and galls are then boiled up together, and afterwards strained.

The phosphoric acid is prepared by placing sticks of phosphorus in a bottle of water, the ends of the phosphorus being uncovered. Air is admitted by making a hole through the cork. This causes the phosphorus to become oxidized, forming a mixture of phosphorus and phosphoric acids, which dissolve in the water as they are formed. The solution will be strong enough to use in a few days. Phosphoric acid can be purchased ready prepared at the druggists', and is, I think, preferable, phosphorus being a dangerous material in inexperienced hands.

Before the etching liquid is used, its strength should be tested in the following manner:—Apply a drop of the etching liquid to a piece of clean, polished zinc plate, and wipe it off after twenty or thirty seconds; the stain should be distinctly visible, though slight, and of a light grey colour. If the stain be deeper, add water; if lighter, strengthen with some phosphoric acid. Some other etching liquids have been recommended, but they contain sulphate of copper, and have the disadvantage of darkening the surface to such an extent that the detail is not sufficiently distinct. The etching liquid is brushed all over the plate with a broad brush, and allowed to remain a few seconds; the excess is then wiped off with a cloth, and the plate is fanned dry; as soon as it is dry, the preparation is thoroughly washed off with water. It may be allowed to remain without any harm if it is inconvenient to wash it off at once, as its action ceases as soon as it is dry. The strength of the etching liquid varies according to the nature of the subject; for fine work it should be used weak, but for vigorous subjects, or if the ink contains a great deal of soap, it may be used stronger. If the etching is not sufficient, the work is apt to run smutty; and if etched too strong, the delicate lines are destroyed.

The etching having been thoroughly washed off, the plate is sprinkled with turpentine and a few drops of water, and gently rubbed with a cloth till all the ink is taken off (for photo-carbon transfers in half tone a mixture of one-quarter glycerine and three-quarters turps is used instead of plain turpentine); it is then damped, and rolled in with the ordinary lithographic printing-ink, rather stiff. The ink is prepared by taking equal parts of middle and thin litho-varnish, and adding a little to a lump of best chalk litho ink, about the size of a hazel nut, or larger if required. This is well mixed with the palette knife, and then worked quite smooth with the roller. The ink should not be too thin, and must be harder for fine work. It is better to have stiff ink. A proof is pulled on thin paper, and any corrections found necessary may be made. Several prints must be pulled on the thin paper before the plate is in good working order; when that is the case the plate paper can be used and the required number of copies printed off. When copies of very fine work are required it is better to print on enamelled paper, which may be prepared as follows:—Quarter of a pound of Russian glue is soaked in 3 quarts of water till quite soft, and then dissolved with heat; 1½ pounds of zinc white are ground with water on a slab, and then mixed gradually with the solution of glue, and passed through a hair sieve. The paper is coated twice with this preparation; the streaks are obliterated by going lightly over the surface with a soft camel's-hair brush. This paper must

be used dry, and the plate must be thoroughly dried after rolling in with ink; if the plate or paper are at all damp there is a liability for the preparation to stick to the plate and damage the drawing.

When printing fine, close work, or in hot weather, it will be found very advantageous to use the following solution instead of water for damping the plate while printing; care must be taken, however, to keep it neutral, otherwise it will act as an etching solution, and the fine details will be gradually obliterated. Take 24 ounces of mucilage of gum arabic, add lime-water till it is neutral to test-paper, then add 2 ounces of glycerine, and mix well. To 2 ounces of the above liquid add 10 ounces of water, mix it well, and use this for damping the plates while printing. Only a small quantity of the first solution should be prepared, as it is liable to get sour; it should be tested before use, and if sour more lime-water must be added. By using this solution the finest work may be printed without clogging up. Further details on the subject of printing will be found in any treatise on lithography. Though very simple in theory it requires a great amount of practice and manual skill to become a good printer. When the plates are put away they must always be protected by a coat of gum, which should be laid on evenly, and quickly dried. If it is intended to keep the plates a long time before printing again they should be rolled up with the transfer ink already described, or with the following:—

Wax	...	...	...	100	parts
Asphaltum	...	...	...	100	"
Tallow	...	...	...	40	"
Lampblack	...	...	...	20	"

The above are divided into small pieces, and digested in turpentine, and stirred up occasionally. After some days they will form a viscous mixture, which should be kept for use in well covered pots.

(To be continued.)

## ON THE PRINCIPLES OF LIGHTING AND OF CONSTRUCTING STUDIOS.

BY DR. H. VOGEL.\*

Now, suppose two points,  $a$  and  $a'$  (fig. 6), situated at

Fig. 6.

different distances from that narrow window. The farther we remove the object from the illuminating aperture the smaller is the angle of light. By the very simple mathe-

matical contemplation above mentioned, we find that the amounts of light of two points opposite to a window decrease in the same measure as the squares of their distances from the window increase.

If we place an object in a glass house twice as far from the window, it will be necessary to draw as much of the curtain as would make the area of the opening four times as great, if we wish to have the same intensity of light; or we might as well leave the opening in the curtains as it is, and increase the time of exposure four times. If the aperture of the window is great, the amount of light do not decrease with the same rapidity. At twice the first distance the strength would be a little greater than a quarter, and at three times that distance a little greater than one-ninth.

We may draw another practical conclusion from these considerations: an answer to a question which has often been asked of late; viz., What is most practical, a high studio or a low one? First of all we must answer a question. What purpose does a studio serve? A studio can be good for taking single portraits, but not for taking groups or reproductions, and *vice versa*. Such studios as, for instance, those of M. Reutlinger and M. Salomon at Paris, are excellent for taking single portraits, but whole groups can never be taken there. The cause is very easily to be recognized. When taking large pictures, drawings, &c., an equal illumination of the whole object is requested; with single portraits, however, the artist demands a rather unequal illumination. The head, being of first importance, must be lighter than the parts of less importance, for the facts to which only half-light is bestowed. These artistic properties are especially perceived in the portraits of Adam-Salomon, of Paris, and Carl Jagemann, of Vienna. If we should like to illuminate in the same way a whole group, all persons but one would only receive half-light, and scarcely become visible. Answering to the above question, I therefore must look to the intended purpose, and I first treat the most simple case, the construction of a studio for taking single portraits.

Suppose a skylight of about 25 feet height, and therein an object, as, for instance, a man,  $a' k'$  (fig 7) of 5' high;

Fig. 7.

above this object we make a certain opening,  $b c$ , in the curtains, which is at a distance of 20' from the head and of 25' from the feet; therefore, the amounts of light will be as  $400 : 625 = 16 : 25$ , which is almost as 2 : 3. Now suppose a skylight of 10' high, all other circumstances being the same, the distance of the head from the aperture will be 5', that of the feet 10', and therefore the amounts of light will be as 1 : 4.

It is obvious how great the differences are. In the first

\* Continued from p. 331.

case, with a high studio, the head is one and a half times as bright as the feet; in the second case, the head is four times as bright. Hence follows that, in the first case, we have only a small contrast of light; in the second case, however, a very great one.

In a portrait the importance of the head is pre-eminent; it must receive more of the light. A contrast of illumination between head and feet, as 2 : 3, is too small for giving brilliancy. A proportion of 1 : 4 gives a much better result. From this point of view it is now clear that for single portraits a low studio is the best.

As instances of such low-roofed skylights, which afford so surprisingly good results, I have already mentioned those of M. Adam-Salomon and of M. Rentlinger.

Till now we have always treated on a spot situated directly opposite to the illuminating aperture. Let us now contemplate the direct brightness of a point situated at the side of the window (fig. 8). We have already stated that the intensity of light is, for this point, smaller than for one opposite to the window. The intensity of light is here decreasing with the inclination of the rays to the wall of the window. We may in this case suppose, instead of our original window, another one perpendicularly struck by the sun rays; its size will be determined by the projection of the original window in the direction of the rays.

Fig. 8.

The angle formed by the rays and the wall being  $a$ , the size of the window  $F$ , the projection  $cd$ , is  $F \sin a$ , and the amount of light at  $a$ , according to our formula,

$$\frac{F^2 \sin^2 a}{E^2};$$

we therefore are able to determine the amount of direct light at any spot of the room if we know the size of the window, the angle formed by the rays and the wall, and the distance of the point from the window.

From these principles we draw another practical conclusion:

Fig. 9.

the production of the effects of backgrounds in the photographs of M. Salomon. This gentleman produces those

good effects by placing his backgrounds into an oblique position. I have, however, reached to the same end by simply drawing a narrow curtain at the side of the background, so that I received the aperture  $oo$ . The diagram—a rough ground plan—shows the arrangement.  $H$  is the background,  $P$  the person, and  $A$  the apparatus. Naturally, with such an arrangement, the different points of the background will appear very differently illuminated. The point  $b$ , with a much smaller angle of light, is brighter than  $a$ , and therefore the background will appear dark at the right-hand side of the person which is brightest, and bright at the person's dark left side.

(To be continued.)

## ON THE ACTION OF BROMINE UPON CERTAIN ETHERS.

BY MM. A. LADENBERG AND H. WICHELHAUS.\*

THE known reactions of bromine upon organic bodies may be divided into two kinds: the first, in which the bromine takes the place of the hydrogen (or chlorine); and the second, in which the bromine is simply added to the organic molecule. The reaction, of which this memorandum forms the subject, belongs to neither of these two classes; it betrays the presence of a new property of bromine towards certain organic bodies, which consists in liberating the alcoholic radical in ethereal substances containing oxethyle ( $OC^2H^5$ ).†

We are far from pretending that the reaction in question is quite general, for, on the contrary, we have in several cases found that the same did not take place; without being able to state positively the conditions under which the change does occur, we believe, nevertheless, that the reaction depends upon the place occupied by the group  $OC^2H^5$ .

The three compounds which contain this group and but one atom of carbon—viz., carbonic ether,  $CO(OC^2H^5)_2$ , the tribasic formic ether (the ether of Kay),  $CH(OC^2H^5)_3$ , and orthocarbonic ether (the ether of M. Basset)—are all capable of losing oxethyle by treatment with bromine. It is with the second of these compounds that we have principally studied the reaction.

If bromine is added drop by drop to tribasic formic ether, the latter becomes sensibly heated, and the colour of the bromine disappears without any formation of gas. When one atom of bromine has been added for every molecule of ether, the liquid ceases to lose its colour if the addition of bromine is continued, and that the ether employed has been entirely destroyed is clearly demonstrated by a distillation of the mixture. The liquid may be divided into three portions, of which the first boils between  $40^\circ$  and  $45^\circ$  Cent., the second between  $45^\circ$  and  $125^\circ$  Cent., and the third between  $125^\circ$  and  $126^\circ$  Cent. The first product is bromide of ethyle, and contains the whole of the bromine employed in the reaction. The liquid boiling at  $126^\circ$  C. is carbonate of ethyle, which yields by treatment with alcoholic potash carbonate of potassium; by combustion it gives 51.25 per cent. of carbon and 8.53 hydrogen, the theoretical quantities being 50.85 of carbon and 8.45 of hydrogen.

In order to understand the formation of carbonic ether, it is necessary to admit the formation of hydro-bromic acid, but, as we before stated, there is no disengagement of gas in the reaction; it is necessary, therefore, to suppose that the hydro-bromic acid reacts itself upon the formic ether. The products of this reaction would be

The third product, which would be intermediate between methylglycerine and its ether (the ether of Kay) does not appear to be stable; it decomposes in alcohol and formic

\* Bulletin de la Société Chimique.

† The formulæ used in this paper are written on the new system of chemical notation, which demands 12 as the atomic weight of carbon.—Ed. P. N.

ether. We have detected the presence of formic ether in the liquid, the boiling point of which ranges between 50° and 100° Cent.; by boiling with potash and distilling with sulphuric acid a strongly acid liquid was obtained, presenting all the characteristic properties of dilute formic acid, and capable of reducing nitrate of silver and mercurial salts. We believe, therefore, that the reaction of bromine upon the ether of Kay is correctly represented in the equations:—

These equations we have verified by taking account of the ether and bromine employed, and likewise the bromide of ethyle and carbonic ether obtained.

The first reaction consists, therefore, in the liberation of an ethyle and one of hydrogen of the tribasic formic acid by the bromine; the carbon of the radical of which one affinity has been liberated combines with an atomicity of an atom of oxygen liberated by the removal of the alcoholic radical. If the reaction is regarded in this light it is possible to realise the inverse reactions of the nascent hydrogen upon bodies containing carbon, connected by two affinities with one atom of oxygen.

Orthocarbonic acid is attacked by bromine in a cold state, giving rise to bromide of ethyle and carbonic ether; upon the latter, bromine reacts only when warm, disengaging carbonic acid and leaving bromide of ethyle. In both cases other bodies are likewise formed, but the nature of these we have not as yet studied.

Acetic ether, when cold, is not attacked by bromine, but on warming the mixture in sealed tubes products of substitution are formed, and bromide of ethyle. Oxalic and benzoic ethers are not acted upon by bromine, even when warm; while, on the contrary, ethylglycolic acid yields bromide of ethyle when heated with bromine.

We propose making a deeper study of the reactions herein mentioned, and will give shortly the results of our researches.

## AN EASY MODE OF OBTAINING THE POSITION AND FOCUS FOR FIELD VIEWS.

BY W. CAMPBELL.\*

MANY years ago, perhaps a dozen, I was very enthusiastic in my profession; indeed I am so still, though it may be there is not that ardor displayed now which characterised my pursuits then. I loved and longed to carry from the field the pretty scene I looked upon, and to obtain it I often showed an enthusiasm which, had it been exhibited in a less laudable undertaking, would, I am sure, have seemed very unbecoming. To ask a perfect stranger to allow me the use of his window, or to run into a man's garden, to obtain a better view without once saying, 'If you please, sir!' was among the least of my impertinences. When I look back upon them I fairly blush: but what will enthusiasm not do? It clouds the vision, dims the light of more refined sentiments, and, if not mean, is certainly selfish. I never dreamed of any wrong. However, I never met with a rebuff; on the contrary, I had many kind invitations, and I am now of opinion that the public are not only tolerant, but indulgent to the enthusiastic photographer.

In my pursuits I often found much time was lost in ascertaining just the right distance required to obtain the field on the ground glass, especially if a house was in the view as a principal object; and also time was lost in the focussing. Now, could I have a sure mode of placing the camera without the trouble of using a black cloth, and have it in focus ready to proceed, I fancied I should be a gainer. So I set to work and overcame the difficulty. I proceeded thus: I soon found that all objects in the field of view were in the right focus beyond a certain distance; there was therefore no further necessity for focussing on the field; all I had to do was to make a line, drawn on the base of the

camera, and consider this as the focal point for field view. The next thing was to get the area of the field of view. To do this, I took a cardboard, and bending it in the shape of a funnel, I looked through the large end, and contracting the smaller, so that it would circumscribe the same area as the lens would circumscribe on the ground glass, I fixed it there. This I kept as a guide, always in my pocket, so that when I wanted to know if a particular spot would be in the field of any view I wished to take, I had only to apply to my cardboard funnel for the information. Exercise, however, soon gave me experience, and I could tell with my bent hand, looking through the opening made by closing the fingers over the thumb, what to expect. I had still another trouble. The point selected as the centre of the view could not be placed on the centre of the ground glass without looking. It was either too high or too low, too much on the left or too much on the right; of course it involved the necessity of shifting the camera with black cloth over my head; this was troublesome, and had to be remedied. After some time I hit upon a plan. I remembered that in fixing a gun it must be so placed that the sight covers the object, so I followed up this idea. I drew a line on the top of the camera corresponding with an imaginary line drawn through the centre of the lens to the centre of the ground glass; and in front, on the top of the camera, I made a small hole, and on the back made another hole; on the line in each of these two holes I placed a peg of wood, and they sighted my object, and was pleased to find that I was right. The ground glass showed on the centre, the object I had sighted on the top of the camera.

The whole affair was now brought to a nicety. When I wished to get a view, I first applied my cardboard funnel; to get the area and distance, of course, if too large a field of view was seen, I had to go forward; if too small, I had to retire from the object. Having got the distance, I then set up the camera, and drew it out to the marked line for the focus; then, looking over it, I brought the two points of sight to cover the centre point, and then proceeded to take the picture. I never looked to see that I was right; I was sure I could not go wrong.

## NEW RED COLOURING MATTER.

DR. ADRIANI describes, in the *Chemical News*, some experiments with rosolic acid, or aurine cake, in the production of various forms of a colouring matter yielding many brilliant tints of red. The tinctorial power is stated to be very great, and although the red rosolic acid has generally been regarded as fugitive, the new combinations seem to give promise of more permanency. Amongst other experiments, he says:—"I tried a solution of aurine in carbonate of ammonia, and precipitated it with chloride of barium; after repeating the process already described again, I obtained in this way a very brilliant flesh-coloured pigment. I mixed, in an earthenware glazed mortar, some aurine cake and strong baryta water, filtered this mixture, and added to the filtrate very weak sulphuric acid, just enough to neutralize the baryta; in this way I obtained a pigment which, after drying (of course some washing, but not to excess), can vie, in beauty and tone of colour, with genuine carmine. I next proceeded to precipitate an aqueous solution of sulphate of zinc with a very slight excess of a solution of aurine in dilute caustic potassa, washing again, slightly, the precipitate, and drying it at 212°; the pigment so obtained has a fine rose colour. On trying sulphate of zinc again, but with a solution of aurine in dilute carbonate of potassa, after drying, a very peculiar and somewhat dull pinkish-coloured pigment is obtained. A most magnificently bright scarlet, of deep hue, is obtained by first triturating together some previously separately-powdered aurine with lime-water (not milk of lime), filtering the turbid liquid, and next passing gently through it a current of carbonic acid gas. A precipitate ensues exhibiting the colour already referred to; on drying it, after having carefully collected it on a filter and slightly washed it, I find that even below 212° its colour is very much altered and impaired. I find, however, on instituting experiments on purpose, that if the pigments referred to are dried over sulphuric acid at the

\* *Humphrey's Journal*

ordinary temperature, their primitive beauty, as seen on precipitation, and while yet moist, is to a very great extent preserved. As already stated, none of the pigments described are fit for oil colours: I have tried them, but none will do at all; but, undoubtedly, mixed with strong solutions of gum free from acidity, or good size, or, better yet, gelatine and albumen, these pigments might be of use in colouring paper-hangings, toys, and other ornaments. As regards the solutions of aurine in weak fixed alkalies and their carbonates, from experiments I instituted, I think I may recommend anrine cake as an article for the manufacture of a red writing fluid—red ink—of great beauty. Of the solutions I tried for this purpose, I find that the solution in carbonate of soda answers best: this red ink can, firstly, be used with steel pens, not only not corroding them, but actually on account of the alkali protecting the steel from rust and corrosion; and, secondly, this ink would not affect blue-laid paper coloured with ultramarine, which latter pigment is decomposed by acids; and, since ordinary red ink is usually very acid, both the pens and paper suffer, if ultramarine blue-laid paper is used for writing. Another advantage of the use of the solution alluded to, instead of red ink, is that it may be safely used by mechanical draughtsmen with their steel drawing-instruments, which will not suffer from its use. Tampering with what is written with the alkaline aurine solution with acids, for instance, will at once become evident by the writing becoming yellow, while the primitive colour cannot be restored.

"I find that anrine cake is to some extent soluble in an aqueous solution of bicarbonate of soda, yielding a solution of a brilliant scarlet-red hue; on writing with the said solution I found that, after drying, a very pale rose, or, when a more concentrated solution is used, an orange-coloured writing, ensues. I prepared all these solutions at the ordinary temperature, by first pulverising the aurine cake in a stoneware or glass mortar, and next adding the aqueous alkaline solution, and rubbing it and mixing together for a length of time, and next filtering through good ordinary white filtering paper. Notwithstanding it is asserted that the colour from rosolic acid is very fugitive, I find that things written now, five, and even eight weeks ago, exhibit no signs of change or fading. Aurine in alkaline solution far surpasses best red ink in brilliancy; if its asserted instability should, on a more severe and lengthy trial, prove incorrect, alkaline aurine solutions may be of use also, instead of water-colours for drawings, for mechanical and other draughtsmen."

### Scientific Gleanings.

**NEW USE FOR COLLODION.**—Dr. Voillemier recommends a method of his own for cauterization in surgery. He applies one or two coatings of collodion to the skin, letting them dry before he applies the canter, in order to avoid setting fire to the ether evaporating from the film. The red-hot iron instantly destroys the collodion at the point where it touches, but the heat radiating from the knob exercises no action on the film, which, being composed of pure cellulose, is a very bad conductor of caloric. If, after the operation, the collodion be removed, the skin under it will be found unscathed; but it is best to leave the coating on till the canterized point is healed.

**ALBUMEN.**—Large quantities of albumen, or the white of eggs, and also of yolk, are imported in Southampton from Normandy. The albumen is used by photographers and calico dressers, and the yolk is used in the manufacture of gloves. The price of prepared white of eggs was two guineas per pound not long since. This arose from the waste it suffered during the process of preparation. This waste amounted to as much as 85 per cent.

**NEW MOTIVE POWER.**—Some of the Italian journals state that Father Secchi, whose name is well known in connection with astronomical photography, has discovered a motive power lighter, stronger, and more economical than steam. They add, that the learned Italian is stated to have laid his invention before the court of Portugal, which is disposed to purchase it.

**GLASS CUTTING.**—A mode of cutting, or rather dividing, glass, which is a slight modification of an old and well-known method, has been recently invented in France, and is practised in the large establishment of the Glass Company of Baccarat. A jet of highly heated air is directed from a tube on the vase or other object to be cut, which, while made to revolve on its

axis, is brought close to the nozzle of the tube. The object being then cooled suddenly, the glass divides at the place operated on with extreme accuracy.

**IODIDE OF STARCH.**—M. Guichard has recently examined this substance carefully, and has arrived at the conclusion that the colourless iodide of starch has no existence; the so-called iodide of starch is simply starch tinted by iodine. Heat separates the iodine from the starch; the iodine remains in the water, either as such or as hydriodic acid.

**ARTIFICIAL METHYLIC ALCOHOL.**—E. Linnemann.—Methylamine was prepared from cyanhydric acid, with slight modifications, according to Mendius's method, and converted into methylic alcohol by means of argentic nitrite in the manner described on a former occasion (*vide Chemical News*, No. 436, page 181). The corrected boiling point of the pure alcohol at the normal barometrical pressure (670 m.) is 67.1° C., sp. gr. at + 21° = .8574. The iodide of the alcohol has the sp. gr. at 25° = 2.269, and boils under a pressure .738 m. at 42.5°. These observations prove the identity of the alcohol obtained from cyanhydric acid with the methylic alcohol from wood spirit. (*Ann. Chem. Pharm.*, cxlv., 42).

**CONVERSION OF METHYLIC INTO ETHYLIC ALCOHOL.**—A Siersch.—Acetonitrile, prepared by acting upon potassic methylsulphate with potassic cyanide, was converted into ethylamine, and from the nitrite of that base alcohol was obtained. This alcohol was found to be a mixture of ethylic and methylic alcohol, in the approximate proportion of 4 to 1. The author explains the presence of the latter by the assumption that during the decomposition of the nitrite of ethylamine alcohol has been regenerated. (*Ann. Chem. Pharm.*, cxlv., 46).

**ELECTRICAL DEPOSITS ON PAPER AND TISSUES.**—The *Scientific American* gives an easy method for depositing copper, silver, or gold, by means of the electric battery, on paper and other fibrous material. The process consists in making the paper a good conductor of electricity by coating it with a material which will not peel off. One of the best methods is to take a solution of nitrate of silver, and pour in liquid ammonia until the precipitate poured is entirely redissolved by stirring. The paper, silk, or muslin is soaked in this solution for one or two hours. It is then taken out and dried, and exposed to a current of hydrogen gas, by which metallic silver is reduced; and the tissue becomes a good conductor of electricity, so that it may be electro-plated with copper, silver, or gold in the usual manner.

### Correspondence.

#### INFORMERS AND PIRACY.—GRAVES v. MERCER.

SIR,—As considerable interest has been displayed in your journal with reference to the raid on photographic "pirates," and remarks made from time to time on the disreputable means often resorted to by eminent print publishers to protect their rights, I beg to enclose you a brief report from the *Irish Times* and *Dublin Mail* of the case of Graves v. Mercer, which, having been dragged through the different law courts during past eighteen months, at length came to an issue, and was tried here on Friday and Saturday last; and with your kind permission I will offer a few observations on points that are passed over in silence in all the newspaper reports.

This action was one of sixteen, all of which were brought separately, and eleven of them by Mr. Graves. Had he succeeded, no doubt we should have heard a great deal about the grave nature of the offences and the necessity for securing exemplary damages; but now the issue is the other way, plaintiff can appreciate with the keenest enjoyment, I hope, the sensations he so kindly intended should be the exclusive privilege of defendant.

Now, I meant to have stated at the outset that I do not dispute Mr. Graves's right to the property he has so liberally paid for, and never did; quite the other way; and the best evidence of which is the fact that I have quite discontinued the production and sale of all copies of engravings, and this notwithstanding the circumstance that there are thousands of engravings accessible, to which no copyright restrictions whatever apply. I made this resolution rather than be in constant col-

\* A report of the case was already in type when those sent by our correspondent reached us. See last issue.—ED.

lision with the print publishers, who, by the way, frequently commence proceedings utterly regardless of the law, which gives them protection *only* in those cases where they comply with its requisitions.

The first remark I wish to make on the case is this, that out of the hundreds of photographs bought of me by King, alias Hyams, alias Hymams (of "gentlemanly appearance," as one reporter writes, who must mix in strange society if he insists on the correctness of his standard of gentility), not one solitary photograph was produced, though, strange to say, several twice as large as mine were exhibited to the Court, and were stated distinctly *not* to have been obtained from me, but which, nevertheless, were handed about and alluded to from time to time in such a manner as must have almost induced some of the jury to imagine they were mine, or, to say the least, had something to do with the case. And how far this succeeds may be inferred from the fact that in one of the newspaper reports they were actually stated to have been bought of me! Now where did these photographs come from? They were dug out of the fire which destroyed Her Majesty's Theatre and Mr. Graves's shop, says plaintiff. But how, I ask, did it happen that these particular photographs escaped the fire, while *all* mine were consumed, and this although Mr. Graves positively declared all these illegal photographs were kept in *one* receptacle at the end of his shop, and which he facetiously termed the "Pirate's locker"?

Secondly, observe the great care used by Messrs. Graves that no confusion shall arise as to the particular spoil obtained from different "pirates." See what extraordinary precautions they adopt to prevent the possibility of confounding the innocent with the guilty. You will please notice Messrs. Graves's *modus operandi* recognizes in the fullest manner the justness of that saying so familiar to lawyers; viz., that it is "better ninety-nine guilty men should escape than one who is innocent should suffer." And how do they accomplish this desirable object in my case? As follows:—These illegal photographs, said to have been got from me, are carried about by King during the devious voyage which brought him to Manchester, Birmingham, Leeds, &c., and which occupied over *two months*, and all the time he is visiting the various depots for sale of these things, and buying goods by fifties and hundreds, relieving the monotony of his delightful calling by getting drunk once or twice a week (I have his own word for the truth of this, and that he never told a lie in his life). In due course, this agent of the eminent publishers arrives in London, and hands over the contraband to the admiral, and all the pictures are put away in the *same* desk for the present. But when the process of classification commences, we can easily imagine the method pursued to distinguish photographs got from "men of straw" from photographs got from people able to pay substantial damages.

Thirdly, it seems to me there is no difference in principle between a spy of King's type and the irrepressible Fenian informer, and that, as the uncorroborated evidence of the latter would not be listened to for a moment, so in these cases no jury could be asked to convict in the absence of *eye-witness* testimony. But what really happens in my case? King called *alone*, and was never accompanied by his accomplice upon one of the eight or ten occasions I saw him; and even King himself stated that Cattermole, his confederate, was with him on *one* occasion only, and then did not enter my house. Cattermole's evidence amounted to this: that having searched King and watched him into my house from a *distance*, so as to avoid observation, he awaits his return, and King then shows him a parcel of photographs he had bought, including those which were the subject of this action. Now, whatever could have possessed Mr. Graves to imagine for a moment that a jury would convict any respectable man upon such a tinkering tale as this, when, to say nothing of the extreme improbability of Cattermole refuting himself, King had only to employ a third confederate (whose existence need not be alluded to) to accomplish the whole transaction, and cheat his own friend into the bargain?

But I must not further trespass on your space, and will only add that the judge who tried the case most emphatically denounced the stratagem used by plaintiff, describing it as a "system that no just mind could approve;" and the jury sufficiently testified their sense of the unmistakable difference between a "a tissue of lies"—to use the judge's own words—and the truth, by handing down, in less than twelve minutes, their verdict for—Yours obediently,

THE DEFENDANT.

#### MR. BOVEY'S MODE OF TONING.

DEAR SIR,—It is with pleasure I have read Mr. Bovey's description of toning, and I must, before proceeding, individually thank him for the many proofs he has given of his love for our beautiful art by making known to his brother photographers his practical experience in many of its details, and particularly for his inviting discussion on his last process of toning. Taking advantage of that invitation, I will ask him a few questions. Of course photographers require a process by which they can always depend upon producing the *tone* they wish; therefore it is necessary to have one in which the component parts of the toning bath will not be changed (with the exception of the loss of gold); and this brings me to the first question. Mr. Bovey says he prefers his prints *not* to be washed from all free nitrate of silver. If that is the case, how can he depend upon the exact amount of silver that remains in the print? Because, if more remains in one than in the other, there will be, of course, a difference of tone in the finished print; and will not every one he tones in that state alter his bath by the formation of "*nitrate of soda*"? I would ask, also, what effect the salt so formed has upon the action of his bath? And does not the formation of chloride of silver over the surface of the print prevent the gold from being deposited on those parts of the picture on which it is required? for my experience has taught me that where *any* deposit of chloride of silver on the surface takes place, I never get the clearness and depth required. This, of course, has been with the acetate and sulphocyanide baths, as I described to you a little time since, and which answer admirably. I can depend upon every lot of prints coming out the same. I know I use a great deal of gold, but I also know that the gold used is on my pictures, and therefore the *more* there is on them the *more permanent* the prints must be.—I am, dear sir, yours truly,

G. H. BRITTON.

10, High Street, Forest Hill, July 8th, 1863.

#### LANDSCAPE BACKGROUNDS TO PORTRAITS.

DEAR SIR,—It has occurred to me that a much more simple and convenient method of taking figures and groups with natural backgrounds than that proposed by Mr. Burgess in your last number, or by any of the usual plans of double printing, would be to take the landscape on a carte-sized plate, and enlarge it on canvas or paper to 7 by 6 feet. This, I imagine, may be done without difficulty, as it would not require to be sharp; indeed, sharpness would be a defect. This background might be used for various groups, whereas by any other method a fresh one would be required for each.

The foreground is very easily arranged from weeds, stones, or other natural objects, in the studio.—I am, dear sir, yours very truly,

BAYNHAM JONES.

Cheltenham, 14th July, 1863.

#### Talk in the Studio.

PERMANGANATE INTENSIFIER.—At a recent meeting of the Philadelphia Photographic Society Mr. Fassitt made a communication respecting the use of our permanganate intensifier. He found great advantage in the use of the chemically pure instead of the commercial article. The solution he used was 3 or 4 grains to the ounce of water, and was of a fine dark rose colour. To prevent the loss of intensity consequent upon varnishing the negative, Mr. Fassitt recommended flowing the plate with gum water. The greatest care was, he thought, necessary in washing the negative after intensifying.

IMPROVED DIPPERS.—A photographer miles from home has sometimes been placed *hors de combat* by discovering that his dipper had been left at home, or by breaking a glass one. We have heard of a forked twig being made to do successful duty in such a case. Our Philadelphia contemporary says that Mr. Garrett uses dippers made out of hickory wood, and finds them unequalled.

THE WEATHER AND PHOTOGRAPHY.—We have heard various complaints of photographic difficulties arising from the extremely hot weather, and also of its depressing influence on professional photography. The American photographers are complaining from precisely the opposite cause. We find it

stated in our Philadelphia contemporary that "twenty-six days in May it rained, consequently the photographers were in bad humour and growled, while umbrella and water-proof clothing makers were happy and smiled. The same condition of things yet exists (June 12) without any promise of a change; how much longer to continue none here can say; even 'the oldest inhabitant' gives up in despair, declaring that such he never knew before. Various causes are wisely suggested by all. Some say the Gulf Stream has changed its course; others, that they don't know."

**PHOTOGRAPH OF THEODORE'S SON.**—Few persons who have read the History of Rasselas have ever dreamed of the possibility of seeing a photograph from life of the Prince of Abyssinia. We have received from the Stereoscopic Company an excellent card portrait, which they have just published, of an Abyssinian prince; not Dr. Johnson's hero, however, but the intelligent little fellow who has recently arrived in this country, the son of Theodore. The child has a pleasing face, somewhat of the Egyptian type, and the photograph is capital.

**A MONSTER PHOTOGRAPHIC GROUP.**—Messrs. Mason and Co., of Bond Street, have recently invited our attention to perhaps the largest photographic group ever produced. It consists of a photograph nearly 12 feet by 7 feet in size, containing the portraits of 76 bishops, upwards of 60 of whom gave especial sittings for the efficient production of the picture. The scene represented is the Pan Anglican Synod, when the bishops of the Anglican Church throughout the world attended the conference at Lambeth Palace. The figures are arranged in front of the building in such natural grouping as could be effected in a few minutes. A good 10 by 8 negative was then secured, from which this enlargement was produced, and then coloured in oil. The difficulty of grouping such a number of male figures, of doing justice to portraits throughout, and of getting relief and variety with such a mass of black coats, may be well conceived; but the difficulty has been very fairly combated, and the portraits are in most cases capital. Such a work has national and historic value, and the picture ought to find a destination where its historic character will be fittingly recognized.

**CURIOUS EFFECT OF GELATINE UPON GLASS.**—A correspondent sends us the following account of a curious result:—

Having for experimental purposes poured a thick solution of gelatine upon a number of glass plates, three of them were set aside upon a shelf for some months; and one day, upon looking at them, I found that in all three cases the gelatine had separated from the glass, bringing away the whole surface of the glass plates in shivers, which firmly adhered to the gelatine. The surface of the glass was left full of ruts, like water-worn stone. I suppose it to be caused by the strong contraction of the gelatine and its firm hold upon the glass."

**PHOTOGRAPHY AT WIMBLEDON.**—Photography has become one of the regular institutions at the camp at Wimbledon. This year Mr. Blanchard goes to secure rapid or instantaneous groups and other effects. Messrs. Moira and Haigh, Messrs. Denezy and Hemery, are taking portraits there.

**IRON INTENSIFIER FOR DRY PLATES.**—At a photographic meeting of the American Institute Mr. Newton recommended alkaline development for tannin plates, followed, as soon as detail appears, by a solution containing sulphate of iron 1 drachm, citric acid 15 grains, water 2 ounces, and a few drops of a 15-grain silver solution. Any amount of intensity can be gained, and pinholes are avoided.

**INSTANTANEOUS PICTURES.**—At the same meeting Mr. Chapman exhibited some most excellent instantaneous stereographs, and suggested the following method of development:—Commence operations with the ordinary iron developer, with which push as far as possible; next wash the plate thoroughly, and treat with a solution of carbonate of ammonia 10 grains to the ounce of water, into which put a few drops of the ordinary pyro, silver, and citric acid solution, and a couple of drops of a 5-grain solution of bromide of potassium in water; after this has developed still further, and done its part, again wash, and redevelop as usual with pyro and silver.

**TRYING FOR CHEMICAL FOCUS.**—A photographer recently sent to a dealer for a lens to try. Not being known to the dealer, the latter proposed to send the lens to the rooms of a photographer in the same village whom he knew, where the other was asked to go and try it. This was objected to, for the reason that "he wanted to try the lens with his own chemicals, to see if there was any chemical focus in it." This reminds us of a

photographer who remarked once that he never made a larger picture than 8 by 10 with his instrument. It would cut 11 by 14, but he feared to attempt it. It strained his lens too much, and he feared he would break it!—*Philadelphia Photographer*.

**STAINS ON NEGATIVES.**—We are indebted to Mr. Garrett for the following plan for protecting the plate-holder from the action of the silver solution:—Sand-paper all stains and varnishes off, and apply a coating of lard all over the holder. It will then effectually resist the action of the silver solution.—*Ibid*.

**RUINOUS COMPETITION.**—A contemporary says that two photographers in Maine are endeavouring to ruin themselves by running down prices. They have whole-size down to twenty-five cents, and "album size" nine for twenty-five cents. A cent is equivalent to a halfpenny.

**STAINS ON TANNIN PLATES.**—Our Philadelphia contemporary says:—"Tannin may be entirely freed from all colouring matter by dissolving 6 parts of common tannin in 12 parts of warm distilled water, and adding 1 part of ether to it. Put the mixture into a bottle, shake it several times, and then set it aside for some hours, after which it is ready for filtering. The filtrate is quite colourless, and has no smell whatever. By using it the black stains, so common with tannin plates, may be avoided, for these stains have their source in the colouring matter of the tannin."

**THE BROMIDE PATENT.**—The decision in regard to the application for an extension of the Bromide Patent in the United States will be given this month. Mr. E. L. Wilson, the esteemed editor of the *Philadelphia Photographer*, is working strenuously, on behalf of the profession, to defeat the application. In reference to Cutting's original claim he says:—"We have proven that Mr. Cutting got his first idea of using it from another, who showed it to him in a printed book. We have proven that its use was well known in Europe before Mr. Cutting thought of it, or gave any evidence that he thought of it. We have the whole history of his pretended invention (?). The patent has been a swindle and an outrage upon the public ever since its birth." It is inexplicable to English photographers how such a patent was ever granted, or for a moment sustained. In view of the possible extension of the patent, photographers are active in experimenting with anti-bromide collodions, and excellent results are said to have been obtained.

**INDECENT PHOTOGRAPHS.**—William Dugdale and James Milson, who pleaded guilty at the last Middlesex Sessions to a breach of Lord Campbell's Act, were brought up to receive judgment. The elder prisoner, it appeared, had since the last session given most important information, which enabled the police to find out the persons by whom the traffic in indecent books and pictures has been carried on. Superintendent Durkin found no fewer than 35,000 publications, and about 500 pictures and photographs which came within the scope of Lord Campbell's Act. The owner of the house in which these nefarious works were discovered said he knew nothing about them. The prisoner Dugdale is 73 years of age, and Milson was his servant. The Assistant Judge, in pronouncing sentence, expressed his opinion that the age of Dugdale was rather an aggravation of than an excuse for his offence, and accordingly committed him for eighteen months. Milson was sent to prison for nine months.

**PHOTOGRAPHY IN EVIDENCE.**—The *Athenaeum* says:—"A new class of evidence has at length, like the electric telegraph, made its way slowly into the Admiralty Court. In a case of damage to a ship, photographs were admitted to show her condition—a development little expected thirty years ago in throwing light on law proceedings. The lawyers, however, are not to be put down by the alleged accuracy of the photographs, for on the ground of conflict of evidence they obtained a reference to the Trinity Masters. Still, some day, we may see a sworn photographer in Chancery and a new class of legal functionaries. Taking photographs may constitute part of the examination on the law of evidence."

## To Correspondents.

CHLOE asks how she can remove photographic stains from a slab of marble which has been used to develop over, cyanide of potassium having been tried without success. We fear that the case is a difficult one, especially if the discolouration amounts to more than

a surface stain, as from the absorbent nature of marble it probably will. The stains probably consist of partly and completely reduced carbonate of silver and of carbonate of iron. Oxalic acid in strong solution would best remove the latter, and cyanide of potassium to which a little iodine has been added would best remove the silver stains; or iodide of potassium might be applied, and followed by cyanide. But in each case a little soaking and scrubbing with a brush will be necessary to do any good at all, followed by well washing in warm water. Possibly rubbing down and re-polishing will, after all, be the only effectual remedy.

WM. STURGEON.—Both the salts of which you forward us examples are really the same thing—iodide of cadmium. That labelled bromide of calcium is not a bromide at all. You may ascertain the distinction between a bromide and an iodide by a variety of tests, some of which are simple and easy. The addition of nitrate of silver will convert an iodide into iodide of silver which is yellow, whilst the bromide of silver is white, or of a cream tint. The addition of bichloride of mercury will convert the iodide into orange-coloured iodide of mercury, whilst the combination with the bromide is not so readily formed, and shows no red tint. An iodide strikes a deep blue tint with starch, but no such reaction takes place with a bromide. All the iodide reactions followed treatment of the salt labelled bromide of calcium.

C. W.—We have never tried the process in question, and cannot say much about it. It is probable that with a bromide only you would not get a very vigorous print. A mixture of bromides and chlorides gives, in our estimation, the best results for printing by development. A solution containing  $7\frac{1}{2}$  grains of bromide of potassium and  $4\frac{1}{2}$  grains of chloride of ammonium per ounce, with a 50-grain nitrate bath, will yield very good results. We have seen good results obtained with a solution containing 6 grains of iodide, 4 grains of bromide, and 2 grains of chloride per ounce. Alkaline development of paper prints would probably produce discolouration of the whites. Hot gallic acid may be used, and the exposure may, in such case, be shortened.

YOUNG.—The fact that you fail to succeed with several processes with which others succeed suggests that there is some want of care or precision in your working. The object of filtering the syrup through charcoal is to remove certain impurities. The solution should not be returned to the stock bottle after being used. The want of sensitiveness and the fog must have been due to error in some part of the operations, or impurity in something used, but we cannot tell in what the error lies. The commercial collodion of which you speak has the reputation of being very good. The fact that you could not obtain an image with it in either the wet or dry process suggests that you probably used it without being iodized. The photographic soap of which you speak we have not tried, but have heard good accounts of it. The nitrate bath being "blackened by a collodion plate" we do not understand. How was it blackened? Possibly the collodion plate had been contaminated with hypo or some other impurity, which decomposed the bath. Without knowing more details we cannot give you a remedy.

A. W.—We cannot tell you when bromide of potassium was first introduced into the market. Bromine was not discovered until 1826. It was first used in photography in 1840, and there is some dispute as to whom the honour of its introduction belongs; in this country we generally accord it to the late Mr. Goddard. Our American cousins dispute this. M. Biard introduced it into the paper process, we believe, the same year. Bromide of potassium was one of the earliest bromide salts introduced into commerce, but we do not know the date.

W. J. A. G.—It is difficult to trace the cause of your failure with morphine plates. It may be due to two or three causes. Many of the ordinary samples of commercial bromo-iodized collodion do not contain sufficient bromide, and the addition of about 1 grain per ounce is necessary to secure good results with most dry-plate processes. The soft water may have been impure: it sometimes contains traces of sulphuric acid and other impurities collected from the atmosphere of towns. The morphine solution may have been exhausted by using over and over a few times. 2. The matt silver stain like a slug-track, extending from the edge of the plate, is generally the result of contamination of the nitrate solution on the plate, from contact with the inner frame. Constant washing of the inner frame and allowing the plate to rest on clean blotting-paper will assist you. See article in the present number; see, also, a paragraph on the use of lard on the inner frame to prevent contact with the silver solution.

T. W. (Thornton).—The yellow stains are spots of imperfect fixation, most probably caused by the formation of small air-bubbles on the prints on immersing them in the fixing bath, the hypo being so prevented from acting perfectly where each bubble is formed. The result of imperfect fixation is the formation of insoluble hyposulphate of silver at each point, which decomposes and causes a yellow stain when the print is removed from the washing water and brought into full daylight; sometimes it becomes decomposed, and causes the stain on applying warm water. The remedy is to examine each print carefully after im-

mersing in the fixing bath, and remove any air-bubbles which are formed. Some samples of paper are more prone to such bubbles than others.

J. S.—You will find an article on enlarging by the magnesium light in our pages a few months ago, in which a good formula is given for the preparation of the paper. See answer above to C. W. As a rule, developed prints do not require toning, the developed image generally acquiring a deep brown or black colour. A fully exposed and rapidly developed print is generally warm in tone; one requiring long development generally passes to a black tone. The best developer is a saturated solution of gallic acid. You will find many articles on the subject on referring to the indexes of back volumes. Articles on pages 247 and 253 of our fifth volume will give you useful information.

B. L.—First apply a solution of iodine to the stain (made by dissolving 1 grain of iodine and 2 grains of iodide of potassium in an ounce of water), then apply the cyanide solution, which will remove the stain; finally, wash well.

Z. H. A.—The scrap of untuned and unfixed print was too much discoloured when it reached our hands to enable us to form much opinion of the marking; but we should judge from its appearance that it was from a defect in the negative. If it is not, we should require a larger example, or two or three of them, to enable us to form an opinion.

NO CHEMIST.—When the albumen is diluted in Mr. England's process the ammonia is still added: about 8 or 10 drops of liquid ammonia to an ounce of albumen solution. 2. The excited plate is washed, then coated with albumen solution, then washed, and then the silver solution is applied. 3. The collodion you mention will answer; but it will be better if you add to each ounce an additional grain of bromide of cadmium. 4. The edges of the plates may be varnished with the varnish you name. 5. Your 30-grain bath strengthened will serve. If it possess great excess of nitric acid, add a little oxide of silver to neutralize a portion of it. 6. Better make a new toning bath. We are glad to learn that our advice helped you so satisfactorily.

THOMAS STOTHARD.—The addition of a little more soluble cotton will probably assist you in obtaining vigorous images more effectually than will the addition of an iodide; or you may try the gelatino-iron developer.

W. H. W.—Thanks for your letter. We are quite of one mind on the subject named. We will speak to the Publisher as to the neglect in question.

THOMAS COLLINS.—We do not know of any stereoscopic slides of the statuary in the Vatican; but, if they are to be had, Messrs. Marion and Co., of Soho Square, will most likely be able to supply you. Specimens of the work of the lens you mention can doubtless be obtained of the manufacturer.

W. H.—Vignetting opal-glass pictures produced in the camera is effected by placing a piece of card with an oval aperture between the lens and sensitive plate, or by placing a vignette glass in contact with the negative. 2. Patent plate flashed opal answers best.

T. MARTIN.—Received. Thanks.

J. STUART.—We have very carefully examined the spots on the prints, which are singular and puzzling. We find that they are of three sorts: bright yellow spots, grey and transparent, and black and opaque. We are disposed to believe that the cause is in the mounting board; the origin of the latter class certainly is. On soaking and removing the print we find the spots chiefly on the board, and not on the print. They suggest the idea of a fungus growth, the consequence of the boards having remained some time damp. The boards contain a great deal of starch, and more hypo than is desirable.

ENAMEL.—On careful examination and testing of the cards sent we find a trace of hypo, but much less than in most commercial samples of cards we meet with. The amount is insufficient to cause serious injury.

Several articles in type are again compelled to stand over.

## TONING COLLODION PRINTS.

THE prevailing defect of the various examples of developed prints on a collodion film which come under our attention is a want of warmth and depth in the tones. Brown tints are rarely obtained, and, when secured, they generally lack richness and intensity. The prevailing tint is a greyish or bluish black, cold, and wanting in depth and force. We have more than once recently described the various modes of toning collodion prints, and the peculiar tints produced by different treatment, and it is unnecessary, therefore, again to discuss here the details of each method. We have, however, a hint to offer in reference to one of the methods, the conditions of success in which are not generally well understood.

Perhaps no tone more perfectly suits the peculiar character of the developed collodion print, whether it be used for enlargements or small pictures, than a rich black, either quite neutral or inclining to warmth. The tone obtained by treating the image first with bichloride of mercury and then with hyposulphite of soda is black, but it is generally a cold or greyish black, not perfectly satisfactory. The tone obtained by the use of a gold salt is generally black, but it too frequently inclines to a blue black, which is not more satisfactory than the grey black of the mercury salt.

We have recently been favoured by Mr. Burgess, of Norwich, with a sight of some examples of his Eburneum process, in which the picture is produced, as our readers know, by collodion printing in the camera. The tone in these specimens was of a singularly fine black, without a trace of blue, resembling the colour of a good engraving. In answer to our enquiries as to the mode of producing this tone, we learnt that gold was the colouring agent, but that success in securing the right tint was dependent upon some other conditions worth noting.

To produce the finest tone in Eburneum prints, and, of course, in all developed prints on collodion, a good negative, good light, a suitable developer, and gold solution of suitable strength are necessary, and it is difficult to produce a good black tone if any one of these elements of success is wanting. The negative need not be very dense, but it must have well-marked gradations, and *must not be fogged*; it must be clean and bright in the shadows. It is assumed, of course, that the collodion and nitrate bath are in good condition, and we need not here dwell on these. The quality of the light is too little considered in the production of collodion prints. It is assumed that a dull light, in which other work would be impossible, may be used for collodion printing, a little longer exposure being

quite sufficient to compensate for a little worse light. Mr. Burgess, whose opinion is valuable, not simply because his experience in this direction has been large, but also because his taste is cultivated and fastidious, states that he finds it impossible to get fine collodion prints, which will receive a rich tone, in a bad light. In this, as in many other photographic processes, protracted exposure does not quite compensate for lack of intensity in the light.

After careful testing and comparison of the iron and pyro developers, Mr. Burgess has given the preference to the latter for producing these prints. The formula which gives best results is as follows:—

Pyrogallie acid	...	...	...	3 grains
Citric acid	...	...	...	3 "
Water	...	...	...	1 ounce
Alcohol	...	...	...	quantum suff.

The exposure should be sufficiently full to enable the image to flash out on the application of this developer without much forcing. Experience alone can guide the operator to what extent the process of development should be carried to secure a tolerably dense reduction in the blacks of the image without getting any trace of reduction on the points of high light. Mr. Burgess fixes with cyanide, and, after washing well, proceeds to tone with a neutral solution of gold, to which no addition of any kind has been made. When all other conditions have been satisfactorily secured, the use of a strong gold solution completes the success, much greater richness being secured than with a weak solution. Mr. Burgess sometimes uses a solution containing a grain of chloride of gold to a drachm of water; but his more usual strength is a grain of the gold salt in from 1 to 2 ounces of water. The time required for toning with a good collodion print and strong gold solution sometimes does not exceed two or three minutes, but generally requires from five to fifteen minutes. The operation is completed, of course, when the black tone is seen through the glass at the back of the print.

As we have remarked, the question of toning is equally important in regard to all the purposes for which developed collodion prints are required. But we cannot forbear, in conclusion, expressing our surprise that a process so simple in its manipulations and so beautiful in its results should receive so little attention amongst portraitists generally. Mr. Burgess gave his process, through our columns, freely to photographers, furnishing full information as to its manipulations throughout. Some of our readers have, from time to time, sent us fine examples of the process, worked according to instructions; but the commercial utilization of the process has not, we think, been at all commensurate with the merit of the process, or with the probable profits it would return.

## PHOTOGRAPHY AND THE ABYSSINIAN EXPEDITION.

ON bringing to a successful issue the Abyssinian campaign, it is gratifying to learn that the scientific staff of Royal Engineers attached to the expedition have contributed in no small degree towards the triumphant termination of the affair. Besides rendering invaluable services to the army, and gleanings of information which has added greatly to our former knowledge of Abyssinia, the engineers, surveyors, signallers, telegraphers, wall-sinkers, photographers, and others have materially helped to civilise the country, and have left behind them works which will, no doubt, prove to be the germs of enlightenment and progress. A railway of 12 miles was constructed, a grand trunk road leading upwards of 400 miles into the interior was made, the greater part of the country was surveyed and mapped out, and a telegraph line of some length established; and although some of these works were removed and others destroyed before the British left, still their existence for a brief period only was sufficient to show the Abyssinians what can be done by European nations.

It is with that branch of the staff devoted to photography that we have at present to do. As we stated on a previous occasion, the chief photographer in charge of the party was Sergeant Harrold, R.E.; he was assisted in his work by seven non-commissioned officers and men, all of whom, however, with one exception, fell sick before Annelsy Bay was reached on the return journey. The equipment was a very bulky affair; it was divided into two portions, one being styled A and the other B, and each consisted of eighteen boxes. B equipment remained at Senafe untouched, and was returned to England without having been opened, while A invariably accompanied the advance guard until the expedition reached Lal, when, as strict orders were issued to leave all baggage behind, Sergeant Harrold and his companions, in preference to remaining in the rear, parted from their paraphernalia, and went forward as fighting soldiers. Subsequently the equipment was forwarded to Magdala, but arrived unfortunately too late on the afternoon of King Theodore's burial to allow of a photograph of the body being taken prior to its interment. This is very much to be regretted, as, with the exception of a sketch made by Mr. Holmes a few hours after the king's death, and since photographed by the Stereoscopic Company, no authentic portrait is in existence.

The number of pictures taken, amounting to sixty-five in all, are for the most part very fair specimens of photography, and when the conditions under which they were taken are considered, the result is certainly very creditable. A view of lake Ashangi, taken from a distance, with grassy slopes and picturesque foliage in the foreground, is exceedingly pretty, and reminds one very much of a Cumberland or Westmorland scene. The Tacazza and Takasi rivers, the latter supposed to be one of the sources of the Blue Nile, both afford charming views of wood and water. Two panoramic views of Zoola and Senafe, each consisting of three negatives, are very fine productions, and testify to great skill and tact upon the part of Sergeant Harrold and his assistants. Then we have a view of the interior of Magdala, showing the description of architecture most in vogue in Abyssinia, the houses being circular in form, built of bamboo and thatched with straw, and resembling very closely English haystacks. Magdala Church and King Theodore's grave form the subject for another picture; and in the next we see a barn-like building, with a few out-houses, which bears the high-sounding title of "King Theodore's house, treasury, mint, &c." Then we have a faithful sketch of the lofty fortress from which the Emperor first saw the approach of our men, and down the steep side of which his soldiers ran in exulting glee to capture what appeared to be a heavily-laden baggage-train, but which, unfortunately for them, was nothing less than a battery of steel guns. The finest picture of the whole series is, in our thinking, a view of a stupendous

cliff overhanging the Bashelo river; the scene is beautifully lighted, and the mass of granite, which forms a sheer precipice some hundreds of feet in depth, stands out from a mass of dark foliage in bold relief. Lastly, we have several groups of native chiefs, of the European and native prisoners, of Kassai and his staff, of the Queen of the Gallas, &c. The European artisans who made King Theodore's cannon are likewise shown, as are also two daughters of the late Mr. B. H., who in earlier and happier times was the King's Commander-in-Chief and bosom friend. One more portrait deserves mention; it is that of a wearied old man, an Abyssinian fiddler, in his native costume, with his one-stringed instrument upon his knee. His grey locks, thrown back from his forehead, reach down to his shoulders, and impart to his grave, thoughtful face a truly venerable air; he is the bard of other days. The pictures, if not all of them faultless in their production, tell their tale with grave fidelity, and form valuable illustrations to the story we have all read of the Abyssinian campaign.

Accidents with the apparatus and chemicals seem to have been of rare occurrence; everything was carefully returned to its proper place and firmly packed in the transport boxes whenever the day's work was ended and a march ordered. Sensitizing and printing had to be carried on whenever there was a short halt, or in early morning before setting out; but seeing that in many cases the day's tramp began at three a.m., and lasted till eight or even ten p.m., the opportunities for working were few and far between. The sand storms in some parts of the country were very troublesome, frequently blowing over the dark tent, which, in order to be very light and portable, had been made somewhat topheavy. The negatives in the plate-boxes suffered also from the same cause, the sand entering the smallest crevice, and sometimes doing serious damage to the plates. The only other misadventure of importance was the bursting of an ether bottle which had been securely packed in a tin case; the heat was so great that the bottle exploded, tearing the case to pieces and making it go off like a small shell. The stock of albuminized paper failed after the first few weeks, and all the prints had afterwards to be taken on plain salted paper. The albuminized paper was found very difficult of preservation, and became blackened and discoloured very soon after being sensitized, so that its absence under these circumstances was of little importance.

One difficulty seems to have been rather severely felt by Sergeant Harrold, a difficulty which it was impossible to combat, and which is inherent with military discipline. In an ordinary way, a photographer, if he cares at all for his reputation, will insist upon taking an object in his own way; that is to say, at such a time and under such circumstances as he may deem most fit. Now, with a military photographer it is different. He is ordered at once to take a certain object in a certain manner, and any little objections that he may make as to the sun shining direct into the camera, or the objects being on the move or too far distant, are treated as so many excuses, and he is there, not to argue, but to obey; and obey he must. It is for this reason that many of the photographs are taken in opposition to every photographic law, and anything like a successful result could not therefore be expected. However, the chief photographer and his principal assistants, Corporals Gardner and Marshall, seem to have met this difficulty without flinching, and have gone boldly to work in a manner that cannot be too highly commended. Contrivances and makeshifts of all kinds had frequently to be resorted to in a quick decided manner; and, as shown by the results, these arrangements were often the saving of the picture.

There was little need of working with dry plates, as the dark tent was always handy. Sergeant Harrold prepared, however, one batch of dry coffee plates, but was unfortunate in their employment. He received directions to photograph the interior of Addigrath Church, and proceeded, therefore, with his camera and his coffee plates to fulfil his instructions. He had focussed some rude paintings on the ground glass,

and had began to expose his plate, when a high priest or ecclesiastic dignitary of some kind appeared on the scene, and made most unmistakable signs to the effect that he must leave the spot immediately. As the exposure had just commenced, the gallant Sergeant attempted to expostulate with him, in order to gain a few moments until the picture was completed; but, unfortunately, as the period required was somewhat long, and the Abyssinian divine was becoming very energetic, both in his language and action, the valiant photographer deemed it prudent to beat a rapid retreat, in the performance of which strategic movement he unfortunately lost his plates.

A Captain Pottinger, an officer accompanying the expedition, made good use of a camera during the expedition, but his results with dry plates were not, we believe, very successful. He was also unfortunate in not having his apparatus at the front during the taking of Magdala, and was therefore, like the Engineers, unable to secure any view of the battle.

We have had an opportunity of inspecting the apparatus and necessities since their return to England, and the perfect manner in which they were selected, fitted, and arranged for transport reflects great credit upon Captain Stotherd, R.E., and Lieut. Harrison, R.E., under whose care and supervision the staff was organized and equipped. It must be some satisfaction to Sergeant Harrold and his companions to know that, in performing a difficult duty, they have been instrumental in securing of the Abyssinian Expedition many valuable mementos, some of which it would be impossible to replace.

## PHOTOGRAPHY IN GERMANY.

BY DR. H. VOGEL.

*The Gordon Gum Dry Process.*—With the greatest interest I have read your communications on the Gordon gum dry process, and I have repeated the experiments with it with the best results. I have made some trials for determining the relative sensitiveness of the gum process and the ordinary wet process, and I found necessary thirty seconds for a picture on a dry plate, under conditions which required fifteen seconds for a wet plate, using the same collodion and the same baths. I have tried collodions with iodide and bromide of cadmium—the first sample, 1 part of bromide to 2 parts of iodide; the other, 1 part of bromide to 1 part of iodide—but I did not find much difference in sensitiveness.

*The Harnecker Dry Process.*—Here, in Germany, a new dry process excites much attention—a dry process, indeed, which, from what I have seen, I believe is the simplest known. M. Harnecker, a very clever photographer and chemist, sells a dry-plate collodion. With this collodion one coats a plate and sensitizes it in the following bath:—

Silver ... ..	15 grains
Water ... ..	135 "
Nitric acid ... ..	2 minims

Wash the plate as in Mr. Gordon's gum process, dry it, and the plate is, without any preservative, ready for use.

The plate is nearly as sensitive as a wet plate. I gave with success twenty-five seconds to a Harnecker plate, and twenty seconds for a wet plate, for a picture of the same details and intensity. The Harnecker plate is, after exposure, put in distilled water, five minutes afterwards dipped in the silver bath above mentioned until the plate is evenly coated with it, and is then developed with the following developer:—

Sulphate of iron ... ..	1 grain *
Glacial acetic acid ... ..	3 grains
Water ... ..	220 "
Alcohol ... ..	4 to 5 "

\* An iron developer of 2 grains to the ounce seems unusually weak; but it is so stated in Dr. Vogel's copy.—ED.

The picture comes as rapidly as a wet plate, and is strengthened in the pyro and silver in the ordinary manner.

I do not know the composition of Harnecker's collodion, but I believe it contains a resin; but it is very curious that the bath does not fog after the preparation of the dry plates as it does with the old sensitive dry plates of Mr. England and others. But, in general, I must confess, that the results of the Harnecker process are excellent.

Perhaps you have already heard of the Mausoleum in Charlottenburg, from our Queen Louise. It is a very dark room, with the celebrated statues of the queen, from the late sculptor Ranch. It was not possible before to make any other photographs of this dark interior except stereo pictures, with very actinic lenses, and these stereos only show a little part of this interior. Recently, Mr. Stiehn had made a large picture of this interior with Dallmeyer's triplet and Harnecker dry plates, in a time of exposure of two hours, and this picture is excellent, and was very much admired in the Photographic Society.

I think the Harnecker collodion will become very important for taking plates in long exposures.

*Photographic Seals.*—A curious novelty has recently been published here by M. Sturmhoefel, in Freiberg. If you send your card picture and two thalers (six shillings) to M. Sturmhoefel you receive from him a seal with your portrait in relief. M. Sturmhoefel does not state the manner of making such a relief, but it is easy to guess:—Take a transparent positive on glass (perhaps one of your collodio-chloride pictures), print it on Swan's bichromate gelatine tissue, and soak the latter in cold water; then you will receive an excellent inverse relief (the lights hollow, the blacks relief). Make from this a copy in plaster, and from this a mould in metal, and you have the photographic seal.

*The German Solar Eclipse Expedition.*—In a few days I shall go with my friends, Dr. Zencker and Dr. Fritzsche, to Aden, in Arabia, for taking the solar eclipse; and perhaps it may interest your readers to hear somewhat of our preparations. We are ordered to take (1) prints of the total eclipse (which in Aden continues three minutes) directly with a large single lens of Mr. Steinheil, which is corrected for optical and chemical focus, and which gives a sun picture of 5.6 inch in diameter; (2) enlarged prints of the sun after and before the total eclipse at a diameter of 3½ inches; for making this we have a large refractor, with an excellent clockwork, like the refractor made by Mr. Dallmeyer for the Wilna Observatory, and described in the PHOTOGRAPHIC NEWS some years ago. We have selected Aden as our point of view, because to nearly all other localities where the eclipse is visible astronomical photographers will be sent from other nations, in Siam the Frenchman, in Persia your countrymen, &c. In this manner a photographic series of the different phases of the eclipse will be secured.

Mr. Warren de la Rue has already described especially the manner for taking photographs of the sun, the moon and in a like manner we think to work.

I fear that we are not so well equipped as your English expedition was, as we have only a single apparatus. It would be better to have two or three, for making more pictures in the same time.

We have tried our refractor (heliograph) here on the Royal Observatory, in taking the moon in a like position as the sun will have in Aden at the time of eclipse. The time of the eclipse in Aden is nearly six o'clock in the morning, and the sun will be at that time so low that I fear its actinic power will be very slight. We have taken the moon in a like low position in a bright weather with five seconds' exposure, and have received a well exposed picture in one second time another day, and have necessary twenty seconds for well exposed images. Now Mr. Warren de la Rue states that the prominences of the sun during the totality are about three times as bright as the moon, and therefore we hope to receive in the time of totality (three minutes in Aden) at least three well exposed pictures of the

arious prominences, which are like clouds visible around the margin of the dark moon during the eclipse.

My experiments with different samples of collodion for taking the moon have given some results different from those of Mr. de la Rue. A pure iodized collodion gave a very hard picture, intense in the high lights, but so feeble in the spots of the moon; a bromo-iodized collodion, on the contrary, gave a soft picture, not so intense in the lights, but better in the shadows.

For this reason we will take for the prominence picture during the totality a bromo-iodized collodion.

For the pictures with the bright sun, taken before and afterwards, we shall take a pure bromized collodion, which gives in the objects of very great intensity of light much more detail than a bromo-iodized collodion, which will be very often over-exposed in the shortest time.

We think, also, to make trials for taking pictures of the stars of the south hemisphere and other things of scientific interest. M. Zencker will make photographic studies of microscopical animals and plants of the Red Sea. Mr. Fritzsche will take pictures of the different peoples—Arabs, and others, in Aden. For my part, I think to make artistic and mineralogical and geological studies of the landscape of Aden.

It is proposed that our expedition shall go afterwards to Upper Egypt for taking inscriptions of the hieroglyphics in the temples of Edfer, Dendera, and Luxor.

Mr. Thümigen, the eminent "Egyptologist," will assist us, and signify the point interesting for the archaeology.

I think it will be an interesting voyage, from which I shall return not before the end of October.

In the intermediate time I hope to write to you upon the success of our works; and closing this letter on the "Photography of Germany," I hope to give you in my next an account over the "Photography in Arabia and Egypt."

### WASHING MACHINES: THE ECCENTRICITIES OF A SYPHON.

BY NELSON K. CHERILL.

NEXT in importance to the perfect action of the fixing agent used in silver printing is the perfect action of the water used in removing that agent.

It is curious, but at the same time characteristic of photographers, that, until quite recently, the two departments of silver printing on which permanency depends were the very two which received the least attention. It used to be taken as a rule that silver prints must fade, and therefore it did not much matter how soon. Now, however, I hope there will be a little more care bestowed upon the matter; the ventilation the subject has lately received has certainly done much good, and has shown photographers that even though they must not hope for absolute permanency, silver printing may be longer lived than has generally been supposed.

The points which have been brought out are, I think, briefly these: Firstly, that by more careful fixing—using, if necessary, two baths, or one of hyposulphite of ammonia—very much more silver may be removed from the whites of albuminized paper proofs than has been done, as a rule, hitherto. Secondly, that by a more scientific application of water in properly constructed washing machines, very much more hypo may be removed from the prints than has been usual up till now. And, thirdly, that by a judicious mixture of scolding and coaxing in proper quarters, a mounting-board can be obtained with, if not absolute immunity from hypo, at any rate less in it than usual.

These three matters are of so great and vital importance to the success of silver printing, that I propose to give special attention to them, with a view of reporting any observations I may be able to make of a suggestive or useful character.

I have already tried enough experiments with the double

fixing bath to render me exceedingly anxious to try more, and I only await the promised commercial supply of hyposulphite of ammonia from Messrs. Mawson and Swan to investigate the matter fully. I feel it would not be so conducive to practical utility were these experiments made with a small home-made sample of the hyposulphite of ammonia, because the result at which I wish to arrive is one which depends mainly upon the cheap and constant supply of the new fixing agent.

While, however, these experiments are brewing, I should like to say a few words on washing machines in general, and on syphon machines in particular.

It appears to me that the most simple and effective washing machine is that which nature provides—a river. Put your prints in, tied by the hind leg, and, provided there is not another photographer next door above, you may expect the hypo to be pretty well washed out in the course of a very short time. The practical objection to this simple and elegant plan seems to lie in the fact that our brethren of the camera are not, as a rule, landed gentry, and that access may not be had to streams and water-courses with sufficient ease to admit of the plan being adopted as a rule.

The plan next best to the one above mentioned seems the one in which the action of the river is the most nearly approached: constant change of the water, and constant motion when in the water, seem the great requisites, and, fortunately, they are not difficult to obtain. A box with facilities to let the water run in at one end, and out at the other; a tap to let the water in with, and a syphon to run it out—and, if the thing is properly made, there is no need for elaborate contrivances of taps, and cock-and-ball apparatus, and sluices, and levers, and chains, fine things for plumbers to fit up, and "a regular annuity" to "the man" who "looks after such things," but which, even on paper, look more like the early efforts to scheme a steam engine than the latest productions of the nineteenth century in such a simple mechanical contrivance.

It is, I think, probably owing to some slight misapprehension on the part of the schemers of some of these very elaborate contrivances, as to the action of a syphon, that it is so usually considered necessary to make the supply cut off all the time the water is running out of the washing apparatus. There cannot, in my opinion, be a greater mistake: a syphon, when properly constructed, will work enormously faster than it is necessary to supply the water to the cistern, so that though the supply-pipe is running all the time, the cistern may be quite emptied in a very few minutes; and I even consider the action of the water which comes in during the process of emptying very beneficial, because it washes (if I may use such an expression) the water off the prints, and gives them a more complete change than they would otherwise obtain.

It may not, perhaps, appear, on first sight, how it is that a slow running pipe used for filling the washing machine can "start" a large one to work as a syphon for the purpose of emptying it; it might seem, at first sight, that the syphon pipe must be no larger in bore than the filling pipe. But this is quite a mistake. I will try and explain why. The action of a syphon is produced by the pressure of the air upon the water contained in the vessel being emptied, which constantly drives the fluid up the shorter arm of the tube to supply the vacuum which would otherwise be formed by the water running out from the longer arm. It is only necessary to form a current of water in the longer arm of the syphon sufficiently rapid to induce the first flow over the bend at the top to ensure a proper action of the instrument. Now let me explain how a very little water coming into the apparatus may effect this purpose easily enough. Let us suppose a case in which a small inflow of water (say at the rate of 10 pints a minute) has to start a  $\frac{3}{4}$ -inch syphon: as the water rises in the apparatus it will, of course, begin by gently overflowing down the syphon pipe by just trickling over the bend of the pipe; the rate of outflow would go on increasing till it was the same as the rate of

inflow; and then it would remain, running in at one end and out at the other without ever starting the syphon at all, but for a very curious and important point, viz. this—that the long leg of the syphon, by going down far below the level of the water in the apparatus itself, gives the water confined in it a very considerable speed in its transit through the pipe, so that the water which only ran quite slowly over the bend of the syphon pipe comes out with quite a rush at the bottom, when it has fallen through some three or four feet. But when water goes through a pipe in this manner—namely, beginning quite slowly as at the top, and running with increased rapidity all the way down—it naturally follows that the air in the pipe gets entangled with the water and carried down with it. The moment this occurs the pressure of the air on the surface of the water in the washing trough sends up some more water into the short limb of the syphon, and so more and more comes down the longer limb, till in about thirty or forty seconds after the first few drops come over, the syphon is at full play, and emptying the trough as quickly as possible.

To ensure the success of this plan, one thing only is necessary, as far as my experience goes; viz., that the longer limb of the syphon must be as *straight as possible*; it must have no eccentric bends or curves to check the progress of the water which comes over first, for it is on the speed of the first few pints that the success of the whole depends.

In setting up an apparatus of this kind not long ago, I found that a bending of the tube only once at right angles, and then carrying it out straight for a few feet, so much took off from the efficiency of the arrangement, that not only would a small influx of water into the tank not start the syphon, but even it did not start when the tank was filled up two or even three inches above the level of the bend; this I quite account for by the peculiar shape of the longer limb of the syphon, which allowed the air to enter freely at the bottom at the same time that the water was running out, thus requiring main force to set up the proper action, and not, as it should be, the gentle influence of the small but rapid flow of water to begin with.

I find that the inflow of the water into the machine is sufficient to cause enough motion in the prints; this refers to only a moderate number, however; when very large quantities of prints have to be washed at once, the ingenious apparatus used in Mr. Bedford's establishment, and described some time ago in the *News*, is most efficient in keeping up a constant agitation of the water and prints; it consists of a flapper kept in constant motion in the water by means of a waterwheel turned by the inflow water.

When the water is draining out of the washing machine, the prints should not lie on the bottom of the trough, but should be provided with a perforated zinc false-bottom on which to drain; this should be kept from the real bottom by slips of wood, or otherwise, so as to be about half an inch clear of it. I find that nothing can be better than three coats of Bates's black varnish to preserve the prints from injury by contact with the metallic zinc. This varnish should, it seems, be renewed every three months or so, as it may require it.

I remember some time ago seeing an account of some experiments with zinc for washing trays unprotected by any coat of varnish; though, in the particular instance referred to, the prints may not have been marked by the metal, I cannot but think that, in all cases, it must be much better to use a coating of varnish to protect the surface of the paper from the metal.

Now all lights—with the exception of those belonging to objects self-luminous, as fire, the sun, &c.—are either the reflections of light from the surfaces of bodies, or transmission of light through those that are transparent or partially so; the focus of light on a globe is, therefore, as much a reflection as that appearance on its shadowed side which, in ordinary language, is called the reflection; and as to the terms half-lights and half-shades, they but express, if literally understood, single degrees among the endless gradations from light to dark."—*Leslie*.

#### CHIAROSCURO—(continued).

ALTHOUGH there are, between white and black, an infinite variety of gradations, it will be convenient to divide them into light (1), half-light (2), middle tone (3), half-dark (4), dark (5). If a picture were composed of light and half-

1. 2. 3. 4. 5.

light only, the effect would be weak and flat. In photographing distant views, which consist principally of light tones, it will be necessary to introduce some dark object in the foreground to give force and consistency to the whole. Turner has carried this principle to perfection. Many of his most beautiful pictures, full of air and space, consisting chiefly of delicate greys and blue, are brought into focus by the introduction of the dark foliage of the stone pine, supported by some dark spots in the foreground, which is generally light, the darks being united to the lights by delicate and infinitely varied half-tones in the middle distance. Rembrandt's method was exactly the reverse of this, but the same in principle; his pictures are composed of half-dark and dark, having one small focus of brilliant light, united in a magical manner to the darks by half-tone. The marvellous effect of his pictures is due, in my opinion, more to the judicious management of the half-tones than to the strong contrasts and forcible effects of his light and shade. In his pictures and etchings will always be noticed a wonderful transparency in the shadows, which is almost entirely due to the half-tones with which they are associated. Claude, Turner, and Rembrandt were alike in their management in one respect: they always forced the brilliance of their lights by the opposition of the strongest darks. When Claude and Turner represent the sun, they place near it their darkest dark. This effect will always be seen in nature; if the sun is setting behind a tree, the tree will be darker than any other object in the scene. In Rembrandt's portraits the head is often covered with a black velvet cap to increase by contrast the brilliancy of the face, and it will be observed that the other parts are, although dark, in half-light in comparison. This principle is carried out to a great extent in the pictures of Adam-Salomon, where the dark velvet so often introduced plays a most important part in the economy of light and shade.

Light and shade varies so much with the subject to be represented that it can scarcely be reduced to anything like a system. But there are a few general arrangements which the photographer would find valuable to have always before him, and they are only, as it were, duplicates of the laws that govern composition.

In chiaroscuro, as in the composition of lines, the centre is the weakest part of the picture. Neither the principal object nor the chief light should be situated in that place where lines drawn from the opposite corners would intersect. A position either immediately above, below, or at the side of this point would better satisfy the requirements of pictorial effect. In a portrait the head, which is the principal object, and light, would be above this position, in a more or less degree, according to the stature of the individual.

When the light spreads through the picture it should never be allowed to form either a horizontal or vertical line. This refers to the general mass of light. The horizontal bars of light seen at twilight are often very beautiful, and their formal straightness give a grandeur and a sentiment of repose to be produced in no other way. This rule, in

#### PICTORIAL EFFECT IN PHOTOGRAPHY; BEING LESSONS IN COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS. BY H. P. ROBINSON. CHAPTER XXVI.

"The vocabulary in use relating to light and shade is utterly inadequate to convey that knowledge of its phenomena that a painter requires. It comprises merely the terms light, shade, reflection, half-light, and half-shade."

other words, would run thus:—The centre of the picture should not be light, with the two sides dark, or with the top and bottom only dark. When the light falls or is spread diagonally it is more picturesque than when it is arranged horizontally or vertically. The same rule would, of course, apply to shadow.

There must be unity of effect in the light and shade as well as in the composition. Chiaroscuro will often "pull a picture together" when the composition is scattered. Where there is too great a repetition of forms, light and shade will break them up or mass them together. Chiaroscuro should produce that effect which is produced upon the retina when the eye is intently fixed upon an object, and is not permitted to wander, and which some artists maintain should be obtained by sacrificing the inferior parts of the picture to the principal, but which will not bear the light of argument. The theory is that the eye sees only one point in perfect focus at the same time, and that there is something unpleasant and imperfect, even to the least experienced eye, in a picture where everything is made out—the drapery, the accessories, &c., all minutely represented with the same finish as the head. This is a fallacy that has led many clever painters astray. It is true that the eye, theoretically, only sees one point at a time, but the eye alters its focus so instantaneously that practically it sees one part almost as well as another; and the same rules should apply to the picture as to nature. Notwithstanding that pictures are usually smaller than nature, if the eye is fixed on the chief feature, the other parts, however highly finished, will naturally go out of focus as much as they do in nature, which, as I have already explained, owing to the instantaneous alteration of focus in the eye, is not much. Here is an illustration. As I write I am looking through a window; a few feet beyond the window is the railing of a balcony beyond a terraced garden; beyond that a grove of trees; yet further a church tower; and in the distance some hills veiled in the blue mist. All this is seen through an aperture two feet square, and as I look at it, the focus of the eye changes so rapidly that I can detect no want of definition—such definition as we get in a photograph—anywhere. The only indistinct part is the distant hill.

But there is no reason why this scene, if represented in a picture, should be a mass of mere detail. Sharp, as we call it in photography, it may be all over, but if it is to have pictorial effect it must be massed: the church tower, which is the principal object, must come out into the strongest relief, the rest must be subordinate, and thus we should obtain that unity without which a picture is a thing of naught. The picture is felt to be true and natural when the eye is at once led to dwell on the chief group or the principal object. By insensible degrees, the painter who is a master of his art keeps down the parts which interfere with the centre of attraction—

"All things seem only one  
In the universal sun."

And so, after a fashion, it should be in the picture produced by his light.

Unity of light and shade, as I have just stated, is imperative; but there is another quality which at a first glance would appear to be antagonistic to unity, but which really aids it. In a former chapter I dwelt at some length on the necessity of repetition in lines and forms; the same rule, only in a stronger degree, applies to chiaroscuro. No light in a picture should be allowed to be single or isolated, but should be repeated or echoed, not in its full quantity or force—there must be no rival near the throne—but in an inferior degree. The strength of Rembrandt, strange as the statement may appear, was not so much in his great contrast of black and white, as in the manner he harmonized and mellowed the violence of either by echoes and faint repetition throughout the picture. It is the repeated but fainter echoes of the chief light that harmonizes and brings together the various parts of a picture into the unity of a perfect whole. The repetition of the air, varied and

less pronounced, in a piece of music, produces a sympathy and connection of thought throughout. The effect is analogous to that of metaphor or simile in literature: a repetition must not be a symmetrical likeness of its original, but should appear to belong to the same family. It must avoid the symmetry of detail, but produce a sort of wholesale symmetry. What is the secret of the delight we take in reflections, if it is not similar to that we take in bearing the repetition of a sound, or in seeing the echoed sympathy of one part of a picture with another? To many the reflection is more beautiful than the reality. Shelley loved the mirror-like reflections to be seen in forest pools—

"Sweet visions, which in our world above  
Can never well be seen,  
Were imaged by the water's love  
Of that fair forest green;  
And all was interfused beneath  
With an Elysian glow,  
An atmosphere without a breath,  
A softer day below."

And Mr. George Macdonald, in his fairy romance and prose poem, *Phantastes*, says:—"Fair as is the gliding ship on the shining sea, the wavering, trembling, unresting sail below is fairer still. Yea, the reflecting ocean itself reflected in the mirror has a wondrousness about its waters that somewhat vanishes when I turn towards itself. All mirrors are magic mirrors. The commonest room is a room in a poem when I turn to the glass."

## PHOTO-ZINCOGRAPHY IN PRACTICE.\*

BY J. WATERHOUSE, R.A.

### CORRECTIONS.

It has usually been stated that the great disadvantage of using zinc for printing from is the difficulty of correcting errors or making additions after the subject has once been put down and etched. If the following directions be observed little difficulty will be experienced. In making corrections care must be taken to avoid touching the surface of the plate with the fingers or to allow the breath or saliva to fall on the plate. In order to prevent this a piece of clean paper should be placed under the hand. A board raised above the surface of the plate should be used to rest the arms on, and a piece of card should be held before the mouth by means of elastic, &c.

Corrections before printing are better made before the plate is etched. Stains, finger-marks, spots, and other imperfections may easily be removed by means of a piece of snake stone, slate pencil, &c. Faint lines may be strengthened with autographic ink and a fine steel pen. Parts may be added by transfer from transfer paper with a small brass roller. If the plate has been etched and rolled in, the following plan must be adopted:—The plate is first covered with gum, and fanned dry. If there is no ink on the part to be altered, remove the gum, and brush the plate with dilute sulphuric acid (1 to 6); this is then well washed with water, and any insertion can be made by being transferred from transfer paper or put in with crayon or pen and ink. The part is then etched, the gum washed off, and the plate is ready for printing. The dry point may also be used for putting in detail, but in this case the print is etched *before* using the point.

If it is required to remove part of the work before making the correction, the plate is fanned dry, a dilute solution of caustic potash is applied to the part with a pen or brush, according to the size of the alteration required. When the ink is removed, the potash is soaked up with blotting-paper, the gum, &c., is washed off, and the part allowed to dry. The dilute sulphuric acid is then applied as before, and the corrections put in. Care must be taken not to allow the alkaline or acid solutions to spread, which may be obviated by placing a mask of card over the surrounding parts.

If the dry point is used the acid is not required; the part

is etched, then covered with gum; the required detail is scratched in with the point; printing ink is then forced into the lines with a dabber made of closely rolled flannel, worked round and round till the lines are well charged. A sheet of waste paper is put over the plate, and a proof is pulled, which drives the ink well into the scratches, and also takes off most of the superfluous ink; the remainder is taken off by sponging the plate, when it comes off with the gum; if necessary, the plate may be washed with turpentine and then rolled in again.

If the part to be altered is large, or the work has been on it for some time, it is better to grain it with a small muller and fine sand, after treating it with sulphuric acid. If the part cannot well be grained, the acid must be allowed to work for a longer time.

#### FAILURES.

I will now notice briefly the principal causes of failure in each part of the process.

1. *Preparation of the Transfers.* The ink refuses to leave the ground of the print.—The paper has become too old and decomposed, or has been dried at too great a heat. The negative was not sufficiently intense, or the print over-exposed.

The ink leaves the lines.—The print has not been sufficiently exposed to light. The detail in those parts of the negative is clouded over, and hinders the action of light. Ink too soft. Pressure of sponge too great. This fault may sometimes be remedied by taking a little transfer ink on the forefinger and dabbing the lines with it.

The lines ragged and broken.—Under-exposure. Coating of gelatine too thick. The washing water too hot.

Surface of the paper spotted over.—The coat of gelatine too thin. The pressure too great when inking. Use a thicker coat of gelatine, or ink by hand.

The close parts clogged with ink.—Too thin a coat of gelatine. Imperfect contact between the negative and paper. Over-exposure. Excess of ink, too hard or too soft.

2. *Transferring to Zinc.* The ink does not leave the paper, or only transfers faintly.—This may arise from long soaking of the transfers in order to get the ink off. The zinc plate has been kept too long. Too little ink on the print. The transfer too old.

The lines are much spread.—The ink is too soft. The coat of gelatine too thick. Excess of ink, resulting from over-exposure, or from too thick a coating being applied.

The ink does not leave the print in parts.—Uneven pressure while transferring. Uneven drying of the surface of the print after washing, which might be obviated by removing the surface moisture by means of blotting-paper before hanging up to dry.

3. *Printing.* The ink is deposited on parts which should remain clear.—This is caused by the plate becoming too dry, from not having been damped enough before rolling up, or, in hot weather, from the rapid evaporation of the moisture, which may be obviated by the use of the damping mixture before mentioned; but if, by accident, it should occur, as soon as it is observed, the parts should be gently rubbed with a flannel, which will generally remove the ink, or the plate may be damped and the ink removed by rolling in quickly and dragging the roller smartly over the parts.

There is a much more serious defect, which, if neglected, may result in the loss of the plate. It is termed "smutting up." The detail becomes obscured in a black patch, which resists all modes of cleaning. The causes of it are very numerous. Among the principal are:—Etching solution is too weak. Excess of moisture on the paper or stone. Extreme heat or cold. Use of soft bad ink. Dirty sponge. Contact of a greasy body. Friction with the finger. It must be remedied, as soon as it is discovered, by washing the ink off with turpentine, and rolling in again with hard ink, damping with the gum solution.

The lines are doubled or spread. This arises from several causes, among them:—Slackness of the tympan causing it to be too close to the plate, which prevents the free extension of the paper. Use of paper too dry or badly damped, and

of which the edges have become drier than the centre. The remedy is to fix the paper in the tympan, which should be raised slightly off the plate, so that the sinner may act gradually on the paper. Most of the failures in this process are the result of simple mechanical defects, the causes of which are not difficult to discover, and which may be easily remedied.

#### PHOTO-ZINCOGRAPHY IN HALF TONES.

Photo zincographs of ordinary photographic views, &c., can be obtained, but the results are not satisfactory unless they are considerably retouched. The process is much more suited for the reproduction of architectural details. Some excellent specimens of this process, consisting of views of Netley Abbey, Jerusalem, and Stonehenge, have been published at the Ordnance Survey Office, and I will describe the process by which they are produced. The sensitive transfer paper is prepared in exactly the same manner as for subjects in line, but is kept for about a week before it is used; the effect of this is to slightly decompose the surface and make it more capable of retaining the ink. The negatives should be good, and may be denser than is usual for silver printing, as the paper is more sensitive, and there is no after-reduction of the intensity. The exposure varies from five minutes to a quarter of an hour, more or less, according to the intensity of the light and the quality of the negative. The inking is conducted in the same manner as for line work, but the ink may be harder and the pressure greater. The development is the most important part of the process, and requires great skill and experience to ensure success. The prints, coated with ink, are laid face downward on lukewarm water, and allowed to remain till the gelatine is softened; the surface ink is then gently removed by washing the surface with a very soft sponge and warm water, taking care not to scrub it at all. The print is then immersed in warm water, which is gently agitated, and the detail will gradually appear; the water is changed after a short time, and the operation repeated, the prints being allowed to soak for an hour or so between each change. When most of the unaltered gelatine has been removed and the print appears to have soaked enough, it may be finished off by again washing with sponge and warm water; it is then hung up to dry. When dry, the print will appear darker than a silver print of the same subject, but that will be remedied when it is transferred to zinc. The transfer to zinc is the same as before described. The printing must be conducted with as great care as is required for the finest chalk drawings, and the damping solution must be used.

#### PHOTO-ZINCOTYPY.

I have made a few experiments with a view to obtaining a raised printing surface on zinc by means of photography, and, from the results I obtained, am of opinion that the process might be practised with success for the reproduction of diagrams, woodcuts, &c., to be printed with type. I have not worked it out thoroughly yet, but will describe the process, in order that others may be induced to experiment in this direction.

A photographic transfer is made on to a fine grained zinc plate in the manner described before. Care must be taken to have the lines very perfect, or good results cannot be obtained. The ink is washed off with turpentine. The plate is rolled in with an ink composed of:—

Bitumen	...	...	...	4 parts
Litho printing ink	...	...	...	2 "
Wax	...	...	...	1 "
Burgundy pitch	...	...	...	1 "
Turpentine middle varnish	...	...	...	1 "

When this is done, the plate is left for twenty-four hours till the varnish is quite dry. The back is then covered with wax or Brunswick black, &c., and the plate is connected with a copper plate at about a distance of a quarter of an inch. The two are then plunged into a 70-grain solution of sulphate of copper, and after a short time the subject will

be found in relief. It is better then to make a cast of it and pile up the white parts. The cast may be stereotyped or electrotyped in the usual way. The process has been practised in France for ordinary work, and, it is said, with success; but I do not think it has been used in conjunction with photography.

### THE WET COLLODION PROCESS.

REMARKS UPON THE PRODUCTION OF BRILLIANT PICTURES.

BY C. STERNBERG.\*

A BRILLIANT negative is the first thing needful in obtaining brilliant pictures. Every possessor of a portrait album must have remarked how comparatively few of the pictures in his collection have any pretension to brilliancy. Many photographs are sharp and full of detail, but at the same time dull and without vigour, or they are sharp and clear, but hard, and without either detail or half tone. But few specimens are plastic and brilliant, and have sufficient gradation of tone.

A process by which brilliant negatives are obtainable includes, of course, many manipulations with which the experienced photographer is perfectly familiar; but, nevertheless, to the general reader, a recapitulation of the different conditions necessary to their production may not be without interest.

In my opinion, the great source of failure lies in the thickness of the film which forms the image upon the glass plate. Although I am perfectly aware that the negatives of many excellent photographers possess a certain amount of thickness, still I am, nevertheless, of opinion that a really good negative should be thin and perfectly clear. A few points in the deepest shadows should display clear glass, and in certain portions of the high lights an almost perfect opaqueness of the film should be visible; and between these two extremes there should be as many gradations of tone as possible. If few half tones only are present in the negative it is impossible to obtain a brilliant print from the same, as the result will either be weak, or hard, according to the difference in the thickness of the film in the lights and shadows.

Very much to the point are Simpson's remarks on this subject. He says: "Let us suppose that a picture possesses twenty different gradations of tone; in order to be able to furnish a good print, the negative must then be composed of twenty different thicknesses of deposit, which are visible when the image is seen by transmitted light. A negative which begins with perfect transparency, presenting no hindrance whatever to the light in the production of the deepest tones, and which possesses the twenty gradations of tone, is capable of giving a perfectly brilliant result, although it may not appear very opaque in its highest lights. But if the deepest shadows are covered with a deposit equal to ten gradations, then the film in the highest lights must be of a thickness equal to thirty gradations of tone, in order to be capable of producing a good print; if the film in the highest lights is equal in thickness to twenty-five gradations of tone only, it will give less brilliant pictures than the negative first mentioned, although the film may at first sight appear of greater thickness."

Under-exposed negatives generally give hard pictures with large masses of white and black, and without detail or half tones. Over-exposure causes a grey precipitate to cover the picture, which fogs the shadows; a print produced from such a negative is too light in the shadows and too dark in the lights, for everything is lost in half tone, and brilliant lights and deep shadows are wanting; in an over-exposed negative a black coat becomes grey. In developing a plate which has been exposed too long, it is best not to allow the developer to go too far, but to wash as soon as symptoms of over-development are recognizable: in this manner many a picture may be saved.

The collodion to be used must not be too freshly mixed, and should be perfectly clear; its consistence should not be too thin, and it must be sufficiently iodized. Thick collodion should be diluted with equal parts of perfectly pure alcohol and ether.

The sensitizing bath must be prepared from recrystallized nitrate of silver, and should be rendered slightly acid in order to produce perfectly transparent shadows; too much acid exerts the same injurious effect upon the negative as too little. One part silver dissolved in twelve parts of water is a good proportion for making a bath; a saturated solution of iodide of potassium is prepared, and to every 400 grammes of silver solution is added one drop of the iodide and one drop of strong sulphuric acid, as under:—

Nitrate of silver	...	...	30 grammes
Distilled water	...	...	360 "
Strong sulphuric acid	...	...	1 drop
Saturated solution of iodide of potassium	...	...	1 "

If the water and chemicals used are perfectly pure, this bath will give beautifully clear negatives; but should not this be the case, and there is formed upon the picture a grey deposit, capable of being removed by the finger, the bath is purified with a solution of—

Caustic potash	...	...	2 grammes
Water	...	...	100 "

which is added by drops to the silver solution (shaking the latter the while) until a slight turbidity is observed. The bath is then exposed to the sun for a few hours, or to open daylight for some time, when a black precipitate will be formed, which is filtered off. For every hundred grammes of bath is then added 1 drop of acidulated water made by mixing 10 grammes of sulphuric acid with 100 grammes of water. After standing for some hours, the following test should be made:—Coat a plate with collodion, sensitize it, and let it drain well; develop it in the ordinary manner, without exposing, and wash and fix the plate as usual. After fixing, if the glass is not perfectly clear, but is still covered with a thin, light deposit which may be removed by the finger, a few more drops of acid must be added, and the experiment repeated: too much acid must never be added at any one time, and care must be taken that the plates used in the experiments are perfectly clean. As the deposit upon the plate may likewise be caused by the action of light, all chemical rays must be carefully excluded from the dark room.

The addition of organic substances to the developer is extremely favourable to the production of brilliant negatives. The three following formulæ are recommended:—

I.—Sulphate of iron	...	...	25 grammes
Loaf sugar	...	...	40 "
Glacial acetic acid	...	...	15 "
Water	...	...	500 "
Alcohol	...	...	15 "
II.—Sulphate of iron	...	...	10 grammes
Loaf sugar	...	...	40 "
Glacial acetic acid	...	...	10 "
Water	...	...	400 "
Alcohol	...	...	1 gramme
III.—Sulphate of iron and ammonia	...	...	22 grammes
Gelatine	...	...	1 gramme
Glacial acetic acid	...	...	8 grammes
Water	...	...	300 "

With regard to the latter, the gelatine is dissolved in the acetic acid and 50 grammes of water (this will take several hours), and the sulphate of iron dissolved in 250 grammes of water, and both solutions are then mixed. In general it will be found that weak developers produce opaque negatives, and strong developers negatives of an harmonious character. No. II. developer is suitable for summer work, and for strongly-lighted pictures. The developer should be used sparingly, for the employment of too much solution impairs

\* *Photographisches Archiv.*

the brilliancy of the negative. For intensifying I would recommend,—

Sulphate of iron	...	...	1 gramme
Citric acid	...	...	1 "
Water...	...	...	100 grammes,

to which a few drops of a weak solution of silver is added.

To judge of the intensity of a negative in the dark room is by no means an easy matter. If the chamber is illuminated through the medium of a yellow window the task is rendered more difficult, from the fact that the intensity of the daylight is continually varying; and on this account one is very liable to be led astray. For this reason I would recommend that the process of intensifying be carried on with the aid of a lamp or candle screened with yellow glass.

### CAUSES OF FOGGING.

BY JABEZ HUGHES.\*

"Fogging;" that is, a darkening of the film all over, directly the developing solution is applied.—This defect has several sources. It may exist in a small degree, only slightly obscuring the shadows of the picture; or it may be to so great an extent as to prevent its appearance. Fogging often troubles the young beginner, and as it arises from many causes it is often difficult to assign it to the right one. Sometimes deleterious vapours are the reason; as, the dark room being built over a stable, and filled with reeking vapour; the room being newly painted with a slow-drying paint; a leakage of gas; a bottle of ammonia with a badly-fitting cork or stopper. A remedy for any of the above is simply to remove the cause.

In extremely warm weather the developing solution is much more energetic, and fogging may thus arise from this increased energy: remedy, dilute it one-half, or double the quantity of acid. The following are, however, the most usual causes of fogging:—

Alkalinity of nitrate bath: remedy, addition of acetic acid till litmus paper is slightly reddened.

Extreme acidity of nitrate bath: remedy, addition of oxide of silver or ammonia until litmus paper is only slightly reddened.

Omission of acetic acid in the developer: remedy obvious.

Over-exposure in the camera: remedy obvious.

Diffused light in the dark room. If yellow calico be used, it has, perhaps become bleached, and must be replenished; or additional folds must be used. Sometimes chinks of unsuspected white light are the cause; if so, they must be stopped up.

Diffused light in the camera or the dark slide, admitted through a joint giving way, or an old screw-hole, or the parts of the camera not fitting: remedy obvious.

Nitrate bath made with impure silver, or bad water: remedy, add a few drops of saturated solution of bicarbonate of soda until the bath solution remains turbid after shaking; then expose it to the sun for a few hours and filter; acidify it if necessary.

Newly-mixed collodion will sometimes cause fogging; it then requires to be kept for a few days, when it may work clean; or it may be mixed with some older collodion, and may then be all right. Sometimes a little more acid added to the bath or the developer will be a remedy. If none of these aids are sufficient, then the collodion must be rejected.

When you make any change—such as having a new camera, a fresh nitrate of silver bath solution, a new quantity of developer, or another sample of collodion—you may be

able at once to suspect, and perhaps detect, the cause; for if some change occurs in the nature of the pictures which did not exist before, it is very probable that this fresh circumstance is directly connected with the changed character of the pictures. Therefore, whatever it is that has been newly introduced should be carefully examined, and very probably the cause of the fogging may be discovered. When, however, you have no such clue, you must adopt a systematic method for its discovery. The following is the plan:—

First, examine your dark room by covering your yellow window with some material that entirely excludes all light. Crevices and cracks admitting white light may then be seen that before were unnoticed, and some of them may have shone on the glass during its preparation, and caused fog. If these are found, they must be stopped up, and your annoyance may be over.

If these be not the cause, next suspect the window, for though it may admit only yellow light, it may not be yellow enough. Yellow materials become bleached, and require renewing, especially yellow calico. To test your window—and it is very important that you be quite certain on this point—proceed as follows:—Collodionize a plate as usual, and immerse it in the bath; then cover up your yellow window entirely, or leave only the smallest possible chink, so that you can just see what to do. Take your plate out of the bath and put it in the dark slide. Now remove the covering from the yellow window, and draw up the shutter of the dark slide half way, to expose one half of the plate; keep the plate to the light of the window for (say) five minutes, then replace the shutter, close up to the window as before, so as to exclude the yellow light, and proceed to develop your plate. Keep the developing solution on about the usual time that is required to produce a picture, for you will not be able to see what is going on; then wash and fix it. Now restore the light and examine the plate, and it must present one of the three following appearances:—Case A, the half exposed to the window is drab, and the half not exposed is quite clear and transparent; Case B, it has a drab deposit—in other words, fog—all over it; Case C, the plate is perfectly clear and transparent all over.

We shall examine each of these cases in succession. Case A shows that the yellow window is at fault, for half the plate exposed to it is fogged, but the other half is clear; therefore sufficient actinic light passes through the window to injure the plate. The yellow covering, if bleached, must be removed, or more coverings must be supplied, and a plate must be tried after each addition, until you have your window so yellow that a plate may be exposed five minutes without being fogged. Yellow glass sometimes allows light enough to pass through to fog the plate; such glass should be removed and a better sample put in its place. I have seen a piece of yellow-brownish glass, though very dark in colour, that admitted actinic light almost as freely as white glass. This is rare, but in photography you try all things, and only hold fast to that which is good. If the window be discovered to be the cause of your trouble, it must be covered with fresh calico, tannin, silk, paper, glass, or other yellow material, or it may be painted yellow; but in some manner the light must pass through a yellow screen in such a way that, while you are permitted to see your manipulations, your plate must remain without fog. You must have no rest until this is accomplished. This done, your fogging trouble is over, and you may proceed to work in comfort; for case A clearly showed the window was the cause of the fog.

It should be borne in mind, however, that the amount of protection that a yellow window gives to sensitive plates depends upon the quantity of light that falls upon the window. Plates may be fogged on a day of sunshine, and yet be perfect on a dull day. A yellow window with a western aspect may suit a morning light, and yet cause fog in the afternoon. When the window of the developing room is thus exposed to a variable light, it should be provided with an additional moveable yellow curtain, to be used when a stronger light than usual falls on the window.

\* Extracted, with permission, from the new edition of the "Principles and Practice of Photography," just out.

If the cause of fogging has thus been satisfactorily traced and cured, it will form an excellent lesson. But as there are other causes of fogging than an imperfect yellow window, let us examine Case B.

Case B, the plate darkens all over under the action of the developer, and you can distinguish no difference between the two halves; this shows that your window is quite right, and you must seek further for the cause. It must now lie between the bath, the collodion, and the developer. First try the bath: test it with a strip of reddened litmus paper, and if it changes to blue the bath is alkaline, and an alkaline bath is a certain cause of fogging. Add acetic acid, drop by drop, testing between each addition, until blue litmus paper is *very* slightly reddened. Again try a plate; the fogging will probably not be quite gone, but much reduced: add a little more acid until it entirely disappears.

Suppose, however, that the reddened litmus paper did not change colour, then test with blue litmus, and if it turn *very* red, carefully neutralize with oxide of silver or ammonia, until only a slight acidity remains; then resume your trial to see if you have expelled your enemy, for excess of acid, especially nitric, will cause fog. Should the test papers show that the bath is neither very acid nor alkaline, the probability is that the error is in the developer or the collodion.

Make up, carefully, a fresh developing solution, being particular not to omit the full proportion of acetic acid. You may even increase the quantity of acid, for some samples are weak, and you may happen to have one; the developing solution, unless it have its proper addition of acid, will always cause fog. If the new developing solution rid you of your difficulty, well and good; if not, you must suspect your collodion. Some collodions cause fog; therefore, get some fresh, and let it have a little colour—a pale golden, for instance—for colourless collodions are more prone to fog than coloured ones. If you are not now relieved, you may assume that the nitrate bath is the defaulter, for it must be one of the three. Make up a new bath, and if you use good silver and clean water you are almost certain to be out of your trouble.

In this way, by carefully and exhaustively examining one thing at a time, you will be certain to trace out the delinquent material. If you have decided that the nitrate bath, for instance, is the cause, then you have, if it be a new one, to find out whether the sample of nitrate of silver is pure, or whether the water is not the cause. The latter is frequently an unsuspected source of trouble. Again, if it be found that the developer is at fault, supposing it to be correctly mixed, each of its components may be suspected and examined in turn—the iron, the water, the acetic acid, and the alcohol. Some samples of methylated alcohol often cause great annoyance by impurity.

To return to our examination: supposing that we have not yet discovered the cause of our fog; the conditions of Cases A or B not applying, let us examine the rest.

Case C, the plate develops perfectly clean and transparent all over; this shows not only that the yellow window is all right, but that the chemicals are right also; in fact, that the origin of the fog must be external to the dark room; and as nothing else but diffused light can now be the cause, we must seek to discover it. First examine the dark slide well; in some unsuspected manner it may admit light to the plate.

If your dark slide be found to be perfect, next examine your camera carefully. You may test it in this manner: prepare a sensitive plate as usual, and place it in the camera as if you were going to take a picture; put the cap on the lens, draw up, *half way only*, the shutter of the dark slide, but do not uncover the lens. Let the plate remain thus for a full minute, then develop and fix the plate. The plate will either be one-half fogged, or it will be quite clear all over. If half be fogged, it shows that the camera admits light in some other manner than through the lens, and thus the fog is caused. To know where the light is admitted, remove the ground

glass; and, excluding all light with the focussing-cloth, put your head into the camera (the lens being still covered), and you will see the light streaming in. You may examine the interior of your camera in another manner. Place the dark slide in its place, and draw up the shutter; remove the lens, and, with the aid of the focussing-cloth again, examine the interior through the flange aperture. If any stray light be admitted, you will see it reflected from the face of the plate. It is necessary, when thus examining the interior of a camera, to wait for a few minutes, to allow the eye to get accustomed to the darkness, or you may deceive yourself, and think there is no light, from your momentary inability to perceive it. The cracks, crevices, or holes being stopped up, your trouble is passed.

Should your plate, however, develop clear all over, it will show that the interior of the camera is perfect. Another cause of fog may arise from the lens itself. If a strong light fall on it, particularly sunshine, fog will certainly be produced. A screen or shade should be provided, so that no light fall on the lens, except from the objects that are being delineated. Occasionally there is reflection from the sides of the lens tube, or the edges of the back lens. Dead-black varnish will be the remedy in these cases.

If you have not now traced out the difficulty, having run through your chemicals and apparatus, it most probably is caused by an error of manipulation, such as over-exposure, or a deviation from the proper mode of developing. It is scarcely probable, however, that you could pursue this inquiry without already having a clue to the real cause; and I have gone through the series of exhaustive experiments to show you that, by this method of inquiry, you may succeed in tracing not only fog, but almost any other trouble, to its true source.

## Correspondence.

### INFORMERS AND PIRACY.—GRAVES v. MERCER.

SIR,—We should much prefer to have remained silent as to your introductory remarks in the case of "Graves v. Mercer," reported in your number of the 10th inst, had not "The Defendant" of his own accord rushed into print. We forbear to remark upon any of the numerous inaccuracies in the letter signed "The Defendant," unless under the advice of our solicitor in the case, which would necessarily involve so much delay in our replying as to lead your readers to suppose that we accept "The Defendant's" assertions as unanswerable. We may perhaps venture to encroach upon your space at some future time, but meanwhile we would remind "The Defendant" of the old proverb, "Don't holloa till you're out of the woods." Others quite as confident and as plausible as "The Defendant" have, nevertheless, eventually come to grief.

As regards the employment of so-called *informers*, we, more than any, do regret that the law should be so ineffective as to leave us no other alternative, in the face of the many *dodges* adopted by dealers and others engaged in this illegal traffic, than the use of such means, in order, in some measure, to defend ourselves from the acts of persons not over-scrupulous as to the proper constructions of "menin" and "tunn."

Had you had the experience that we have had of the difficulty in tracing out these matters, in order to suppress a traffic ruinous to ourselves, but doubly serious as it affects the fine arts in this country, we cannot but think you would readily endorse the opinion expressed from the Bench by one of our ablest London magistrates, that "we are justified in adopting any means short of felony" in such cases. We have selected as we consider respectable men, who are under our own control, and we see no reason to question either their truthfulness or their sobriety. We trust sincerely that the law in this respect will ere long be amended, so that the necessity of proving a sale will be done away with, and some other more simple, speedy, and effective remedy provided.—We are, your most obedient servants,

HENRY GRAVES AND CO.

6, Pall Mall, July 22nd, 1868.

## Talk in the Studio.

**A VALUABLE TONING BATH.**—A correspondent signing "Silex" says:—"Mr. Bovey lately gave us an unfailing toning bath. I can give you another, but mine is not a new one. However, it is worth repeating. I have used it for two years without a single failure, and with several samples of paper. Before that time I had used the acetate, but, like Mr. Bovey, I found there was no certainty with it. As sometimes a new bath, mixed only twenty-four hours, often refused to tone at all, I purchased the following formula from a travelling process-monger for 10s. 6d., and I have felt thankful to him ever since. I think it has since been made public in the *News*. It is this:—3 grains chloride of gold, 20 grains chloride calcium, about half a teaspoonful of powdered chalk, 20 ounces common water. It must be mixed twenty-four hours before use, or with boiling water one hour will be sufficient. It never refuses to tone, and will keep; and more gold, chalk, and calcium may be added to it, although I generally make it fresh after re-uewing it two or three times. I never saw a mealy print produced by it."—[The examples sent to illustrate the action of this bath are very excellent.—Ed.]

**ANOTHER PHOTOGRAPHIC DETECTION OF A MURDERER.**—The brutal murder of the wife of a coffee house keeper in Norton Folgate, and the escape of the murderer, a youth of nineteen, will be fresh in the minds of many. He has been recently discovered solely by means of a photograph. A youth, giving the name of George Jackson, was recently committed to Maidstone Gaol for a theft at Woolwich. As we have before explained, photographs of prisoners and persons "wanted" are circulated amongst our prisons as a means of detection or identification. Among others, the photograph of the boy Andrew Mackay, the absconded murderer, was sent to the prison. For some time it did not appear to have attracted any attention, but a thought suddenly seemed to have struck a warder belonging to the prison that the boy Jackson, who was under his charge, resembled one of the photographs of persons who had absconded after the commission of a crime. In consequence of this he communicated his suspicions to Major Banuister, the governor of the prison, and examined the photograph carefully, and this confirmed the suspicion he had entertained previously, that the prisoner George Jackson was in reality the murderer Andrew Mackay. He took an opportunity upon this to enter into conversation with the prisoner, and in the course of it he asked him if he had ever gone by any other name than George Jackson, and he at once replied that his name was Andrew Mackay, and he admitted that he was the person who was charged with the murder in Norton Folgate. Major Banuister at once telegraphed to London to Serjeant Duuaway, an officer of the metropolitan police, and he went down to Maidstone yesterday, accompanied by a person who was acquainted with the lad Mackay, and who at once identified him as the person against whom the coroner's jury returned a verdict of wilful murder.

**PHOTOGRAPHY IN CHICAGO.**—A recently established American "Art Journal" of considerable merit gives, in its notices of "Art Teaching and the Studios" in Chicago, a highly complimentary notice of the new establishment of our old friend Mr. Carbutt, whose occasional articles our readers are always glad to find in the *News*. The critic points out the fact that Mr. Carbutt is catholic enough in his taste to exhibit conspicuously in his gallery examples by the best artists of Paris and London, amongst the latter our friend Mr. Blanchard is mentioned, expanded into a firm as "Valentine and Blanchard."

**NEWMAN'S DIAMOND VARNISH.**—We have received from many correspondents very warm praise of Newman's diamond varnish, and our own experience has confirmed all we have heard. We always avoid, however, giving notices of any article which might be construed into puffing. We hold that if a good thing be kept prominently before the public, by the legitimate process of advertising, it will make its way without puffing. A fact regarding this varnish has, however, just been brought under our attention which ought to be recorded. A correspondent states that a negative varnished with it was left out recently the whole of a wet night, and then, when taken in, the print was forgotten until it was dry and firmly stuck to the negative. The print was, however, again

moistened, and, by the aid of a little care, removed without the varnished surface of the negative suffering the slightest injury.

**BROMO-IODIZED INDIA-RUBBER.**—A method has been patented in the United States of incorporating india-rubber with bromine and iodine instead of with sulphur, which is generally used in producing vulcanized india-rubber. By adding to iodine one-half its weight of bromine, proto-bromide of iodine is formed, and this, when combined with rubber or equivalent gum, will produce a composition which will harden on being subjected for about an hour to a heat of 250° Fah. Owing to the volatile properties of proto-bromide of iodine, it cannot be applied without difficulty to practical purposes. To obviate this difficulty, we treat both the bromine and iodine, prior to combining the same, with oil of turpentine, or similar oil, which has previously been mixed with about one-fourth its weight of sulphuric acid, to prevent the formation of an explosive composition. The paste mixture produced as above described is combined with caoutchouc or equivalent gum, in the proportion of about three ounces of the paste to a pound of gum, the proportion of gum being increased if a more elastic product is desired. Can any photographic use be found for such a compound?

**BLACK VARNISH.**—An aniline black varnish, of recent Parisian production, is the following:—In a litre of alcohol, 12 grammes of aniline blue, 3 grammes of fuchsine, and 8 grammes of uaphthaline yellow are dissolved. The whole is dissolved by agitation in less than twelve hours. One application renders an object ebony black. The varnish can be filtered, and will never deposit afterwards.—*Scientific American*.

A PHOTOGRAPHER in Canada advertises as follows:—"Deceased persons taken at their own residences." "Parties wishing to learn the business can do so cheap."

A WESTERN ARTIST (?) in "An Ode to All," gets off the following in his circular:—

"Oh, who would live where Art is unknown,  
Where shadows of dear and loved ones are not?  
Perhaps of those who for country died without a groan,  
Or even of those who went of too much 'pot.'"

"FIXING A DYE."—A report on the colouring matters derived from coal tar shown at the French Exhibition has the following:—"A dyer, like all others of his craft at that time, was busily occupied experimenting with the aniline dyes. Amongst other things he tried a reaction which had been described by M. Lauth at the end of 1861, viz., that of aldehyd on a sulphuric solution of aniline red. In this reaction a substance is produced which gives to solutions an extremely evanescent blue colour. M. Lauth had given up all idea of utilizing this blue colour in practice, and M. Cherpin endeavoured to fix the same colour on silk or wool with similar want of success. His attempts, although fruitless, were incessantly renewed, exhausting his purse, but not his patience. One day, however, discouraged at the want of success attending some recent experiments on which he had founded great hopes, he was on the point of relinquishing the attempt at conquest over this fugitive blue, when the idea struck him to confide his troubles to an old friend, a photographer. 'A trouble shared is a trouble halved,' says the proverb. Cherpin proceeded to test this saying, and experienced the reward of his perseverance and his confidence in the consolations of friendship. He found his photographic friend, and confided to him the history of all his hopes, his experiments, and his fruitless results.—'Fix the blue?' said his friend. 'Is that the only difficulty? Why it's the easiest thing in the world! Have you tried hyposulphite of soda?'—'Hypsulphite of soda? *Mon Dieu*, no! Do you think it will fix my colour?'—'Of course it will. Don't you know that hyposulphite of soda is the fixing agent *par excellence*, and that when we want to fix anything in photography, that is the substance we always employ?' Happy he who possesses faith! Cherpin tried hyposulphite of soda, and his joy and admiration of the chemical knowledge of his friend may be imagined when he saw his blue colour metamorphosed into a splendid green, this time perfectly stable. It is scarcely necessary for us to add, that the mode of action of hyposulphite of soda in this case is entirely different from its photographic action, and that it would be quite impossible to predict the one by knowing the other. This anecdote contains a moral. It shows, in our opinion, not the result of chance—for that is common to all the world, for where is the discovery to which chance has not more or less contributed?—but it shows the power of

the will, the power of perseverance. Chance only favours two kinds of persons: those sufficiently instructed or endowed with talents eminent enough to observe it, to seize it, and to profit by it; and those who, by patience, perseverance, and the power of their will, force it in time to become useful to them.

## To Correspondents.

**MR. BOVEY'S METHOD OF TONING.**—In answer to the various querists who have written on this subject, we regret to state that hot weather and close application to dainties have, during the last few weeks, prostrated Mr. Bovey, and he has been instructed by his medical adviser to abstain from all kind of labour, bodily or mental. He is, we are glad to add, recovering, and hopes shortly to answer the various questions addressed to him.

**P. C. (Subscriber).**—The necessity of forcing the intensifying process until the whole image is buried in a universal dark deposit, in order to obtain sufficient vigour, may arise from several causes. It may be due to the use of a new or thin collodion. If it be from using a new collodion, the addition of a little of an old sample will help you. If from the collodion being thin, the addition of a little more pyroxyline to the collodion will help you. The use of the gelatino-iron developer will probably help you; or the use of a weaker developer, containing a little more acetic acid, may help you. Take care not to over-develop, and in intensifying use plenty of acid in the solution. By intensifying after fixing you may probably get rid of your difficulty.

**J. W.**—The print you enclose has the appearance of being a reproduction, not printed from a negative from life. If it be from a negative from life, we should judge it to be a thin, flat, fogged, imperfect negative, from which it would be difficult to obtain a good print. The print itself is, however, a poor, mealy one; but whether it would be possible to get one much better from the negative we cannot say without seeing it.

**ANSWER.**—We have met with examples of opal glass with the surface of which the silver image seemed to combine, and remained perfectly visible after removing the collodion. We do not know of any remedy except procuring another sample. We have tried almost every method of cleaning without removing traces of the image. We presume that the material used in obtaining the opal surface has an affinity for silver, and readily combines with it. The example of the Eburnum process you enclose is very good indeed.

**W. M.**—You will find it difficult either to weigh or estimate with accuracy the iodide which has deliquesced. You had better employ it in making an aqueous solution of iodine, to be used in intensifying, in which absolute accuracy is not necessary.

**SILEX.**—Thanks for your further remarks. The subject is very interesting, and we shall be glad to examine it as carefully as possible. 2. Undoubtedly the quantity of tungstate of soda you mention is erroneous. It should have been 20 grains. It has doubtless been an error of the press. 3. The infinitesimally small proportion of chrome alum necessary to render the gum insoluble, used for retouching prints, would not, we think, produce any action on the silver image. 4. Which is the ivory process you use?

**W. B. B.**—The photographic qualities of the card forwarded are very excellent indeed; the tone is unusually rich, and the print is at once vigorous and delicate. The lighting is good, although, for our own taste, we should have preferred a little more direct side-light, to pick out points of high light on the face.

**W. J. A. G.**—It is one of the puzzles in connection with photographic practice which we have not been able to solve, that some persons who succeed well enough with the wet process fail signally with almost all dry processes. In describing their operations they appear to comply with all conditions of success, but in result they meet with nothing but failure. Yours is not a solitary case by any means. In trying the morphine process again, proceed as follows:—Take the collodion, either 2, 4, or 6, add to each ounce an additional grain of bromide of cadmium, agitate until it is dissolved, and then allow it to rest a few days. After coating and exciting the plate, allowing each plate to remain somewhat longer in the bath than usual, transfer the plate to a dipping bath of distilled water, where allow it to remain until another plate is ready; then transfer to a dipping bath (or dish) of common water, there to remain until another plate is ready. After that, again rinse with distilled water, either in a bath or poured on; then apply the morphine solution; allow it to remain on the plate a minute or two, and then throw it off, and allow the plate to dry. Give such a plate three or four times the exposure of a wet plate, and develop with a gelatino-iron developer to which a few drops of silver solution have been added. The collodions we have men-

tioned, with the added bromide, may be used for either Mr England's or Mr. Gordon's process.

**SORE BESET.**—When fog assumes the character of a dull grey deposit between the film and glass, it is generally the result of using dirty glasses; but the same thing sometimes arises from under-exposure and pushing the development and intensifying. Sometimes the white-looking deposit you describe on the surface of the negative is due to using a water for the developer containing much of a chloride or of a carbonate, and chloride or carbonate of silver is thrown down on the film. If your acetic acid is pure, the use of considerable addition of it in the developing or intensifying would probably prove a remedy; but if it be not pure, every addition would only increase the evil. In a recent case of persistent fogging which came under our attention we found it due to the use of an impure sample of acetic acid, which contained a reducing substance. Try the use of the gelatino-iron developer; it is a great aid to the production of clean shadows; also try, if necessary, intensifying after fixing instead of before. See article by Mr. Hughes in this number.

**J. S.**—The spots on the excited paper forwarded are due to irregular drying of the surface; the silver solution, instead of draining off and drying off evenly, collects in drops, which dry very slowly, and wherever a drop rests a light-coloured spot appears, which prints of a blue tint. The cause of this irregular drying is not quite certain; it is alleged by one manufacturer of albuminized paper to be due to the dry and horny state of the paper at the time of exciting; another manufacturer asserts that the use of a nitrate bath too strong will cause it. It is easy to try the remedy implied in both cases: allow the paper to remain in a damp place a few hours before use, so that it shall not be absolutely bone dry when floated. Also use a weaker bath: we believe that no commercial sample of albuminized paper requires an 80-grain bath; as a rule, a 40-grain or a 50-grain bath is strong enough for all commercial papers. A certain remedy for the spots, when others have failed, consists in blotting off the excited paper on clean white blotting-paper after exciting.

**B. MAGIC.**—As a rule, a 15-grain iron solution is strong enough, especially for summer use; but in presence of dull light, under-exposure, old insensitive collodion, excess of acid, or other retarding conditions, double that strength may be required. The example enclosed with the 30-grain developer is certainly better than that with the 15-grain solution. The former is very good, but the light is a little too directly in front.

**YOUNG.**—When you speak of a plate coming out of the bath black, do you mean that it was literally black? If so, some very curious addition must have been made to the collodion by some one. We have seen a plate blacken all over with fog on applying the developer, but never saw a plate black when it came out of the bath. 2. So far as you describe your operations with the honey process you appear to have acted rightly: why your results should be wrong, and your experience different to that of others, we cannot tell. 3. The collodion you mention is rarely sold iodized; but it appears to us incredible that you should purchase a sample of iodized collodion by a maker of high repute, and not be able to get an impression with it. We shall have pleasure in trying it. 4. In our hands the ebonite baths have proved satisfactory; but there is nothing so satisfactory as glass, and if used with care in a proper travelling case there is little risk. 5. In many cases a swing bath is useful in portraiture. 6. Your question as to the use of the carbon process can be best answered by the patentees. Write to the Autotype Company, 5, Haymarket. 7. Either will answer well, but probably No. 1 best. 8. The cabinet portrait enclosed is very good indeed.

**WM. PIMLOTT.**—It is somewhat difficult to give an answer to your question in this column. When you ask how to take transparent photographs for the magic lantern, we are uncertain how much you know, and at what point to begin to give you hints. You will find, however, tolerably full instructions in an article on page 73 of our last YEAR-BOOK. Get that, and if, after reading it, you require further information, write again.

Several Correspondents on our next.

### COLLODIO-CHLORIDE PRINTING PROCESS.

It has been our good fortune during the last three or four years to receive from various parts of Continental Europe and from America many examples of collodio-chloride printing, and letters of thanks for having given the process to the public. Some of the most promising examples which have come under our notice are those produced on the paper prepared by Herr Obernetter, of Munich, which may be kept sensitive for many months. We had heard much of excellent results of this paper, and seen various fine pictures produced upon it, before we were informed of its precise character; but in the course of some recent interviews with Dr. Liesegang, the able editor of the *Photographisches Archiv*, he informed us that the Obernetter paper, which was extensively used in Germany, was simply the result of an application of our collodio-chloride process. He kindly gave us various hints based upon his own experience in working with the paper, which we put to the test in some experiments upon a sample of the paper submitted to us for trial, the results of which we shall place before our readers.

The paper possesses a highly glazed and delicate surface, possesses about the same sensitiveness as excited albuminized paper, and readily receives any tone, from a rich chocolate tint to a blue-black. According to the information we received from Dr. Liesegang, the basis is one of the ordinary enamelled papers, in which the surface is prepared with some white pigment. This is treated with gutta-percha dissolved in chloroform, and finally with collodio-chloride of silver. The use of a paper the surface of which is formed of a neutral pigment which does not combine with silver seems to be an essential element in the keeping qualities of the sensitive paper. In our experiments with collodio-chloride of silver we have found that English papers prepared with animal size most readily discoloured, whilst a commercial sample of enamelled paper treated with collodio-chloride of silver has kept in our hands for upwards of a month without any deterioration whatever. Certain qualities in the collodio-chloride of silver also modify the keeping properties of the paper prepared therewith: of these qualities we shall probably have something to say shortly.

As a further illustration of the effect of a surface of neutral pigment, as a means of securing keeping qualities in paper prepared with collodio-chloride of silver, we may mention here some examples recently brought under our attention by Mr. W. H. Smith, who has been giving some attention to the subject. Some months after the publication of our collodio-chloride process Mr. Smith patented a process of printing with gelatino-chloride of silver, which he has brought to great perfection for printing on wood: he has also tried the same material for

printing on paper, but not with sufficient success to satisfy himself. The examples of collodio-chloride printing which he recently brought under our attention were exceedingly fine. The paper was first prepared with a neutral white pigment, china clay having answered best. This pigment, being mixed with a suitable size, is applied to the paper and rolled; this is followed by a coating of a solution of india-rubber, and then the collodio-chloride is applied. The paper is found to retain its sensitiveness for some time: an example placed in our hands for trial was unchanged at the end of a month. In some cases a slight tint is given to the enamel surface, and the points of high light being scratched out in the finished print, the effect of a drawing in black and white chalk on a tinted ground is obtained.

One of the advantages claimed for the Obernetter paper is its fitness for development, so that in dull weather printing is expedited. The paper is exposed under a negative for a minute or two until a mere trace of the image is seen, and then, on the application of a developer, a vigorous print of fine colour is obtained. The developing solution proposed consists of—

Gallic acid	...	...	...	½ drachm
Citric acid	...	...	...	7 grains
Water	...	...	...	2 ounces

After development the print may be toned with the toning bath recommended for the paper generally, which we shall state presently, and fixed and washed as usual.

With the example of the Obernetter paper placed in our hands we produced a score or two of good prints, all presenting a vigorous and rich effect in the printing bath, and readily assuming in the toning solution a rich deep sepia tint, or purple brown. The toning bath recommended, and which we used, is prepared in the stock solutions as follows:—

1. In 50 ounces of distilled water dissolve—  
Sulphocyanide of ammonium 1 oz. 2 drachms  
Hyposulphite of soda ... 45 grains  
Bicarbonate of soda ... 15 „

2. In 50 ounces of distilled water dissolve—  
Pure chloride of gold... 30 grains

If the double salts of gold and sodium or potassium are used, take the double quantity.

The two solutions keep any time. Mix equal parts of them. The mixture can be used at once. The prints never become yellow in this bath.

In two to ten minutes the prints are toned. Wash them in water, and fix in—

Hyposulphite of soda...	...	1 oz. 2 drachms
Distilled water	...	32 ounces

Five or ten minutes will suffice.

For washing, two or three hours will be sufficient.

In the qualities of delicacy and richness, and the perfect rendering of every detail in the negative, nothing could surpass these prints; but we nevertheless found certain drawbacks, not inherent in the process, but due to traceable causes. The first defect was one to which any paper sent out ready sensitized must be liable, but to which this paper seemed especially sensitive: we mean a tendency to imperfect toning in patches wherever the prepared surface has been touched by damp or soiled fingers, the impression of finger marks in many cases being rendered distinctly visible in the course of printing. Another difficulty consisted in the liability of the prints to break or scratch whilst in the various solutions. This appeared to be due to two causes: the thin and inferior character of the paper on which the pigment was applied to form the enamelled paper. This thin, soft paper quickly absorbs a good deal of water, and becomes limp; the pigment on its surface remains, on the other hand, tolerably waterproof and rigid, and, receiving little support from the limp paper on which it rests, there is a tendency to easy breaking or cracking. The final disadvantage is one partly due to the paper and partly to the quality of the collodion used; the film in many cases curls from the edge of the print as soon as the whole becomes perfectly desiccated. This is not a necessary defect; we found it occasionally in our experiments when first working out the collodio-chloride process, and quickly found the remedy in the use of a less horny and contractile collodion. But even when this tendency is present from the use of an unsuitable example of collodion, it may be to a considerable extent counteracted by mounting the prints before they are absolutely and unmanageably dry. Our friend, Dr. Vogel, who speaks very highly of the paper, states that the addition of nitrate of soda to the toning bath has been found also to check the occasional tendency of the film to leave the paper.

In order to secure the best results and to avoid the failures which commonly attend experiments with a new process, certain suggestions and cautions are issued by the manufacturer of the paper, with a summary of which Dr. Liesegang kindly furnished us. They run as follows:—

The printing is best effected in diffused light.

The prints should be washed in three changes of common water before toning, and as these waters contain much free nitrate it should be saved.

Never break the paper; cut it with a scissor or sharp knife.

In the first washing water the prints curl very often; but in the gold bath, if the print side is put downside, they will become flat again.

Do not put too many prints into the gold bath nor into the hypo, or they will get red stains.

Cut the prints while they are in a wet state with scissors, and mount them directly before they are dry; mount with fresh starch.

The prints obtain their finest beauty by rolling.

Coat with wax varnish.

#### CAUSES OF FAILURE.

1. *The prints become browned in the gold bath, and do not tone.*

Too much hyposulphite in the fixing bath, or the chloride of gold is not pure. Try whether the gold bath is acid, and, if so, add bicarbonate of soda until it is neutral. Acid gold baths do not tone, and makes the collodion film come off from the paper. If the gold bath is not acid, and does not tone, the bath does not contain enough gold.

2. *The collodion film comes off from the paper.*

(a) The paper has been broken.

(b) The prints have not been sufficiently washed before toning.

(c) The gold bath was acid.

(d) The solutions were too concentrated. If the solu-

tions are more concentrated than indicated, the film will surely come off.

3. *The prints have not sufficient gloss.*

Coat them with any good enamel varnish. Prof. Bottger's, of Frankfort, formula (copal dissolved in alcohol) is recommended.

We conclude this desultory article on the subject of collodio-chloride printing by giving a formula as stated by Dr. Vogel to be successfully used by Herr Voigt for development printing:—

Twenty grains of nitrate of silver are dissolved in an ounce of alcohol, diluted by a small quantity of water. The nitrate should be powdered finely; it will dissolve very slowly. To the solution is added, with constant agitation, one ounce of plain collodion containing 2 per cent. cotton, and half a drachm of an alcoholic solution containing 16 grains of chloride of calcium; lastly, 1 or 2 drops of a strong solution of citric acid are added. With this collodion unsized paper is coated in the dark, in exactly the same manner as a glass plate in the negative process. When the paper is dry, it is exposed under the negative until the outlines commence to show, and is developed with—

Water ... ..	1,000 parts
Pyrogallie acid... ..	$\frac{1}{2}$ part
Citric acid ... ..	$\frac{1}{4}$ to $\frac{1}{2}$ „

Add a few drops of silver solution, in case the development should progress too slowly. For toning, Obernetter's gold bath, with sulphocyanide of ammonium, is used.

#### ON THE RESTORATION OF THE NEGATIVE FILM.

In the *Photographische Correspondenz* M. Alois von Anreiter communicates a method for restoring negatives injured by the formation upon their surfaces of blisters or vermicular markings. These defects, which are the result of exposing negatives to a damp and variable temperature, or of varnishing the plates before they are thoroughly dry, M. Anreiter remedies in the same manner as that pointed out recently by M. Bloede, in the *Philadelphia Photographer*, and by Mr. Spiller in this Journal as far back as August, 1864.

The method prescribed is a very simple one. Instead of covering the negative with alcohol, and pouring the same on and off continually until the varnish is removed or softened, such as was formerly done, the plate is placed in a bell jar, or supported in a flat earthenware dish, the bottom of which is covered with spirits of wine, and placed in a warm locality; the utensil is covered up, and the spirit then evaporates and becomes condensed upon the varnished surface. After a short time the film becomes so soft that the inequalities on its surface collapse of themselves, or may be pressed down by means of the finger; if the operation is prolonged, the whole of the varnish will be dissolved away, and a fresh coating of the latter must then be applied when the plate is again dry.

Mr. Spiller's present mode of operating to remove the varnish or restore the film of a negative is as follows:—The plate is placed inside a deep porcelain dish, varnished side downwards, each corner of the negative being supported by a small piece of cork about an inch in height. A little methylated spirit, just sufficient to cover the bottom of the dish, is then poured in, and a piece of blotting-paper somewhat smaller than the negative is moistened with the same spirit, and placed upon the top of the plate: care must be taken that the sheet of blotting-paper is not too large, and that it is merely moistened, and not fully impregnated with the spirit. The dish is then covered up and placed in a warm locality, when the spirit evaporating from the blotting-paper will keep the plate cool, thus favouring the condensation of the alcoholic vapour upon the undermost and varnished surface of the negative. The dish should never

be placed in a temperature higher than 100° Fahr., and under these conditions forty minutes or one hour will suffice to moisten the film thoroughly.

On taking the negative from the dish, it is placed face upwards upon a flat surface, and if the blisters do not go down of themselves, they are pressed gently with the finger; or, should they be veritable air-bubbles, pricked carefully with a pin's point. The plate must be held occasionally against the light for inspection, as many of the markings which are shown by reflected light are invisible when the negative is regarded as a transparency.

### Foreign Miscellanea.

THE commission appointed by the French Photographic Society to award the medals for the year 1867 have presented their report, in which they recommend the names of Mr. John Talbot and M. l'Abbe Laborie to receive these distinctions.

M. Pector, at a recent meeting of the French Photographic Society, exhibited some pictures printed on matt lepto-graphic paper, which had been kept untuned and unfixed for a period of eighteen months in a drawer screened from the light. Some white paper, and prints upon glazed paper of the same description, had been stored in the same place, but these were completely destroyed on their immersion into water.

The *Photographische Mittheilungen* speaks in high terms of praise of a work just published by M. J. Grasshoff on retouching photographs. Being practically acquainted with every branch of the subject, M. Grasshoff's printed experiences should command a wide circulation.

The commission appointed by the Prussian Government to take note of the forthcoming total eclipse of the sun includes three photographers, viz., Drs. Vogel, Zenker, and Fritzsche. These gentlemen left Berlin in the middle of July for Aden, where they propose to make their observations.

M. Johannes Bienert discusses in the *Archiv* the relative value of certain varnishes, and points out that in many cases of splitting of films the mode of preserving the negatives is more at fault than the composition of the varnish. According to his experience he has never known the films of any of his negatives to crack when preserved in a locality of even temperature, but that when they are stored in glass studios or light out-buildings where the temperature is constantly changing, accidents of the nature in question are of frequent occurrence. A varnish which has been patented in France by M. Hanfstengl may be recommended very strongly; it is thus composed:—

Alcohol 80°	...	...	1000 grammes
Bleached shellac	...	...	100 "
Venetian turpentine	...	...	20 "
Sandrac...	...	...	10 "
Mastic	...	...	5 "

M. Bienert prefers to use in this recipe a somewhat stronger alcohol than that mentioned, viz., 92° to 93°; stronger than this, however, the spirit should not be, as it is otherwise apt to dissolve away the collodion film. A good varnish, which may be used with but little warmth, but which should only be employed for negatives kept in an even temperature, may be made with—

Ordinary turpentine (thick)	...	16 grammes
Venetian turpentine	...	16 "
Sandrac...	...	80 "
Sugar and camphor, of each	...	1 "
Alcohol 92°	...	600 "

Finally, M. Bienert gives the formula of a positive varnish to be rubbed over photographs by means of a small tuft of

cotton wool, and which, notwithstanding its curious composition, is said to impart a beautiful gloss to the prints:—

White wax	...	...	11 grammes
Ether	...	...	32 "
Normal collodion	...	...	24 "
Alcoholic solution of white shellac (not too strong)	...	...	16 "
Alcohol...	...	...	8 "

Dr. Liesegang makes a few remarks upon international photographic nomenclature. He complains that words are often badly rendered in translations, and that sometimes the very reverse of the writer's meaning is expressed. As an instance, Dr. Liesegang cites the English word "discolouration," which has been translated into *décoloration* and *entfärbung*, signifying bleaching or becoming colourless; in this case, if the discolouration of the whites of a print is being alluded to, the translation is a simple reversal of the original sense. Other words of a technical nature are often quite untranslatable, and the doctor therefore suggests that in order to render such terms intelligible they should be illustrated by wood cuts, or, better, by original photographs. As a recent example, Dr. Liesegang alludes to M. Carey Lea's article upon "blurring," a term which is used by that gentleman in quite a different sense to what it is employed by Hardwich in his *Manual of Photography*, and it must therefore receive a different translation. Dr. Liesegang suggests the compilation of a German-English-French photographic dictionary which should contain all the acknowledged terms used in the photographic journals of the different countries, and which should, moreover, be copiously illustrated with photographs.

In the *Photographische Correspondenz*, Professor Pisko describes Ladd's new magneto-electric machine, which he recommends for photographic purposes in connection with Foucault's or Serrin's electric lamp. He states that an apparatus of this description yields, at the distance of one metre, a light equal in intensity to that of the sun in March during mid-day.

M. Wendling, in the same journal, contributes an article on the fading of photographic prints. He lays great stress on the employment of pure water in manipulating the prints, and suggests a careful purification of the same prior to its employment in the toning and fixing operations.

### SKETCHES OF TRAVEL FROM A SUN-PAINTER'S PORTFOLIO.

BY STEPHEN THOMPSON.

#### No. 2.—SKYE SCENERY.

SKYE is a *wraith* to the denizens of Cheapside and High Holborn, and even to the majority of travelled men. It looms out of the grey mists of the Northern Sea like a ghost in some wild Norse legend, told by the light of a dying fire. Skye is like a fossilized sea-king, storm-beaten and scarred all over with grisly seams and rents. Robed in cloud wreaths and ever gathering rain-swirls; the hem of his sea-bound skirts hollowed out along the shore into weird-like caves of grotesque and fantastic shape by the worn weary waves; grottoes where the night winds sigh and the kelpies keep court and revel. The *entourage* is in perfect keeping with "the subject." The grey torn sea that seethes around "MacLeod's Maidens,"\* with their breasts of foam, and breaks with wild wolfish leap into the hollow caves that fringe the shore between Loch Scavaig and Loch Slappin, is not more savagely picturesque than the dark splintered peaks of the Cuchillin Mountains. Riven and split in every direction, their serrated crests have an outline as sharp and jagged as a saw, and their craggy ledges foster the callow caglet still. The "beauty of repose" is the antithesis of Skye. Ever the wind blows and the

\* Three spires of rock rising sheer out of the sea on the coast of Skye and shaped like women.

fleecy vapours gather around "Blaavin" and "Cornisk," and break and reform into solid phalanx, and break again like armed hosts on a fiercely-contested battle field. The untempered breeze that always ends each gust with a swirl of rain on your unprotected head, is the same as that which played amid the yellow locks of the Vikings! Visions of storm-tost Norwegian galleys bearing the banner of King Ilaco, or Tørrquil, or Sigurd, naturally fill the foreground. The very names of rock and headland, from Vateruish to Trotternish, tell of other and earlier associations than oars. The Norse element is uppermost—a leaven that leaveneth the whole mass. The boatman, as he rows, sings you long interminable Gaelic songs embodying Norse legends, melancholy in their monotonous chant, but which have taken his imagination captive in boyhood, over peat fires in Skye-bothys on drear winter nights, and will never leave him more. The very pipes, for which Skye boasts a rude college, though they can sound a love song, seem only to *speak* when raising the wailing coronach or the impetuous battle march.

Sea-birds perch on every crag by the shore, and eye your camera with a shy and puzzled look. Cormorants and curlews scream around you and fly across your field of view. You grow familiar with Solan geese and the lonely scart with outstretched neck and attenuated wing; sea swallows abound, with their keen restless eye; and even seals sometimes disport themselves before your eyes. You will see, too, the golden eagle wing his majestic flight: where else more fittingly, if the Laureate paints from nature?

"He clasps the crag with hooked hands,  
Close to the sun in lonely lands,  
Ringed with the azure world he stands.  
The wrinkled sea beneath him crawls;  
He watches from the mountain walls;  
And like a thunderbolt he falls."

At certain seasons it is never dark here. I have been out on the hills all night, and the northern lights glowed till dawn, like

"As mournful light  
That broods above the fallen sun."

There is something strange and abnormal even in the outline of some of the mountains—"Glamaig," and especially its companion, the monstrous "Marsco," where Hilda, the Scandinavian Princess, was laid, after death, with her face turned towards Norway, that her spirit might have rest.

"I wept out all my tears. Amongst my kind  
I cannot sleep; so upon Marsco's head,  
Right in the pathway of the Norway wind,  
See thou and make my bed.  
And upward to a sea-o'erstaring peak,  
With lamentation was the Princess borne,  
And, looking northward, left with evening meek  
And fiery-shooting morn."

Here, then, within two days' sail of the Broomielaw at Glasgow is a new sensation for the *blasé* tourist! The Pyrenæes are more beautiful; the Alps more picturesque (and of a height beside which no Scotch mountain can be named, and comparisons are odious); but Skye and the *Cuchillins* are unique—a wild desolate picture to hang in your mental gallery—full of the wild-flavoured poetry of a bold restless race, beside which our own seems effeminately tame. A London swell—no; for some of them can climb a big Alp or steer a yacht with any one—say, rather, a Parisian exquisite in tight pantaloons and black shiny sticking-plaster boots, would find himself not simply in a foreign country, but in another world—the first stage on the way to Hades.

I believe it may be said that the wildest and most historically interesting part of Skye had never before been photographed; indeed, it is almost impossible to do it, and but for a lucky termination of a most hazardous venture, my own fate would be best described by the homely but graphic simile of a dog coming home with his tail down. There is no place for your base of operations other than the shelter afforded by the little inn in Glen Sligachan, and the mere excursion thence to the *Cuchillins*, and the scenery of the *Lord of the Isles*, occupies the whole of a long day, and leaves

no time for photographing. Thus, through Glen Sligachan to Camasunary, four hours; thence by boat (10s.) round to Loch Cornisk, one and a half hours; allow for stoppages, launching boat, &c., say another hour:—total, six and a half hours. The same time is occupied in returning, making altogether thirteen hours. By using dry plates and starting very early, enough time might be gained for exposing them, though not for much selection of points of view. But the scenery, with its every-varying cloud and rain-swirl, is just that most difficult to render satisfactorily by a dry process. Hazardous as it was, after ascertaining as a matter of certainty that there was *one* human habitation where I might find shelter at Camasunary, and be nearer the "*Cuchillins*" than in Glen Sligachan, I determined, to the consternation of some of the passengers, on being landed from the steamship at Loch Savaig, and trusting to the resources of an old mountaineer. Accordingly, I was landed in a small boat on the spot described in the *Lord of the Isles* as that where the Bruce landed—

"Where a wild stream with headlong shock  
Comes brawling down a bed of rock,  
To mingle with the main."

The silence and solitude of the place were most oppressive. After scrambling over some large boulders and crags, I hid my cases of apparatus in one of those caves such as abound nearer Prince Charles's Cave—where he was hidden by Flora Macdonald—and *Bloody-Nose-Point* (which last ought to be painted by Telbin for a sensational drama), and then essayed the scramble round the rocky shore towards the solitary farmhouse. After proceeding some distance I reached a point inaccessible to the foot of man in the (at that time), state of the tide, but was greatly relieved by finding a boat with some queer specimens of the old Gael, who volunteered to take me to Camasunary Bay for "ten shillin'," nearly all the English they could muster. I objected, and finally made a bargain for "six shillin'." A place was made for "the gentlemen" amid a lot of old crones and children, whose clothing may be described as nothing in particular; a bit of ragged tartan wrapped round their middle and secured with—well, a bit of string. The children eyed me curiously, and scanned my costume, particularly the buttons of my coat, as if they had never seen any civilized being before. After landing and reaching the little roof seen from the steam-packet in the morning, imagine my horror on finding it *uninhabited*! Some repairs were being made, and the family had migrated for the time. However, an old gillie who had been there for some purpose came to the rescue, and, after a long corrobory, I elicited that if I could cross the hills I should find in the lone district of Strathaird an equally lone house—Dr. McAlister's—where I might obtain shelter. The hills looked formidable in the gathering rain-mist, but there was no choice, and girding up my loins like an antique, and donning a modern mackintosh, I commenced the ascent. After an hour or so the rain became heavy, and the mist thickened so much that it was almost impossible to keep the track. I lost it repeatedly, but after reaching the highest point caught one glimpse, and but one, of a white building far away. This reassured me. To keep the sheep-track was impossible in the waning light, so I struck off through bog and slush, as the crow flies, in the direction where I had caught a glimpse of a roof with my glass, oblivious of everything but reaching it before darkness closed upon me, knowing well, by former experience, the danger of a night on the moors. Again imagine my feelings after a long tramp, with the nervous system braced up to a degree of tension that renders it super-sensitive, to find, on reaching the point to which my instincts and not my vision had safely led me, that it was but the white walls of an abandoned kirk, desolated, like many others, by the disruption in '43, when the great emigration of pastors, with—in some cases—their whole flocks, to Canada took place. I cannot say that my heart sunk within me, or that anything sensational took place, but I felt queer, though believing I should get through it somehow, although the *how* was not then

very apparent. Again I struck out; this time following "a burn," in remembrance of an old Highlander's advice given me twenty years before, under somewhat similar circumstances, in the Perthshire Highland; "Follow a burn, sir; always follow a burn; it's sure to lead to some place of abode." It did lead, indeed, to a rude bothy, where two old hags were sitting, like the witches in Macbeth, over a pot above a peat fire, but silent and contemplative. From them I learned the way to Dr. McAlister's, of "Strathaird," mentioned by Sir Walter Scott in his Notes to the "Lord of the Isles." A real Highland welcome awaited me, and dry clothes in exchange for my dripping garments, and the pleasure of cultivated society, for the doctor's house is a kind of sanatorium for officers and others who may have suffered from the effects of climate or a too free indulgence in the pleasures of the mess-table; and in this lone retreat from all temptation I found Crimean and Indian officers, who had regained that health amid the wilds of Skye which they had sought in vain elsewhere.

My way was now clear. The pressing invitation of the worthy doctor to make his house my base of operations, as it was so much nearer than the inn in Glen Sligachan, made the scenery of Loch Coruisk and the Cuchillins *un fait accompli*. The doctor's Skye ponies conveyed us over the hills each day, and boats awaited us thence to Loch Scavaig. Captain L. and Captain B. made pleasant what would otherwise have been a physical impossibility; Malcolm was the best of gillies; Ronald the best of ponies—when you let him have his own way, which sometimes brought him to grief. What fishing and what photographing we had! Wet through were we nearly every day, and sometimes unable to effect a landing on the rocks for the surf and swell; but what matter? a warm welcome always awaited us, and seawater never inflicts cold. That seal we just missed shooting; that eagle which passed so near; that tremendous sea we shipped, and spoiled the tobacco and cigars, were all afterwards pleasant recollections. Night-fishing was popular and exciting. Captain L., after a successful night on Rat Island, planned a night at Loch Coruisk. Malcolm collected drift-wood for a bivouac fire by a cave thereabouts the day before, and provender sufficient was taken at the time. Talk of a formal London dinner party!—that night, by the lonely shores of Loch Coruisk, under the shadow of the "Coolins," was something to be remembered for evermore. A successful day, both with fish and negatives, was closed by a night with nature in her wildest aspects. Around us was the scene which Scott makes Bruce describe:—

"The good Bruce to Ronald said,  
 'St. Mary! what a scene is here!  
 I've traversed many a mountain strand,  
 Abroad, and in my native land,  
 And it has been my lot to tread  
 Where safety more than pleasure led;  
 Thus many a waste I've wandered o'er,  
 Clombe many a crag, crossed many a moor:  
 But, by my halidane,  
 A scene so rude, so wild as this,  
 Yet so sublime in barrenness,  
 Ne'er did my wandering footsteps press,  
 Where'er I hap'nt to roam.'"

The night was fine, and the echoes for which this place is remarkable sounded still more strange. A gun fired gave a prolonged reverberation like the noise of the Dutchmen's bowls heard by Rip Van Winkle in Sleepy Hollow. The Alma was reascended by the light of a bivouac-fire of drift-wood, amid the smoke of cigars and tobacco. Such a summer night was all too short, and long before we were wearied of it, Coolin's Cliffs glowed red in the morning sun.

But all things must come to an end, and the moment of my departure, too long delayed by the urgent hospitality of the whole party, at length arrived. After another day like the preceding ones, a late dinner, an evening cigar, and Malcolm was ordered to have the horse and dog-cart ready at twelve p.m. for a long midnight ride through the mountains to Broadford Bay, to catch the Hebridean steamer

at five a.m. going south. One brought a rug, another a watch-coat that had done duty in many campaigns, another cigars, another something else, and, amidst hearty farewells and real regret, the horse's head was turned southward. The night was chilly, and the huge hills stood out dim and mysteriously on either hand, except in one quarter, where the Aurora Borealis glowed like a reflection from some great conflagration until morning dawdled. In no part of the Alps or the Appenines have I seen a sunrise to exceed in beauty that which spread itself above the Rosshire Hills on that morning. The steamer stood in for the bay soon after five p.m., and, with a good-bye and a gratuity for Malcolm, I jumped into the boat waiting to take me to the packet. Another long day of dreamy quietude while steaming along the coast and through the Western Islands, and late at night the red lights streaming across the bay told me we were going into Oban.

## ON RETOUCHING NEGATIVES.

BY DR. VOGEL.

[A recent number of Dr. Vogel's *Mittheilungen* contains two prints from a pair of card negatives of the same person at the same time: one negative is touched to remove freckles, spots, and physical imperfections, and the other left in its natural photographic state. The improvement effected by working on the negative, without in any degree altering the likeness, is very great indeed. We subjoin a condensation of Dr. Vogel's article on the subject.]

There was a time when photographers used to take a pride in furnishing untouched pictures, and were apt to regard with feelings of disdain any photograph which required subsequent mending or beautifying.

The object to be fulfilled in retouching is to rectify inherent faults in a picture. These faults, or imperfections, are of two kinds, viz., those produced through the ignorance and carelessness of the photographer, from insufficient illumination, faulty exposure, bad manipulation &c., and those which may be said to be inseparable from the art of photography, which, as the painter justly observes, gives too much detail, and renders the unimportant points of a picture with as much force and vigour as the important ones; moreover, in the reproduction of lights and shadows photography is sometimes guilty of exaggeration, depicting the former too glaringly, and the latter too darkly, and when different colours are included in the picture, often reversing the order of their brilliancy. For the first named imperfections the photographer is alone responsible, and retouching for the purpose of covering up these faults is certainly a practice to be deprecated; on the other hand the employment of a method capable of correcting blemishes inherent to the art itself is quite as justifiable as the subsequent finishing process to which an engraved copper plate is subjected prior to its deposit in the printing press.

As M. Grasshoff remarks in his recently-published work on retouching, the rectification of faults may be brought about either by a previous treatment of the original object, prior to its being photographed (as, for instance, by powdering or covering up dark spots with ultramarine), or the modification may be effected upon the negative or the positive. There are, therefore, three kinds of retouching; viz., the original, the negative, and the positive methods; the last being the least recommendable on account of its being the least permanent. Pictures improved by this method are affected by simple rubbing, whereas retouching by the other processes secures positives which are as permanent as perfectly untouched photographs, inasmuch as any improvements which may have been effected are copied into the paper. Besides, in using the positive retouching process the work has to be repeated for every separate print, while one retouched negative will yield several hundred serviceable positives. For this reason the negative process is most frequently practised, and has been in vogue in some establishments as long as fifteen years. Rabending, of Vienna<sup>1</sup>

was the first to call public attention to the method, and although it is still regarded by many photographers with some contempt, this mode of retouching is extensively employed.

With reference to the technical elaboration of the negative retouching method, M. Lindner [the photographer who furnishes the illustration] remarks:—"The retouching takes place upon the varnish. In several experiments of retouching, undertaken upon the plate prior to its being protected, I remarked that the subsequent application of the varnish altered the opacity of the material employed, whether it was blacklead or colour, in the same manner as the negative itself is altered. The operation may be performed in two ways; the easiest and quickest method being to employ a blacklead pencil (Faber's No. 3 or 4, according to the composition of the varnish) for the purpose, and where the intensity of the lead is not sufficiently great, to cover up with darker colours. A negative retouched in this manner does not, however, possess anything like the delicacy and brilliancy of one manipulated with a pigment possessed of light-covering properties, yielding an uniform film,—as, for instance, a mixture of Chinese white and sepia. As the colour must be laid on in a dry state, and very sparingly, it is necessary to work with a soft brush, as a hard one would require a considerable amount of moisture to render it sufficiently pointed for the purpose. As a support I use the well-known transparent retouching plate."

"This is the whole of the process as seen from a technical point of view; as regards artistic finish there is naturally plenty of scope for one's talents. For instance, the outline of the nose may be improved, the eyes may be opened wider, the mouth may be curtailed (by skilful covering up of the corners), further improvements being afterwards made upon the positive, if desired. The lights may likewise be modified by the application of colour to the glass surface of the negative, and the shadows softened down; the latter being well effected by the employment of carmine. Details in the drapery, the hair, or background, may also be effected."

According to M. Lindner's process, then, it will be seen that not only is it possible to correct any faults which may arise in photography, but it is likewise possible to cover up any imperfections existing in the original. Large noses may be made small, dark spots may be lighted, old women may be made young, and, in fact, the method may be regarded as a perfect "Adonisising process;" indeed, so effective is it, that if extensively applied in studios, ladies of doubtful age might always be asked the question how old they desire to appear in their pictures, whether above or under fourteen years of age. We will not, however, recommend the carrying too far of any retouching process which, while it may gratify the vanity of the public, and thereby help to fill the pockets of the artist, fails to reproduce the truth.

## PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN

COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXVII.

"The highest finish is labour in vain, unless, at the same time, there be preserved a breadth of light and shadow. It is a quality, therefore, that is more frequently recommended to students, and insisted upon, than any other whatever; and, perhaps, for this reason, because it is most apt to be neglected, the attention of the artist being so often entirely absorbed in the detail."—SIR JOSHUA REYNOLDS.

CHIAROSCURO—(continued).

The light and shade of a landscape cannot be materially altered by the photographer, nor is it necessary that he should do so; but the chiaroscuro of nature is so continually changing that he may select the effect that gives the most pleasure to the educated eye. A few sketches of the arrangements of light and dark as employed by the best artists may assist him in making his selection.

It is desirable that all lights should have a focus, just as light falling on a globe is more brilliant on one small spot

than on any other part; and all lights in a picture should be treated as parts of a whole, and subordinated in various degrees to the principal light. Fig. 1 represents a simple form of chiaroscuro much used by many artists. In this

Fig. 1.

arrangement the highest light is opposed by the darkest dark, and the light fades away in every gradation of middle tones. The two extremes assist each other by contrast, and produce a most forcible and startling effect, with great breadth. It will be found in the works of Bonington, Collins, Cuyp, Both, and many other painters of coast and flat scenery, to which it is well adapted. Many admirable examples—especially by Collins—may be seen in the South Kensington Museum. The reverse of this, in which dark takes the place of light, is shown in fig. 2. This effect may

Fig. 2.

often be noticed in moorland scenery or in a flat country, when the clouds graduate upwards from a dark horizon. The shadow of a cloud may be thrown over the distance, while the foreground may be illuminated by intense sunlight; or the effect may be caused by belts of trees. However produced, the effect is very beautiful, and is one that, now greater attention is paid to passing effects and the sky, may be easily produced in photography. In this arrangement a mass of extreme dark in the light part of the foreground will be found invaluable; or, still better, a figure or other object in which is combined the extremes of black and white. This will be found to throw the rest of the picture—consisting of gradations short of black and white—into harmony, by creating a focus, as it were, more brilliant, and overmastering the other lights and darks in the picture. Turner's "Temeraire" is an example of this form of composition.

In figure 3 the darkest shade is relieved by a light object, and the highest light by the principal spot of dark. Burnet, in writing of a similar design, says:—"If a diagonal line be drawn through the picture, and the extreme dark and extreme light be placed at opposite sides, we must of necessity have the greatest breadth of effect. If a balance or union between the two sides be wished, there is no other way but by borrowing a portion of the one and exchanging it for a portion of the opposite; and not only may this prac-

tice be made use of for the harmony of the whole, but the light and the shade will be thus rendered more intense by

Fig. 3.

the force of opposition. Now, whether the dark which is carried to the light side be very small or very large, and *vice versa*, we have the groundwork of some of the most powerful and most natural effects. If the light is placed near the horizon—as in evening skies, for example, such as it frequently is in Cuy—we see it rising upward until lost in middle tint in the upper part of the picture, and the middle tint descending into shadow by means of trees, figures, &c., thus making a sweep round the picture, and thereby affording the greatest opportunity for breadth of effect. If the two extreme points are connected by intermediate figures, so as to form but one group, we have the greatest firmness, as the light part of the group will be relieved by a dark ground, and the dark part of the group by a light ground; if we pursue the contrary practice, and place the dark part of the group on the dark ground, we have more breadth and softness of effect. There is no want of examples in nature or in pictures to warrant our following either mode."

It is, perhaps, necessary to state that the illustrations are purposely exaggerated to show the effect more clearly, but the truth of nature should never be violated to produce an effect. Photography gives facilities for approaching sufficiently near to the rules of art without that. Midnight shadows should never be mixed with the light of day, even in painting, although it has been managed with great effect by some great masters of the art—Tintoretto and Carravaggio for instance. Leslie says: "This is the boldest fiction of chiaroscuro, but it is generally managed by the painters I have mentioned with such address that it silences criticism, and forces us to admire, whether we can approve or not. All that can be said in its defence is, that the elements of such a combination are from nature, though united as nature does not unite them. Conventionalities like this must be forgiven to genius, but I do not think they are to be recommended to imitation; and in saying so I have no fear of repressing the daring of genius, for genius—such as the men I have mentioned possessed—will always have its own way. Great ability may, however, exist short of theirs; and I would gladly repress all who possess it from attempting things which the success even of greater painters cannot entirely sanction. And there is much need of this caution, because it is far more easy to imitate exaggeration of effect than to make simple truth so impressive as it has been made by Paul Veronese, by Claude, and by the best painters of the Dutch and Flemish schools, including Rembrandt, when he pleased to be included."

Photographers, therefore, must never rely on the excuse for departing from nature, "Painters did it thus." They must not defy, but court criticism—leaving themselves at liberty to reject it if it is obviously wrong—and they must rely on nature for success. Photographers even of "daring genius" cannot afford to depart from nature, as these old painters did, partly because nature is a sure guide, and partly because it has not yet been settled what "daring genius"—as far as it applies to photography—really is.

## THE DIAMOND.

BY JAMES MARTIN.\*

A FEW practical hints and observations may now, perhaps, prove of service to those of your readers who may have occasion to use the diamond as a tool for cutting glass for photographic or other purposes. The diamond used for this purpose is, as I have said before, generally of the spheroid variety, as being the hardest, and is used in its natural state. Polished diamonds are useless; they will scratch, but not produce a clean cut; and so with all other gems or crystals. The only hard diamonds used by glaziers are the plow and the swivel; the latter is that usually employed; it is, I believe, more costly than the former, but far easier of application. The form of the swivel diamond is so well known as to need no illustration. Its parts consist of the shank or handle (sometimes called the stick), the ferrule, and the steel swivel upon which the diamond is set, and which turns to enable the workman to lay the diamond rightly. The great secret of being able to cut with a diamond lies in observing the angle at which the bottom of the swivel inclines, and keeping this, when cutting, perfectly parallel with the face of the glass to be cut. The angular form of the facets of the diamond varies greatly, and must therefore influence the slope at which it can cut; the bottom of the swivel is sloped accordingly, and acts as a guide. A good diamond, well used, will cut so thoroughly through a piece of glass that it will fall in two without pressure from the hands. The cause of the fracture of the glass at times not following the cut made by the diamond, and so spoiling the work, is from the workman not keeping the diamond at an equal slope from beginning to end of the cut; and also may be caused by unequal pressure. It is found that the diamonds used by some cannot be used by others. The bones of the shoulder, the elbow, and wrist are not set alike in all men, and have something to do with this, also their particular habits of motion, arising in great measure from their different callings; but I believe, by practice, any good diamond can be used by any one; but it is better to purchase such an one as suits the usual habits of the hand of the purchaser, and never to permit its use by any one else, or it will soon need resetting, and perhaps become worthless, as all diamonds have not got more than one cutting facet.

I have heard many complaints about deception being practised by dealers in glaziers' diamonds, but do not think that any respectable house would be guilty of it. Before purchasing, the diamond should be examined with a strong magnifying lens, to see that it has not been chipped or split by a fall. The setting should be looked to. It should then be tried on a piece of glass, and the cuts made examined, to see that it cuts deep and clean without scratching. If (say) half a dozen clean deep cuts, the glass afterwards separating readily, can be made with a diamond right off, I do not think its suitability and usefulness need be feared. Diamonds are sometimes set in the handles of pocket knives, and are very portable and convenient for amateurs. Diamonds are set of different sizes, according to the thickness of glass to be cut. Thus the plate glass or flush diamond is of large size, while the one used for cutting thin microscopic glass is small. There are also what are termed circular diamonds, and diamonds cutting upon movable circular tables, used for cutting glasses for magic lantern slides, clocks, &c. Ovals are also cut generally by shapes applied upon the glass, but are sometimes executed by machinery.

## TWO SIMPLE AND PRACTICAL METHODS OF PRINTING UPON IVORY.

BY DAVID DUNCAN

IVORY is difficult to manipulate for photographic purposes, and success has been rare except in the hands of a few skilful votaries of the art. Having succeeded with the follow-

\* Continued from p. 292.

ing, I add my mite to photographic lore. Professional secrecy I regard as wrong. "There is that scattereth, and yet increaseth." One grain of wheat may produce sheaves, and thousands of shot may be got from a lump of lead.

**COLLODIO-CHLORIDE PROCESS.**—Very much depends upon the ivory having a smooth or polished surface. There are various methods of obtaining this. A nice surface can be obtained by rubbing the ivory with a piece of wash-leather, occasionally dipped in putty powder. When polished, immerse the ivory in a thin solution of spirit varnish, and dry gently over a gas stove or before the fire. Any kind of varnish will do that is white and clear. Then prepare the following:—

French gelatine ... ..	1 drachm
Water ... ..	1 ounce
Loaf sugar ... ..	$\frac{1}{2}$ drachm.

Coat one side of the varnished ivory (the polished side) by pouring collodion fashion, or with a camel-hair brush. The gelatine solution should be strained through fine muslin, or filtered through cotton wool, until very clear. When dry, coat with collodio-chloride of silver in the dark room; dry, and print deep; wash, either under the tap or in a flat dish. Any old toning bath will do to tone the picture. Fix in a weak solution of hypo; say,—

Hyposulphite of soda ... ..	2 $\frac{1}{2}$ ounces
Water ... ..	20 "

Very beautiful pictures can be obtained by the above.

**PHOTO-DIAPHANIE PROCESS.**—The following is interesting, and the results are beautiful, but it is difficult to manage. Procure albuminized transfer paper—that made expressly for photo-diaphanie; float five minutes on—

Nitrate of silver . . . . .	120 grains
Water ... ..	1 ounce.

Print in the sun, if possible, and until the high lights are well covered. The right amount of printing required can only be judged by experience. Wash, and tone in—

Distilled water ... ..	10 ounces
Pure chloride of gold ... ..	15 grains.

It will take some time to tone. When toned, wash, and immerse the picture in a saturated solution of hyposulphite of soda for five minutes. Now wash in several changes of water until the albumen film upon which the picture is printed loosens itself from the paper. When detached, the film floats on top of the water as a delicate transparency. The polished ivory is now brought under the film in the water, and gently arranged by the fingers. The picture, after coming from the water, is placed between smooth note-paper, inserted in a book, and left until dry.

## ON THE MEASUREMENT OF THE LUMINOUS INTENSITY OF LIGHT.

BY WILLIAM CROOKES, F.R.S., ETC.

THE measurement of the intensity of a ray of light is a problem the solution of which has been repeatedly attempted, but with less satisfactory results than the endeavours to measure the other radiant forces. The problem is susceptible of two divisions—the absolute and the relative measurement of light.

1. Given a luminous beam, we may require to express its intensity by some absolute term having reference to a standard obtained at some previous time, and capable of being reproduced with accuracy at any time in any part of the globe. Possibly two such standards would be necessary, differing greatly in value, so that the space between them might be subdivided into a definite number of equal parts; or the same result might, perhaps, be obtained by the well-known device of varying the apparent intensity of the standard light by increasing and diminishing its distance from the instrument.

2. The standard of comparison, instead of being obtained once for all, like the zero- and boiling-points of a thermometer, may be compared separately at each observation; and the problem then becomes somewhat simplified into the determination of the relative intensities of two sources of light.

The *absolute* method is, of course, the most desirable; but as the preliminary researches and discoveries are yet to be made, before a photometer, analogous to a thermometer in fixity of standard and facility of observation, could be devised, the realisation of an absolute light-measuring method appears somewhat distant. The path to be pursued towards the attainment of this desirable object appears to be indicated in the observations which from time to time have been made by Becquerel, Herschel, Hunt, and others, on the chemical action of the solar rays, and the production thereby of a galvanic current, capable of measurement on a delicate galvanometer, by appropriate arrangements of metallic plates and chemical baths connected with the ends of the galvanometer wires.

Many so-called photometers have been devised by which the chemical action of the rays at the most refrangible end of the spectrum have been measured, and the chemical intensity of light tabulated by appropriate methods; and within the last few years Professors Bunsen and Roscoe have contrived a perfect chemical photometer, based upon the action of the chemical rays of light on a gaseous mixture of chlorine and hydrogen, causing them to combine with formation of hydrochloric acid.

But the measurement of the chemical action of a beam of light is as distinct from photometry proper, as is the thermometric registration of the heat rays constituting the other end of the spectrum. What we want is a method of measuring the intensity of those rays which are situated at the intermediate parts of the spectrum, and produce in the eye the sensation of light and colour; and, as previously suggested, there is a reasonable presumption that further researches may place us in possession of a photometric method based upon the chemical action of the *luminous* rays of light.

The rays which effect an ordinary photographic sensitive surface are so constantly spoken of and thought about as the ultra-violet invisible rays, that it is apt to be forgotten that some of the highly luminous rays of light are capable of exerting chemical action. Fifteen years ago\* the writer was engaged in some investigations on the chemical action of light, and he succeeded in producing all the ordinary phenomena of photography, even to the production of good photographs in the camera, by purely luminous rays of light, free from any admixture with the violet and invisible rays. When the solar spectrum, of sufficient purity to show the principal fixed lines, is projected for a few seconds on to a sensitive film of iodide of silver, and the latent image then developed, the action is seen to extend from about the fixed line G to a considerable distance into the ultra-violet invisible rays. When the same experiment was repeated with a sensitive surface of bromide of silver instead of iodide of silver, the result of the development of the latent image showed that in this case the action commenced at about the fixed line b, and extended, as in the case of the iodide of silver, far beyond the violet. A transparent cell, with parallel glass sides, one inch across, was filled with a solution of 25 parts of sulphate of quinine to 100 parts of dilute sulphuric acid; this was placed across the path of the rays of light, and photographs of the spectrum were again taken on iodide of silver and on bromide of silver, the arrangements in all cases being identical with those in the first cited experiments, with the exception of the interposition of the quinine screen. The action of the sulphate of quinine upon a ray of light is peculiar; to the eye it scarcely appears to have any action at all, but it is absolutely opaque to the ultra-violet, so-called chemical rays, and thus limits the photographic action on the bromide and iodide of silver to the purely luminous rays. On developing the latent images it was now found that the action on iodide of silver was confined to a very narrow line of rays, close to the fixed line G, and in the case of bromide of silver to the space between b and G. Designating the spaces of action by colours instead of fixed lines, it was thus proved that, behind a screen of sulphate of quinine, iodide of silver was affected only by the luminous rays about the centre of the indigo portion of the spectrum, whilst bromide of silver was affected by the green, blue, and some of the indigo rays.

It is very likely that a continuance of these experiments would lead to the construction of a photometer capable of measuring the luminous rays; for although bromide of silver behind quinine is not affected by the red or yellow rays, still it is by the green and blue; and as the proportion of red, yellow, green, and blue rays is always invariable in white light (or the light would not be white, but coloured), a method of measuring

\* The Journal of the Photographic Society, vol. 1.

the intensity of one set of the components of white light would give all the information we want; just as in an analysis of a definite chemical compound, the chemist is satisfied with an estimation of one or two constituents only, and calculates the others.

Method based upon the foregoing considerations would supply us with what may be termed an *absolute* photometer, the indication of which would be always the same for the same amount of illumination, requiring no standard light for comparison; and pending the development of experiments which the writer is prosecuting in this direction, he has been led to devise a new, and, as he believes, a valuable form of *relative* photometer.

A relative photometer is one in which the observer has only to determine the relative illuminating powers of two sources of light, one of which is kept as uniform as possible, the other being the light whose intensity is to be determined. It is therefore evident that the great thing to be aimed at is an absolutely uniform source of light. In the ordinary process of photometry the standard used is a candle, defined by Act of Parliament as a "sperm candle of six to the pound, burning at the rate of 120 grains per hour." This is the standard from which estimates of the value of illuminating gas are deduced, hence the terms "12-candle gas," "14-candle gas," &c. In his work on "Gas Manipulation," Mr. Sugg gives a very good account of the difficulties which stand in the way of obtaining uniform results with the Act of Parliament candle. A true sperm candle is made from a mixture of refined sperm with a small proportion of wax, to give it a certain toughness, the pure sperm itself being extremely brittle. The wick is of the best cotton, made up into three cords and plaited. The number of strands in each of the three cords composing the wick of a six-to-the-pound candle is seventeen, although Mr. Sugg says there does not appear to be any fixed rule, some candles having more and others less, according to the quality of the sperm. Sperm candles are made to burn at the rate of one inch per hour, and the cup should be clean, smooth, and dry. The wick should be curved slightly at the top, the red tip just showing through the flame, and consuming away without requiring snuffing. To obtain these results the tightness of the plaiting and size of the wick require careful attention; and as the quality of the sperm differs in richness or hardness, so must the plaiting and number of strands. A variety of modifying circumstances thus tend to affect the illuminating power of a standard sperm candle. These difficulties, however, are small, compared with those which have resulted from the substitution of paraffine, &c., for part of the sperm; and Mr. Sugg points out that candles can be made with such combinations of stearine, wax, or sperm, and paraffine as to possess all the characteristics of sperm candles, and yet be superior to them in illuminating power; while, on the other hand, candles made from the same materials otherwise combined are inferior. When, in addition to this, it is found that candles containing paraffine require wicks more tightly plaited and with fewer strands than those suitable for the true sperm candle, our readers will be enabled to judge of the almost unsurmountable difficulties which beset the present system of photometry.

But assuming that the true parliamentary sperm candle is obtained, made from the proper materials, and burning at the specified rate, its illuminating power will be found to vary with the temperature of the place where it has been kept, the time which has elapsed since it was made, and the temperature of the room wherein the experiment is tried.

The Rev. W. H. Bowditch, in his work on "The Analysis, Purification, &c., of Coal Gas," enters at some length into the question of test-candles, and emphatically condemns them as light measures; one experiment quoted by this author showed that the same gas was reported to be 14.63 or 17.36 candle gas, according to the way the experiment was conducted.

The present writer has taken some pains to devise a source of light which should be at the same time fairly uniform in its results, would not vary by keeping, and would be capable of accurate imitation at any time and in any part of the world by mere description. The absence of these conditions seems to be one of the greatest objections to the sperm candle. It would be impossible for an observer on the continent, ten or twenty years hence, from a written description of the sperm candle now employed, to make a standard which would bring his photometric results into relation with those obtained here. Without presuming to say positively that he has satisfactorily solved all difficulties, the writer believes that he has advanced some dis-

tance in the right direction, and pointed out the road to further improvement.

Before deciding upon a standard light, experiments were made to ascertain whether the electric current could be made available. Through a coil of platinum wire, so as to render it brightly incandescent, a powerful galvanic current was passed; and its strength was kept as constant as possible by a thick wire galvanometer and rheostat. To prevent the cooling action of air-currents the incandescent coil was surrounded with glass; and it was hoped that by employing the same kind of battery and by varying the resistance so as to keep the galvanometer needle at the same deflection, uniform results could be obtained. In practice, however, it was found that many things interfered with the uniformity of the results, and the light being much feebler than it was advisable to work with, this plan was deemed not sufficiently promising, and it was abandoned. The method ultimately decided upon is the following:—Alcohol of sp. gr. 0.805, and pure benzole boiling at 81° C., are mixed together in the proportion of 5 volumes of the former and 1 of the latter. This burning fluid can be accurately imitated from description at any future time and in any country, and if a lamp could be devised equally simple and invariable, the light which it would yield would, it is presumed, be invariable. This difficulty the writer has attempted to overcome in the following manner.

A glass lamp is taken of about 2 ounces capacity, the aperture in the neck being 0.25 inch diameter; another aperture at the side allows the liquid fuel to be introduced, and by a well-known laboratory device the level of the fluid in the lamp can be kept uniform. The wick-holder consists of a platinum tube 1.81 inches long and 0.125 inch internal diameter. The bottom of this is closed with a flat plug of platinum, apertures being left in the sides to allow free access of spirit. A small platinum cup, .5 inch diameter and .1 inch deep, is soldered round the outside of the tube 0.5 inch from the top, answering the three-fold purpose of keeping the wick-holder at a proper height in the lamp, preventing evaporation of the liquid and keeping out dust. The wick consists of 52 pieces of hard-drawn platinum wire, each 0.01 inch in diameter and 2 inches long, perfectly straight and tightly pushed down into the platinum holder until only 0.1 inch projects above the tube. The height of the burning fluid in the lamp must be sufficient to cover the bottom of the wick-holder; it answers best to keep it always at the uniform distance of 1.75 inches from the top of the platinum wick; a slight variation of level, however, has not been found to influence the light to an extent appreciable by our present means of photometry. The lamp having the reservoir of spirit thus arranged, the platinum wires parallel and their projecting ends level, a light is applied, and the flame instantly appears, forming a perfectly-shaped cone 1.25 inches in height, the point rate of maximum brilliancy being 0.56 inch from the top of the wick. The extremity of the flame is perfectly sharp, without any tendency to smoke; without flicker or movement of any kind, it burns, when protected from currents of air, at a uniform rate of 136 grains of liquid per hour. The temperature should be about 60° F., although moderate variations on either side exert no perceptible influence. Bearing in mind Dr. Frankland's observations on the direct increase in the light of a candle with the atmospheric pressure, accurate observations ought only to be taken at one height of the barometer. To avoid the inconvenience and delay which this would occasion, a table of corrections should be constructed for each 0.1 inch variation of barometric pressure.

There is no doubt that this flame is very much more uniform than that of the sperm candle sold for photometric purposes. Tested against a candle, considerable variations in relative illuminating power have been observed; but on placing two of these lamps in opposition no such variations have been detected. The same candle has been used, and the experiments have been repeated at wide intervals, using all usual precautions to ensure uniformity. The results are thus shown to be due to variations in the candle and not in the lamp.

It is expected that whoever may be inclined to adopt the kind of lamp here suggested will find not only that its uniformity may be relied upon, but that, by following accurately the description and dimensions here laid down, each observer will possess a lamp of equivalent and convertible photometric value, so that results may not only be strictly comparable between themselves, but within slight limits of accuracy comparable with those obtained by other experimentalists. The dimensions of wick, &c., here laid down are not intended to fix the standard. Persons engaged in photometry as an important branch of their

regular occupation will be better able to fix these data than the writer, by whom photometry is only occasionally pursued as a means of scientific research. Already many improvements suggest themselves, and several causes of variation in the light have been noticed. Future experiments may point out how these sources of error are to be overcome; but at present there is no necessity to refine our source of standard light to a greater degree of accuracy than the photometric instrument admits of.

The instrument for measuring the relative intensities of the standard and other lights next demands attention. The contrivances in ordinary use are well known. Most of them depend on a well-known law in optics; namely, that the amount of light which falls upon a given surface varies inversely as the square of the distance between the source of light and the object illuminated. The simplest observation which can be taken is made by placing two sources of light (say a candle and gas-lamp) opposite a white screen, a few feet off, and placing a stick in front of them, so that two shadows of the stick may fall on the screen. The strongest light will cast the strongest shadow; and by moving this light away from the stick, keeping the shadows side by side, a position will at last be found at which the two shadows appear of equal strength. By measuring the distance of each light from the screen, and squaring it, the product will give the relative intensities of the two sources of light.

In practice, this plan is not sufficiently accurate to be used except for the roughest approximations; and from time to time several ingenious contrivances, all founded upon the same law, have been introduced by scientific men, by which a much greater accuracy is obtained; thus in Ritchie's photometer the lights are reflected on to a piece of oiled paper in a box, and their distances are varied until the two halves of the paper are equally illuminated. In Bunsen's photometer, which is the one now generally used, the lights shine on opposite sides of a disc of white paper, part of which has been smeared with melted spermaceti to make it more transparent. When illuminated by a front light, the greased portion of the paper will look dark; but if the observer goes to the other side of the paper, the greased part looks the lighter. If, therefore, lights of unequal intensity are placed on opposite sides of a piece of paper so prepared, a difference will be observed; but by moving one backwards or forwards, so as to equalize the intensity, the whole surface of the paper will appear uniformly illuminated on both sides. This photometer has been modified by many observers. By some the disc of paper is moved, the lights remaining stationary; by others the whole is enclosed in a box, and various contrivances are adopted to increase the sensitiveness of the eye and to facilitate calculation; but in all these the sensitiveness is not greatly augmented, as the eye cannot judge of very minute differences of illumination approximating to equality.

In 1833, Arago described a photometer in which the phenomena of polarized light were employed. This instrument is fully described, with drawings, in the tenth volume of the *Œuvres Complètes de François Arago*; but the description, although voluminous, is far from clear. The principle of its construction is founded on "the law of the square of the cosines," according to which polarized rays pass from the ordinary to the extraordinary image. The knowledge of this law, he says, will not only prove theoretically important, but will further lead to the solution of a great number of very important astronomical questions. Suppose, for example, that it is wished to compare the luminous intensity of that portion of the moon directly illuminated by the solar rays with that of the part which receives only light reflected from the earth, called the *partie cendrée*. Were the law in question known, the way to proceed would be as follows:—After having polarized the moon's light, pass it through a doubly refracting crystal, so disposed that the rays, not being able to bifurcate, may entirely undergo ordinary refraction. A lens placed behind this crystal will therefore show but one image of our satellite; but as the crystal in rotating on its axis passes from its original position, the second image will appear, and its intensity will go on augmenting. The movement of the crystal must be arrested at the moment when, in this growing extraordinary image, the segment corresponding to the part of the moon illuminated by the sun exhibits the intensity of the ashy part shown by the ordinary image. From these data it is easy to perceive, he says, that the problem is capable of solution.

In another part of the same volume, after speaking of the polariscope which goes by his name, Arago writes:—"I have

new arrived at the general principle upon which my photometric method is entirely founded. The quantity (I do not say the proportion)—the quantity of completely polarized light, which forms part of a beam partially polarized by reflection, and the quantity of light polarized rectangularly, which is contained in the beam transmitted under the same angle, are exactly equal to each other. The reflected beam and the beam transmitted under the same angle by a sheet of parallel glass have in general very dissimilar intensities; if, however, we examine with a doubly refracting crystal, first the reflected and then the transmitted beam, the greatest difference of intensity between the ordinary and the extraordinary images will be the same in the two cases, because this difference is precisely equal to the quantity of polarized light which is mixed with the common light."

In Arago's astronomy, the author again describes his photometer in the following words: "I have constructed an apparatus by means of which, upon operating with the polarized image of a star, we can succeed in attenuating its intensity by degrees exactly calculable after a law which I have demonstrated." It is difficult to obtain an exact idea of this instrument from the description given; but from the drawings it would appear to be exceedingly complicated, and to be different in principle and construction from the one now about to be described. The present photometer has this in common with that of Arago, as well as with those described in 1853 by Bernard,\* and in 1854 by Babinet,† that the phenomena of polarized light are used for effecting the desired end. But it is believed that the present arrangement is quite new, and it certainly appears to answer the purpose in a way which leaves little to be desired. The instrument will be better understood if the principles on which it is based are first described.

Fig. 1 shows a plan of the arrangement of parts, not drawn to scale, and only to be regarded as an outline sketch to assist in the comprehension of general principles. Let D represent a source of light. This may be a white disc of porcelain or paper illuminated by any artificial or natural light. C represents a similar white disc, likewise illuminated. It is required to compare the photometric intensities of D and C. (It is necessary that neither D nor C should contain any polarized light, but that the light coming from them, represented on each disc by the two lines at right angles to each other, forming a cross, should be entirely unpolarized.) Let H represent a double refracting achromatic prism of Iceland spar; this will resolve the disc D into two discs, *d* and *d'*, polarized in opposite directions; the plane of *d* being, we will assume, vertical, and that of *d'* horizontal. The prism H will likewise give two images of the disc C; the image *c* being polarized horizontally, and *c'* vertically. The size of the discs D C, and the separating power of the prism H are to be so arranged that the vertically polarized image *d*, and the horizontally polarized image *c*, exactly overlap each other, forming, as shown in the figure, one compound disc *c d*, built up of half the light from D and half that from C.

(To be continued.)

## Proceedings of Societies.

### LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The second out-door meeting was held on Monday, the 22nd ult., at Llangollen, North Wales. Notwithstanding that the morning opened rather unfavourably, between twenty and thirty

\* *Comptes Rendus*, April 25, 1853.

† Proceedings of the British Association, Liverpool Meeting, 1854.

ladies and gentlemen assembled, and passed a very pleasant day. Several of the party elected to continue their journey a few miles past Llangollen; the rest, who were content with the town and its picturesque vicinity, were able to secure several pictures before the rain came, just as the "onward" party were getting to work. The rain continued steadily for about two hours, after which, until dinner time, Sol was in the ascendant, and cameras in full occupation.

At four o'clock both detachments met, and, at the President's kind invitation, sat down to a sumptuous repast at the "Hand" Hotel. Owing to a misunderstanding with regard to the time of departure of the return train, the party was compelled to wait for the next one, about half past eight; and to relieve the tedium of the "long wait"—everybody else's plates being exposed and cameras packed up—Mr. Mawdsley took two groups in the court-yard of the "Hand," upon collodio-bromide plates. The return journey was by far the least pleasant part of the day's proceedings; as, with the total disregard of punctuality generally observable on that line, the train arrived at Birkenhead a few minutes before midnight, and passengers were landed at Liverpool too late for all out-going trains and omnibuses, and cabs at extra fares were in great demand.

THE ordinary monthly meeting of the same Association was held on Tuesday evening, the 30th ult., the President, the Rev. G. J. BANNER, in the chair.

The minutes of the previous meeting were read and confirmed, and Mr. Alfred Tyrer was elected a member of the Association.

A vote of thanks was passed by acclamation to the President for his hospitality on the occasion of the excursion to Llangollen.

After some desultory conversation,

The President asked Mr. Henderson if he could explain the cause of the peculiar tones noticeable in some of his prints on the table.

Mr. HENDERSON attributed them to the paper, while the opinions of others leaned towards acidity in the printing or toning baths.

Mr. HUGHES exhibited some prints mounted with india-rubber, and which were peeling off the mounts, and gave it as his opinion that "india-rubber mounting" is a "delusion and a snare."

Mr. GUYTON made some remarks bearing out Mr. Hughes's opinion, and stated that he had been warned of the effect years ago.

It was decided to hold the third out-door meeting at Beeston, on Thursday, 9th July.

The meeting was adjourned at an early hour, the attendance of members being very small.

THE usual monthly meeting of the Association was held on the evening of Tuesday, the 28th July, at the Free Public Library, the President, the Rev. G. T. BANNER, in the chair.

The minutes of the previous meeting and of the Llangollen excursion were read and confirmed.

Mr. MAWDSLEY submitted for inspection some 8½ by 6½ prints from negatives on the Liverpool Company's plates, which were much admired. They consisted of views on the Sussex coast; and two were presented to the Society's album.

Mr. GUYTON brought forward some first-class views, &c., including "The Prize of Prizes," by Dr. Hemphill; in emulation of which Dr. Watling showed an admirable print from a wet collodion negative, both subjects consisting of studies of "Still Life."

Many members being inadvertently prevented from competing for Mr. Green's prize, the time was extended, and the large print will be awarded at the August meeting for the best twelve stereos taken during June, July, and August.

Mr. GREEN also offered one of his 24 by 18 prints "for the best year's work" shown at the end of the year.

The thanks of the Association were unanimously awarded to Mr. Greene for his generosity.

On the motion of Mr. HENDERSON, seconded by Mr. HUBBACH, it was decided to have an excursion to the "Old Hut" on Saturday afternoon, the 15th of August.

A paper by Mr. BOLTON, on "A New Preservative Medium," was then read, and a vote of thanks was passed to the author.

Mr. BOLTON, however, and his results being absent, it was

considered that further experiments were necessary to establish the superior claims of quassia over tannin.

Mr. GREENE related his experience with a new toning bath recently described in the PHOTOGRAPHIC NEWS by Mr. Bovey, who finds that the ordinary adjuncts to chloride of gold in the toning bath, while acting as retarders, have a tendency to precipitate the gold as powder. He proposed:—

Chloride of gold (orange)	...	...	8 grains
Common salt	...	...	1 grain

Pour on 1½ pints boiling water, and let stand till lukewarm and then add 2 gallons cold water. It improves by keeping only requiring to be strengthened. In rather more than the above quantity Mr. Greene recently toned simultaneously forty-four prints 10 by 12 inches, and one print 24 by 18, obtaining rich sepia and black tones, with an available surplus of gold.

Mr. WILSON considered the action somewhat similar to that of the double chloride of gold and sodium.

The President showed some prints toned and fixed at one operation, as lately recommended by Dr. Liesegang, but the results were unsatisfactory.

A short discussion ensued, and the meeting then adjourned.

## Correspondence.

### REMOVING SILVER STAINS FROM OPAL GLASS.

SIR.—I see that one of your correspondents has met with a difficulty in removing the image from opal plates. There is no need for him to get a fresh sample, it this be the only thing wrong. After removing the film, should the impression remain, let him subject the plate to a strong heat from a spirit-lamp, having previously covered it with much diluted nitric acid. The ghost of the picture will slowly vanish, and the plate be as good as ever.—Your obedient servant, P. S. DRAYTON.

Horton Court, Chipping Sodbury, 27th July, 1868.

PS—I do not know if this plan will answer with collodio-chloride or collodio-bromide plates, but it has never failed with the ordinary wet plates.

### WASHING MACHINES.

DEAR SIR,—I can fully endorse Mr. Cherrill's remarks upon washing machines. The most efficient one—and which I have had in use many years—may be found fully described, as used by the Government at Southampton, in one of the early numbers of the PHOTOGRAPHIC NEWS. Not only small but whole sheets can be thoroughly washed without tearing, and it may readily be made by any country carpenter.—I am, dear sir, yours truly, AN OLD PHOTOGRAPHER.

July 25th, 1868.

## Talk in the Studio.

FINAL MEDALS OF THE FRENCH EXHIBITION.—Our readers will be gratified to learn that Dr. Diamond has just received from the French Imperial Commission a medal "for services rendered," in acknowledgment of his labours as a juror in the photographic department of the Exhibition of last year. This is the more complimentary to the recipient of the medal, and will be the more gratifying to English photographers, inasmuch as it is a somewhat exceptional honour, not conferred upon the jurors generally, but only upon such as have been especially marked out for honour for the especial value of their assistance.

RETOUCHING NEGATIVES.—We have been favoured by Mr. J. B. Mohr with a sight of some touched negatives, and prints therefrom, which aptly illustrate the value of the method in giving refinement without detracting in any degree from the likeness. Portraitists are becoming more and more familiar with the fact that the truth of photography may be materially aided by the truth of art, and that yellow freckles, &c., scarcely perceptible in nature, are not truthfully rendered when represented by coarse, black spots. Skillful retouching of the negative removes all this, and makes the photograph come nearer to the truth of nature. Our readers may learn, on reference to our advertising columns, that Mr. Mohr is for a short time de-

voting himself to teaching photographers his method of touching, which will be a boon to many. We note that in the advertisement Mr. Mohr is to be addressed as "N.," at the office of this paper.

**SILVERING IRON WIRE.**—A patent has been granted in Bavaria for the following method of silvering hooks and eyes and other small articles made of iron wire. The articles are suspended in dilute sulphuric acid until the iron shows a clean, bright surface. After rinsing in pure water, they are placed in a bath of a mixed solution of sulphate of zinc, sulphate of copper, and cyanide of potassium, and here remain until they receive a bright coating of brass. Lastly, they are transferred to a bath of nitrate of silver, cyanide of potassium, and sulphate of soda, in which they quickly receive a coating of silver.

**DECOMPOSITION AND RECOMPOSITION OF LIGHT.**—Mr. W. J. Lane used, in place of the costly apparatus generally employed for this beautiful and instructive experiment, a glass tube 8 or 10 inches long and  $\frac{1}{2}$  an inch in diameter, with a bore of .05 to .09 of an inch. In a room containing only one light (a gas flame, for instance), while standing a few feet from and facing it, place the tube horizontally across the eyes and as near to them as possible, and on looking toward the light a beautiful arc of a large size will appear, which is composed of a series of splendid spectra, more or less brilliant, according to the refractive powers of the tube and the distance of the observer from the light. Now, upon revolving the tube while so placed, the arc of light will apparently revolve very rapidly, the colours will be bleuded, and white light produced, thus affording a pleasing experiment. With large tubes of greater dispersive power the effect would probably be more beautiful.

### To Correspondents.

**BILL JENKINS.**—In strengthening a negative bath you can add the necessary proportion of nitrate of silver direct to the bath, or you can add a little of a fresh strong solution; but the mode of proceeding which we prefer, and which we find answers best, is first to add a few ounces of distilled water to the old bath, which will cause a precipitate of iodide of silver, and then, after filtering, add sufficient nitrate of silver to make the whole of the desired strength.

**LYTTE'S STUDIO.**—The defect in the print you forward arises from imperfect fixation. The solution of hyposulphite has been too weak or exhausted, or the print has not been immersed for a sufficient time. No such result will ever arise if you fix in fresh strong hypo, immersing the prints for a period of not less than ten or fifteen minutes, and keeping them in motion, by turning over from time to time, to prevent them sticking to each other.

**D. WELCH.**—Thanks. The specimens are very good and interesting, and, as you observe, attest the value of the various formulae you mention. It is satisfactory to us to know that the formulae we have published give such good results.

**W. J. A. G.**—If you wash the negative after development, and then cover it with a mixture of equal parts of golden syrup and water, you can intensify and fix at your leisure without any disadvantage. Before proceeding to intensify, take care to remove all the golden syrup solution, as if any portion remain on or in the film it will act somewhat like acetic acid, having a restraining action. There are several good reasons why it is better to fix at home. It enables you to judge of the intensity of the picture deliberately, without the inconvenience of limited space, limited amount of water, &c.; and, further, it dispenses with the necessity of carrying any fixing agents amongst your other chemicals, or the danger of splashing the fixing solution into the bath, a danger which working in little space sometimes renders imminent.

**J. R. G.**—If you neutralize and sun thoroughly the negative bath with which you have accidentally mixed a little of the printing bath containing sugar and nitrate of soda, it is probable that any injurious matter which may be present will be eliminated; or it may be done without sunning by means of permanganate of potash. The only injurious matter will be the sugar and any traces of albumen. The nitrate of soda will be harmless in the negative bath. This course will be better than boiling down the solution in order to use it as a printing bath, because it is difficult to eliminate all iodide of silver, and that is sometimes found to interfere with toning operations; but if you prefer the latter, first add double the bulk of distilled water to the bath to throw down iodide, filter, and then boil down to the proper strength.

**A. W.**—During the period in which the Daguerreotype process was used, bromine itself, and not its salts, was employed. A mixture of bromine and iodine, called bromide of iodine, was at that time used, and in 1846 Mr. Bingham introduced what was called "bromide of lime," a mixture of bromine and lime, somewhat similar in character to chloride of lime. In the paper processes bromide of potassium was employed, and as this was freely soluble in water no other salt was needed. It was not until after the introduction of the collo-

dion process that a new bromide salt became desirable, bromide of potassium being very slightly soluble in collodion. In 1853 we find record of the bromides of iron, nickel, cadmium, and ammonium having been tried: some by the Abbe Laborde, and some by Mr. Crookes. The latter gentleman had, we believe, used some of them earlier than that; but we cannot state at what date.

**A SUBSCRIBER.**—As your letter contains grave charges, which might be made the subject of legal enquiry, they should be substantiated by your name, which we shall be glad to receive. The case is not at an end, we believe, and facts like those you mention bear seriously upon it, and should be brought forward and substantiated.

**II. II.**—Your idea of the shape of the glass room in question is correct. You will find the dimensions in our description of it. 2. Generally, photographs intended for finishing in crayons are produced on rough drawing-paper, which presents sufficient tooth without further preparation. Sometimes the surface is treated with size in which a little powdered pumice or cuttle-fish bone is mixed, so as to secure a tooth. As a rule, soft crayons are preferred; but much depends on the choice of the colourist. For finishing in black and white, a few sharp touches with *conté* crayon are often employed.

**J. H. JOHNSON.**—If the nitrate of soda were quite pure it should cause no precipitate at all when added to a silver solution. The turbidity has probably been due to the presence of some slight impurity. 2. It is probable that you will find that the strong solution will be useful to add to your regular solution from time to time to strengthen and replenish it. Add a little sugar; but the nitrate of soda will scarcely be necessary, as the bath is robbed of the latter in less proportion than it is of silver.

**COLLODION.**—The term "equivalent focus" always applies to compound lenses, and means the focus at which it will give an image the same size as a single lens of the same power. For instance, if a single lens give, in rendering an object twenty feet distant, an image six inches in length, a portrait lens of similar equivalent focus will give exactly the same sized image of the same object at the same distance. But measuring from the back of each lens to the ground glass the distance will be slightly different. The single lens has (say) a focus of six inches measured from its back surface to the ground glass; but the portrait lens will probably only have about five inches between its back surface and the ground glass; to get the equivalent focus, the measurement must be from the ground glass to a point between the front and back lenses of the combination. The simplest mode of ascertaining the equivalent focus is to take an engraving or map, and produce a sharp image on the ground glass precisely the same size as the original, then unscrew the lens, and measure the distance between the object and the ground glass: one-fourth of that distance is the equivalent focus of the lens. 2. Chloride of calcium and chloride of lime are two different things. The former is a combination of chlorine and the metal calcium, the latter is an incorrect term used to describe a mechanical mixture formed by passing chlorine through the hydrate of lime; it is supposed to consist of chlorine, hypochlorite of lime, and hydrate of lime. 3. We do not know whether Harmer's collodion will or will not be introduced into this country. 4. Coffee plates carefully prepared are said to keep some months. How the recent hot weather would affect their keeping qualities we cannot say. The dryness would be favourable to keeping. 5. Either the D. or the new rapid, we should think. The optician will give you the best advice.

**II. S.**—The marks on the negative appear like those produced by over-iodized collodion, for which the best remedy is a little more plain collodion, or the addition of a little more soluble cotton and a little stronger bath. Age will mend the matter; the addition of about half a grain of bromide per ounce, and the use of a stronger bath, may help you. We have not had time yet to examine your collodions, but will take an early opportunity of doing so.

**R. M. F.**—We prefer sugar-candy for the developer, but ordinary sugar may be used; molasses restrains too much. In some experiments we made, 1 grain of molasses was equivalent to 20 of glacial acetic acid in restraining power.

**G. C. C.** quotes the following from the *Engineer*:—"Cyanide of potassium, much used by photographers, is an exceedingly dangerous poison; and they will be glad to hear that the painful ulcers and bad symptoms which it produces may be effectually prevented by rubbing the hands, when soiled with it, with a mixture of protosulphate of iron reduced to a very fine powder, and linseed oil." He adds:—"I never heard of the hands being 'soiled' with cyanide of potassium. I do not quite understand the meaning of the paragraph, unless it is that the use of the sulphate of iron, &c., should follow the cleansing of the hands from the stains of nitrate of silver with cyanide of potassium." G. C. C. should remember that the word "soiled" is used doubtless in the sense which Lord Palmerston regarded dirt, as simply "matter in the wrong place." He is right in his idea that the iron salt should follow the cyanide in order to neutralize it; a thorough good rinsing with water should follow both; but we counsel our reader to avoid cyanide, and use simply pumice-stone and water.

**J. MARTIN.**—Received. Thanks.

### NEW SUBSTITUTE FOR GROUND GLASS.

A VARIETY of substances have been proposed, and some of them successfully used, as substitutes for ground glass as used in photography, either for focussing-screens or as a backing for transparencies for the stereoscope. Our attention has been recently called by Mr. Woodbury to another, which is, we think, better than any that has been proposed or tried. The material proposed is not, indeed, new, but its application for the purpose in question is, we believe, new, as well as efficient.

Mr. Woodbury proposes to use gelatine rendered semi-opaque by the addition of a white pigment. This may be either applied direct to the front or back of the transparency, or it may be made in thin sheets and used as required. For stereoscopic transparencies this appears to us, from the examples we have seen, to give a better result than either ground glass, opal glass, or dull varnish. The ground glass, unless it be very fine indeed, when used with stereoscopes with powerful lenses, gives an unpleasantly sparkling or frosted appearance, and interferes with the delicate definition of the picture; and this is true, but perhaps in a less degree, of the dull varnishes. Opal glass generally obstructs too much light, but it gives a delicate soft effect to the picture. White pigmented gelatine gives an effect scarcely distinguishable in kind from opal glass, but as it can be used in a much thinner and more transparent layer, the softened delicate effect can be obtained without dullness; in fact, the degree of opacity is quite under the control of the photographer himself.

For focussing-screens we cannot imagine anything better. All photographers who use an eye-piece in focussing, in order to secure the greatest sharpness, are familiar with the difficulty they experience from the grain or texture of the ground glass being magnified, rendering the focussing of fine detail difficult. The infinitesimally fine particles of white pigment which produce the semi-opacity of the screen when formed of this substance will in no case confuse the finest definition, even under very high magnifying power. The one disadvantage which a screen of opal gelatine may possess would arise from the ease with which it may be soiled or scratched; but this may be prevented to a considerable extent by treating the gelatine with a solution of alum, which will render its surface hard and insoluble.

For preparing sheets of opalized gelatine the formula used by Mr. Burgess in his eburneum process will answer admirably; it stands as follows:—

French clear gelatine	...	...	5	ounces
Water	...	...	20	"
Glycerine	...	...	$\frac{1}{2}$	ounce
Oxide of zinc	...	...	1	"

After soaking the gelatine in the water for a few hours it is dissolved by gentle heat, and then filtered through flannel. The zinc white is placed in a mortar with the glycerine and one ounce of the water, and made into a soft paste. It is then stirred into the warm gelatine, and allowed to stand for a couple of hours, keeping the solution warm to allow the coarser particles to settle to the bottom; the upper portion is then carefully decanted to get rid of the sediment, or, if it be allowed to cool and become a jelly, a slice can be cut off the bottom, removing all the coarse particles. Where the photographer desires to make the sheets for use it will be wise to use up his solution at once, as it will not keep well, especially in hot weather. Where he wishes to keep it at hand ready to coat glasses, its keeping properties may be improved, and decomposition arrested, by the addition of a trace of carbolic acid, or a little essential oil of cloves will help to preserve it. Or if it be desired to keep the mixture ready for use on redissolving, it may be poured out on sheets of glass and allowed to dry; it may then be cut up into strips, and kept as dry opaline gelatine, which can be readily redissolved on adding the proper quantity of water.

We may add that it is Mr. Woodbury's intention, we believe, to prepare sheets of opaline gelatine ready for use, and supply them to photographers commercially.

### THE MILITARY SCHOOL OF PHOTOGRAPHY AT CHATHAM.

On the occasion of a recent visit to Chatham, we availed ourselves of the opportunity to visit the military school of photography at that town. The school forms part of the Royal Engineer establishment at Chatham, an institution established for imparting instruction to officers and non-commissioned officers of the Royal Engineers in all branches of technical education. Surveying, construction and estimating, fortifications, telegraphy, and photography are the principal subjects taught, and these in a theoretical as well as practical manner; all young officers, on first joining the corps, being first ordered to Chatham to undergo a course of scientific instruction at the establishment before they are despatched to various stations to enter upon their ordinary duties. At the present moment, H.R.H. Prince Arthur, who has recently been gazetted to a lieutenancy in the Royal Engineers, is pursuing his studies at Chatham, and is going through the same course as that prescribed for all Engineer officers.

Instruction in telegraphy and photography is imparted under the superintendence of Captain Stotherd, R.E., the latter subject being taught by Serjeant Instructor Church, to whose immediate care the whole of the arrangements con-

nected with photography are entrusted. Mr. Church, who has been connected with the establishment for nearly ten years, and possesses, therefore, very considerable experience as a theoretical and practical photographer, has been successful in devising a thoroughly systematic and effective mode of instruction. The students are mostly young non-commissioned officers, who, to the number of eight or ten, are formed into classes and trained in the art for several months; on their being deemed sufficiently skilled in their duties they are drafted away to stations where their qualifications may be made use of.

The school consists of a suite of rooms for operating, printing, and mounting, together with a glass studio of very fair dimensions. All the mechanical parts of the process are first taught, such as cleaning the glass plate, sensitizing and squaring the paper, collecting residues, &c.; then instruction is imparted in printing, toning and fixing, and similar subjects, and, finally, the students are allowed to operate. If any of the pupils show particular aptness for their work, these are entrusted with the more delicate operations of the processes, and in this manner the plan of instruction laid down is made to answer with much success. After a comparatively short period of training, Mr. Church is able to turn out photographers who are proficient in every branch of their art; and it may not be out of place to mention that Serjeant Harrold, who recently obtained considerable reputation in the manner in which he acquitted himself as chief photographer in the Abyssinian expedition was one of Mr. Church's pupils.

In passing through the printing-room our attention was called to a very fine series of dry-plate negatives which had been obtained by the coffee process. The films of these were very delicate and thin, and even in the highest lights there was a slight transparency; but although there was no portion of the image which could be termed opaque, nevertheless the pictures produced from these plates were remarkably brilliant, and free from all suspicion of flatness. An explanation of this apparent contradiction was readily offered upon a second inspection of the negatives, for it was found that the coffee had given to the films a yellowish, non-actinic tint, and had thus imparted vigour to what would otherwise have been but very feeble productions. The plates had been prepared about a week before they were used, and required a somewhat long exposure—about three minutes in a good light, or six times as long as would have been necessary with an ordinary wet plate. Mr. Church is of opinion that if a dry plate requires more than a minute's exposure, it matters very little whether they remain in the camera for two, three, four, or five minutes; he also believes that when working with coffee plates, which acquire a yellowish tint from the colouring matter of the preservative material, a prolonged exposure of the negative is always beneficial. For architectural or landscape photography the coffee plates were found to be everything that could be wished, and, owing to the soft, delicate detail always obtainable if the negative has been sufficiently exposed, there was a greater certainty of obtaining a good result than with wet plates in this particular branch of the art. A little care was necessary in the development of the first few plates, but after the operator had acquired some experience in the operation the negatives might be developed with the same ease and certainty as wet plates.

The unmounted prints in the establishment are kept piled upon one another in a perfectly flat condition, and the method adopted to prevent their curling up is a very simple one, although, we believe, not generally known. The dry albuminized print is laid, face downwards, upon a square of plate glass, and upon the middle of it is placed a stout paper folder, or angular piece of wood. The latter is pressed down upon the print with one hand while with the other the picture is drawn from beneath; after passing under this scraper two or three times, the print will be found to roll itself up inside out, becoming afterwards perfectly flat, in which condition it will remain for any length of time if

kept under slight pressure. The process of mounting is thus greatly facilitated, and the pictures, not being moist, are less liable to be torn in the operation.

The photographic duties of the school are not confined to the taking of landscape views and subjects connected with engineering, but a large portion of the work performed consists in the reproduction of plans and drawings, to be printed either by means of photo-lithography, or merely on plain salted paper. Thus we saw on the eve of completion a survey of the whole of the route taken by Lord Napier in Abyssinia, from Zoulla to Magdala, the mountains, rivers, and principal localities being all marked and noted. The map in question was of a somewhat large size, and had been constructed, we believe, from as many as eight negatives.

Again, in order to give the pupils sufficient opportunity for practising their art, a certain amount of private photography is allowed; strict regulations are, of course, in force to prevent a privilege of this kind being abused, and pictures of members of the corps of Royal Engineers only are allowed to be taken, the photographers paying the cost price of their portraits. In this way the non-commissioned officers under instruction enjoy greater facilities for gaining skill in their profession than could be obtained in the ordinary routine of their duties.

No special arrangements have yet been devised for carrying on photography in the field. Mr. Church, *en attendant* the advent of a perfect dry-plate process, prefers to use the ordinary dark tent, which is packed in a box fitted on wheels, ready to be run out at a moment's notice. This may not be so convenient as a dark wagon or portable laboratory, but when packed it is much more likely to resist the dangers of transport and rough handling, and, being of small dimensions, it is readily conveyed to its destination. For campaigning the expanding camera is of course used, and the bottles, trays, developing cups, and other utensils employed are either of ebonite or gutta-percha; duplicate articles of a perishable and fragile nature, such as focussing glasses, &c., are always carried, and the packing of the apparatus in a perfectly rigid manner is a subject carefully attended to. By dint of a few simple precautions of this nature, strictly enforced, out-door photography is carried on in a sure and systematic manner, and failures and mishaps are of rare occurrence.

## ECHOES OF THE MONTH.

BY AN OLD PHOTOGRAPHER.

SUMMER TROUBLES—PHOTOGRAPHIC SECRETS—PHOTOGRAPHIC IDENTIFICATION—THE NEW MILTONIC POEM—PHOTOGRAPHY AT WIMBLEDON—A NEW MANUAL OF PHOTOGRAPHY—PIRATES AND SPIES—RETOUCHING NEGATIVES—THE SOCIETIES.

SUMMER, although the season of sunshine, is not generally the best season for sun pictures. Either spring or autumn is better, as a rule, either for portraiture or landscape. The portraitist, indeed, generally anticipates a variety of troubles in the shape of fog, stains, and pinholes, arising from the high temperature. It is not a little surprising that this summer, the hottest, driest, within the memory of middle-aged folk, there have been fewer photographic troubles than usual. I mean, of course, that I have heard of fewer, after consulting a moderately large circle of photographic acquaintances, and I have experienced fewer myself. The drying of the plate when long kept is the only trouble I have had, and the excellent system of washing the plate and re-dipping before development, which you recently described, has proved a perfect cure. I had tried the system before, but always with a necessity of giving longer exposures, in order to secure good results. Mr. Hughes's plan of prolonging the second immersion of the plate until the film is again thoroughly permeated by the nitrate solution, however, removes every difficulty, and, with the ordinary exposure, gives

perfect results, and I for one am deeply indebted to you and Mr. Hughes for the hint.

Speaking of this indebtedness, suggests to me some thoughts on the extent to which photography as an art, and photographers as a body, are under obligation to the large band of experimentalists and volunteers who have contributed so largely to the unparalleled progress made in little more than a quarter of a century. I heard a photographer remark the other day that he thought nothing had contributed so much to ruin photography as a profession as the practice of some of the best professional photographers of publishing all they know, and so enabling the least cultivated photographers a fair chance of competing with more experienced men. I could not help smiling to think how little the speaker recognized his own obligations to this habit of communicating their knowledge, in which our best men most frequently indulge. I wonder how many, or, rather, how few, of even the most capable photographers would have found out for themselves all that is known of photography, unaided by the published experiences of others. Surely never was an art to the devotees of which the injunction could so properly be applied: "Freely ye have received; freely give."

The value of photographic identification is so well recognized that it scarcely needs affirming; but it is interesting to note the specially important cases in which it serves great ends. We all remember the important part it played in securing the capture of the murderer of Mr. Briggs; the discovery and identification of another murderer has just been made by its means. The wife of a coffee-house keeper, in Norton Folgate, was some months ago beaten to death with a rolling-pin by her husband's apprentice, who got clear off, and no clue could be obtained as to the direction of his flight. It seems that just after committing the murder he was convicted at Woolwich for stealing a meerschaum pipe, and sent to gaol; there a warder, having seen the photographic portrait of the murderer, which had been circulated, noted the likeness to the prisoner committed for theft, and so on further examination he was identified, and will, doubtless, suffer the penalty of his crime.

Yet another aid to identification has come under my notice. Literary circles have been in a state of excitement during the last few weeks in regard to the discovery of a new poem supposed to be Milton's. Mr. Henry Morley, Professor of English Literature at the London University, has found written on the fly-leaf of a copy of Milton's works, at the British Museum, an unpublished epitaph, or, rather, as Mr. William Sawyer has justly pointed out, three epitaphs, bearing the signature J. M. The style is regarded by good critics as essentially Miltonic, but the genuineness of the lines as those of Milton has been the subject of hot discussion. Decision on the matter depends chiefly on the question of handwriting. If it can be shown that the lines are in Milton's handwriting, and that the signature is veritably J. M., and not, as some assert, P. M., the point will be virtually settled. As the lines can only be examined at the Museum, and as the best means of comparing them with the handwriting of Milton do not exist at the Museum, photography comes in as a *deus ex machina* to meet the difficulty. Mr. Valentine Blanchard has, I understand, been commissioned by Mr. Hain Friswell (the editor of the series of works in one of which Mr. Morley was engaged when he made the discovery) to make a photographic facsimile of the epitaph for publication in the new work. The facsimile can be readily compared with Milton's handwriting, and will, I understand, be compared with the original MSS. of Milton's Poems, in the library of Trinity College at Cambridge, as affording more complete evidence than can be obtained by comparing it with Sotheby's facsimiles, which have so far been used as the test.

The mention of Mr. Blanchard's name reminds me that I have seen some capital instantaneous groups secured by that

gentleman at Wimbledon, although working without shelter in such a tropical heat must have been trying work, and in no wise favourable to instantaneous photography.

A new scientific manual of photography, or rather of the chemistry of photography, by Mr. Carey Lea, will, I understand, shortly be published. Photographers will doubtless look with interest for such a work from the pen of Mr. Lea, who is doubtless an able contributor to scientific photographic literature. It is odd enough that in this country no great work on photographic chemistry has been published. In France the Photographic Chemistry of Barreswill and Davanne forms an extended and important work. In this country Hurdwich's "Manual" has been the only work devoted to this subject; and that never very complete or satisfactory work,\* has necessarily been getting out of date since Mr. Hurdwich's retirement from photography half-a-dozen or more years ago. I shall look for the new work with interest.

The case *Graves v. Mercer*, tried at Dublin, possesses considerable interest for all concerned in the use of photography as a means of popularizing art by means of photography. I believe that few things can have a more valuable influence on the art education of a country than the circulation of good photographic reproductions of works of art. A very large store of the best things of this kind are not copyright, and may be circulated freely without trenching on the privileges of any one. But if the statement of the case as it at present appears be correct, no one can enter into the business of publishing such reproductions without being subject to the machinations of informers, who, if they fail in all means of inducing the dealer to procure for them copyright works, are under the temptation, in order to secure penalties, to swear falsely that they have been supplied with copyright works by persons who have honestly determined to steer clear of all connection with copyright reproductions. When spies or informers are used to detect crime, there is always a risk that they will manufacture cases rather than fail. On the other hand, publishers such as Mr. Graves have suffered so severely that they are naturally resolved to avail themselves of all legal means to hunt down and root out the dishonest destroyers of their trade. No one can blame them. They must possess the sympathy of right-minded people. They will doubtless, as they affirm they do, obtain the best men they can for the work, but stamp out piracy they will at all hazards. It is a hard thing in such a case to hit the *juste milieu*; when sweeping means are used to secure the punishment of criminals, it is hard to avoid at times involving the innocent in the punishment.

The *dernier mot* on the question of retouching negatives has not yet been said in this country, I apprehend. Very few of our English portraitists seem as yet to have fully realized all the advantages to be gained. The example which appeared in Dr. Vogel's *Mittheilungen* strikes me as almost startling. Two portraits have been taken at one time on one plate. The face is that of a young girl with an apparently coarse, spotty, and freckled skin. Such at least is the effect of the print from the untouched negative. Such a portrait could scarcely be acceptable to any one: it exhibits in a forcible manner the offensive exaggeration with which photography at times treats physical defects. The adjoining print is from the touched half of the negative. It is impossible to detect any alteration which should affect the likeness. Form, light and shade, everything is the same except the coarse spotty texture, which is substituted by a refined smooth skin; a change which most persons would hail with delight, even if it erred a little in a direction opposite to the exaggeration of photography pure and simple. I think experiment in this kind of modification is well worth the attention of all portraitists.

Few of the societies are meeting. It is refreshing to

\* I looked the other day to the Vocabulary of Photographic Chemicals in this work for "bromide of cadmium," and found no mention of it.

find that some of them have the courage in this exhausting weather to hold meetings. I see that the Liverpool Amateur Society is active. The system of giving prizes adopted appears to induce a pleasant emulation, and is, I think worthy of the consideration of other societies. A gentleman present at one meeting of this society, I find, pronounces india-rubber mounting, after some experience, a "delusion and a snare," an opinion in which I cordially concur. Another gentleman gave strong testimony to the excellence of Mr. Bovey's toning bath. Mr. Bolton described his experiments with a new preservative, for further particulars of which I shall look with interest.

## SHORT ESSAYS ON PHOTOGRAPHY AND ART.

### No. I.—THE ACADEMY EXHIBITION OF 1868.

BY NELSON K. CHERILL.

ANOTHER exhibition of the Royal Academy has run its appointed time and has closed, not without its lessons to the art student and the public at large. The show of pictures this year has been considered, on most hands, as very far inferior to that of former years, not that it was less in number, for the academy is always full, and more pictures are rejected than hung every year, but simply, in the opinion of most people, the pictures were not up to the mark of excellence, which, from the productions of former years, they might have had reason to expect. However this may be, there was this year an abundance of material from which the photographer might take a lesson in the artistic application of the power so easily within his control; no exhibition of the Academy ever yet was so bad that nothing could be learnt by it, even if nothing in it could be admired; the very defects of the pictures would form a most valuable lesson in art to those who may wish to improve.

It is not from a wish to dogmatise about what ought to be and what ought not, that these few general observations are penned, but more from a desire to promote that discussion of the art powers of photography, which has of late tended so much to improve its practice.

There is a much disputed question which now and then crops up with regard to portraiture in the open air, namely, one about the proper height of the horizon line. Some have argued that if the junction of the sky and land be at any other level than the height of the head in the sitter it is simply wrong; this seems nonsense to me, because, suppose there are two sitters in the picture of different height, or suppose one sits down and one stands up—a thing I suppose more or less possible in nature, if not in art—where is the horizon line to be put? Of course the real position of the line in question is the height of the eye of the spectator, or, in photography, of the lens of the camera; but it is not at all necessary that the lens should be the same height as the eye of the sitter, indeed, when it is so, it has to be considerably inclined downwards, therefore in most cases the horizon line should be below the height of the head in the picture. About one third the way up the plate seems to be a proportionate height in the usual way; and in confirmation of this view I am glad to notice that it is decidedly the rule in the Academy Exhibition this year, and that in almost every case the horizon line was below the shoulders in pictures of the kind I have been speaking of. So long, however, as photographers wish it to be their boast that their art is more true to nature than painting, they must remember in each picture to keep the horizon line at the exact height which it makes in that picture.

Another point seems worthy of notice here, it is one which, although not exactly bearing on any subject connected with photography, cannot, I think, fail to be of interest among photographers; the amount of colour which may be used in a picture. There is a fashion in everything, and just now the fashion among a certain set of artists is to paint, in various shades of white, instead of in colours, as it is usually understood. The object seems to be to obtain "tone,"

literal and exact tone, instead of colour which may be a little out of tone if carried out fully. The question, how far this may be right, will not, I think, prove uninteresting to photographers, at least it should not do so. The pictures in tone may be divided into two classes, merging more or less into one another—those which absolutely represent the thing they profess to do, and those which represent only the tone of a subject which must contain a great deal of colour as well. In the first of these, of course, the absolute representation is all that can be given, and so long as that is obtained the only question left to the critics are those concerning the choice of subject and general treatment; but when a highly-coloured subject is represented in a tone mostly composed of white, with a slight sensation only of any other tone, it seems to me open to very grave objection; objection, I mean, on the score of setting up such work as a standard of comparison of art works in general. No doubt any man has as much right to paint a picture all white as another has to paint one all blue or all green, only let not a picture which is true to fashion but not to nature be set up as a standard of such paramount excellence as to rule not only the present but all future generations of artists. Fresnoy not inaptly says,—

"The hand that colours well must colour bright,  
Think not that praise to gain by sickly white."

This idea has been, as I before mentioned, rather to obtain all the tone, and but little of the colour of a picture, than all the colour, or as much as possible, and but little tone, or only as much as may "come." This seems to me wrong upon the face of it, for painting is essentially the art of colouring and not of monochrome; it is the object of engraving to translate colour into black and white; while it is the object of painting to transcribe colour as it is, or as it may be supposed to be, in the eye or mind of the artist.

A photograph should be the most perfect picture for tone that can be produced; the relation should be absolute between all the several parts. There is, however, another reason, a more complete and perfect one why painting in this "tone," which is coming now so much into fashion, is wrong; it is that the harmony of tone so much prized is gained by what looks very like a sacrifice of truth. The harmony of tone in nature begins with white, or the lightest shade of some colour which for the present purpose we may consider white, and ends, frequently, in the deepest black possible, so deep that no amount of black paint or any mixture of paints, can come near to it. But these painters of tone do not by any means represent this long range of natural colour or gradation; they say, we will paint harmonies, beginning with white and ending with white, with a little colour in it. A harmony, no doubt, they paint, but not one that can be found in nature, and it seems to me a very grave question whether nature should be represented in a manner in which it does not represent itself. It is, of course, thought tremendously clever to be able to paint a picture all of one colour, and yet to have the wonderful harmony of tone in it. But are cleverness and "trick" the highest aims of art? or even aims worthy of art at all? I think not. So long as photographers possess their present powers it is much to be hoped they will use them to the best advantages they can, and not be led by a false notion of aping art to try and make "symphonies" instead of pictures, because if they do they will certainly fail and that without remedy.

There is another thing worth mentioning as being a thing to avoid in a more or less mechanical art like photography, even as it should be more avoided than it is in all art; I refer to the introduction of absolutely impossible accessories. In one notable picture in the exhibition this year was an incongruity, which if any smaller man, a "Lancelot or another," in art had done, it would be said by all to be nothing less than absurd. On the same canvas, and at the same time, are represented in different parts of the same picture, two incidents which by their very nature must have been in reality separated from each other by some fifteen

hundred or two thousand years. It may be said that art is imaginative and, therefore, cannot be bound to time, or place, or circumstance. True; but should art not be in some sense bound to possibilities? Why should it not be so? All things in reason are possible, even if they may not be probable. Photographers have certainly no right and no power to attempt strictly imaginative pictures; it is even argued by some that nothing should be represented by the camera prior to the invention of photography; that is, that no scene should be "got up" and photographed, and then said to represent something that occurred prior to the invention of the art of photography; and the argument on which this is based is not so much the incapacity of photography to represent such scenes with good pictorial effect and even some degree of truth, but from a feeling of inaptness or incongruity in a modern art being used to portray ancient events. How far this argument holds good it is not my present purpose to consider; but it seems to me that if photography is not allowed to represent events at which the camera might have been present, much less should artists represent events at which not only they were not present but which never happened for them to be present at. Here seems to me to lie the great distinction between an art mechanical and an art not limited as to its means of representation. The one is compassed by the uniformity of present accidents while the other is bounded only by the imagination of the artist. But should artists use this greater freedom to imagine things not only impossible but absurd in themselves? And should not photographers, also, take a hint, and in their arrangements of present pictures avoid such accessories as may lead to the same "blooming errors"?

#### THE LATE M. CLAUDET.

THE last number of our excellent contemporary, the *Scientific Review*, contains a long and able article entitled "Claudet: a Memoir." The writer—one of M. Claudet's most intimate friends, and one with whom we have had the fortune to spend some very pleasant hours in M. Claudet's company—gives a very complete and graphic sketch of the public life and scientific labours of the veteran photographer, regretting, however, that owing to the death of Sir David Brewster, who had undertaken to write a memoir of Claudet, an adequate testimony to his scientific worth must remain unwritten.

After briefly stating the birth of M. Claudet, in Lyons, in 1797, and his connection with the glass works of Croisy le Roi, he proceeds:—

M. Claudet came to London to establish the sale of glass shades, sheet, and other glass not then manufactured in England. In 1833 he invented the machine now generally used for cutting all cylindrical glass. For this invention Prince Albert awarded him the medal of the Society of Arts, in 1853. But all this while he was a student of science, training and waiting for the object to which his true life was to be devoted. The path was opened to him by the almost simultaneous realizations of photography by Daguerre and Fox Talbot. In citing those well-known names, we do not forget Niepce, the noble pioneer of the photographic art. His imperfect results, and those of Wedgwood, Davy, and others, had not aroused the interest of men of science. Even the achievement of Daguerre was received with the coldness of incredulity; but Claudet saw at once the breadth and beauty of the prospect it opened, and dashed into photography with a warmth and resolution that took his associates by surprise. He was by title a "photographer" before the name was known or photography believed in. We remember him then. Ours was the spring-time of life, his the meridian. We caught his enthusiasm, we became his disciple—as who would not that felt the influence of his gifts and acquirements, and witnessed his unflagging energy, his heroism of purpose? There he would be, day after day, among the fumes of mercury and iodine—careless of life or health—experimenting, producing, expounding, never tiring, never exhausting the fecundity of his expedients, never desponding in his aspirations. And, happily, he was found equal to what he undertook. When at first chemistry had to be called in aid, he was a chemist (as testifies Francois Arago).<sup>\*</sup> When later, optics had to

be appealed to, he was a mathematician; when mechanical science was to be invoked, he was an ingenious mechanic; when art was required, he was an artist of consummate taste; whatever new resources had to be sought, he was ever ready, for the spark of genius was there, needing but the breath of opportunity to fan it into the flame of achievement.

Thus qualified, Claudet (1840) took up photography as a philosophical pursuit; and henceforth literally his days were devoted to the practice, his nights to the theory of the new art and science.

Referring to M. Claudet's early experiments in increasing the sensitiveness of the Daguerrotype plate, the writer says:—

The operation was thus made a hundred times more rapid, and hence Claudet has the credit of first rendering possible the effectual portraiture of animate objects. So sensitive had he now made his metal tablet that he obtained a portrait by the oxyhydrogen light in fifteen seconds; an impression of black lace by the light of the full moon in two minutes, and by the light of the stars in fifteen minutes; an impression of a sculptured figure by the light of a candle in fifteen minutes, and the same from the light of a lamp in five minutes; and an image of the moon in four seconds.

After enumerating many of the early scientific contributions to photography of M. Claudet, he gives, in speaking of the stereoscope, an excellent extract from one of his papers on the subject:—

"The stereoscope is the general panorama of the world. It brings to us, in the cheapest and most portable form, not only the picture, but the model, in a tangible shape, of all that exists in the various countries of the globe; it introduces us to scenes known only from the imperfect relations of travellers; it leads us before the ruins of antique architecture, illustrating the historical records of former and lost civilizations, the genius, taste, and power of past ages, with which we have become as familiarized as if we had visited them. By our fireside we have the advantage of examining them without being exposed to the fatigue, privation, and risks of the daring and enterprising artists who, for our gratification and instruction, have traversed lands and seas, crossed rivers and valleys, ascended rocks and mountains with their heavy and cumbersome photographic baggage."

"Claudet was," remarks the writer, "endowed by nature to be an investigator. A watchful and sagacious observer, he was quick to detect coincidences or exceptions, and untiring in pursuit;" and he proceeds to point out the acuteness which distinguished his researches in the by-paths as well as the high-roads of science, especially as related to his favourite studies. "Thus," he says:—

In his paper on "The Phenomenon of the Relief of the Image," he observed "that the image formed on the ground glass of the camera obscura appears as much in relief as the natural object when seen with two eyes, and his experiments have disclosed the singular and unexpected fact that, although only one image seems depicted on the ground glass, yet each eye perceives a different image. The image seen by the right eye is the representation refracted by the left side of the lens," and *vice versa*. "Consequently, these two images presenting two different perspectives, the result is a stereoscopic perception, as when we look through the stereoscope at two images of different perspectives." He then explains that he ascertained these facts by many experiments, "the most decisive of which consists in placing before one of the marginal openings of the lens a blue glass, and before the other a yellow glass. The result is two images superposed on the screen of the camera, one yellow, the other blue, forming one image of a grey tint, the mixture of yellow and blue, when we look with both eyes at an equal distance from the centre. But when we shut alternately, now the right eye and then the left eye, the image appears first yellow, and second blue."

And, again:—

Sometimes, too, he allowed himself to stray from his chief garden of delight into outlying paths; and we find him at the British Association describing his "Star Chromatoscope—an instrument for examining and comparing the rays of the stars." The purpose of this instrument is "to develop an infinitely small spot of light into a large circle, exhibiting on its periphery the various rays emitted by the star, all following each other in spaces corresponding with their duration; showing also blank spaces between two contiguous rays, corresponding with the black lines of the spectrum. We have, in fact, a spectroscope by which we can analyse the particular light of any star; and, further, by this instrument we may arrive at the discovery of the real cause of the scintillation, and compare its intensity in various climates and at different altitudes of a given star." Or, again, we have a discourse "on moving photographic figures, illustrating some phenomena of vision connected with the combination of the stereoscope and the phenakistoscope, by means of photography." "Our sensation of vision," he says, "is not in the eyes, but only in the single sensorium of vision, to which both eyes convey their separate perceptions." Again, he gives us "A new fact

<sup>\*</sup> "M. Claudet, qui a trouvé le moyen de réduire à quelques secondes la durée d'exposition dans la chambre obscure."—Œuvres complètes de Francois Arago. Tome vii., p. 516.

relating to binocular vision," to illustrate the persistence of the impression made by light upon the retina. At the conclusion of this paper he modestly as justly adds that Professor Wheatstone by his admirable discovery—the pseudoscope—has left very little for further investigation in the physiology of binocular vision. He expounds with generous praise the inventions of others, as in his paper "On the principles of the solar camera." "Such," he says, "is the essential principle of Woodward's solar camera. \* \* \* This principle is truly marvellous. \* \* \* Without question, its introduction into the photographer's studio will mark a period of considerable improvement in the art."

The demands upon our space preclude further extract this week, but we shall return to the article in our next.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XXVIII.

"When the composition is kept dark, forming a mass of shadow in the centre of the canvas, the light is often conducted round it by means of the sky, water, or light foreground; and as the dark becomes, in a manner, isolated, it receives great vigour and importance. If a clump of trees, such as we often find in Claude, is to be represented, their stems shoot out from a ground of the same darkness, thereby producing a union of the trees with the shadow which they cast on the ground. As a light in the centre of dark tints must thereby acquire an increased consequence, so a dark in the middle of light tints receives the same importance."—BURNETT.

CHIAROSCURO—(continued).

An arrangement of light and shade not so much regarded now as a strict rule, called "the three lights," at one time was considered to be indispensable to a good picture, and is, indeed, a very pleasing effect of chiaroscuro, including in itself every element of success, unity, variety, and repetition. It was Sir Joshua Reynolds who first enunciated this precept: "The same rules which have been given in regard to the regulation of groups of figures must be observed in regard to the grouping of lights; that there shall be a superiority of one over the rest, that they shall be separated and varied in their shapes, and that there should be at least three lights: the secondary lights ought to be of nearly equal brightness, though not of equal magnitude, with the principal."

The following sketch will give some idea of the arrangement.

Fig. 1.

It will be seen that the three lights are placed at unequal distances from each other, and form an irregular triangle. The chief light—that in the sky—is brighter and broader than the others; it is repeated by the secondary light on the cliff, and carried off by the light reflected in the water on the left hand.

The most beautiful effects are often produced with the simplest materials; but it is very difficult to persuade photographers, who have such ample means of rendering detail, and whose pictures are as easily and as highly finished if they are full of subject as if they had very little in them, to be content with sufficient material for pictorial effect. With

painters all the force of the palette and all the skill of the artist are frequently employed by such simple materials as a straight and low horizon meeting the sky. On such subjects the most skilful resources of the art are necessary, and enable the artist to show his strength. How very seldom is a photographer content to keep his horizon low, and depend on the sky for effect! Fig. 2 is from a photograph in which this arrangement has been observed, and in which the view, without being too much suppressed or neglected,

Fig. 2.

has been subordinated with great advantage to the general effect. A proper union and sympathy between the parts of the picture have been kept up by means of the broad mass of light which occurs in the sky, and is repeated on the ground. This illustration also shows the extreme value of carefully chosen and placed figures in a landscape. The one figure being white and the other black, collects the scattered lights and shades in the picture, and reduces them to proper subordination. The use of extreme black and white in small quantity and in juxtaposition is also exemplified in fig. 3.

A method pursued by Turner, and followed since by many artists, is most effective. Instead of relying on a small portion of light surrounded by large masses of dark, as Rembrandt did, Turner understood and exemplified in many of his best works the extreme value of small masses of dark set in a border of light, but never unsupported by other spots of dark. This was often obtained by rearing a dark tree against a light sky, balanced by dark figures in the foreground, which is usually light; between the foreground and the distance is generally a mass of shade uniting the two. The illustration figure 3 is constructed on his

Fig. 3.

"View of Orvieto," and is one of the many pictures painted by Turner that shows the principle clearly. This was one of the pictures so treasured up by the artist, in order that he might leave them to the nation, that no money could buy them. A bold sweep of landscape, to the left of which rise a tree and a dark mass of foliage; in the foreground, which is varied with that minute subdivision of lights and darks which made this artist's effects, like photography when

rightly understood, so elaborate and yet so broad, the dark parts of the dresses of two women, who are washing at a classic fountain, repeat and support the dark tone of the tree; the dark vine leaves brought out prominently on the light masonry also perform the same office, and extend the shadow to the extreme right. The only bits of pure white in the original are on the woman's dress in connection with extreme dark (see last chapter), and the piece of paper on the lute. These minute bits of pure white are placed with a definite purpose and with extreme art, and help to bring forward the foreground and throw back the distance. In the distance, on a rocky eminence, stands the town of Orvieto backed by mountains, which is all treated with great tenderness and delicacy. The general arrangement of masses will be found somewhat similar to that described in chapter 27, figure 2.

Few photographs have been taken uniting extreme force in the foreground with delicate and tender distances and skies. There is no reason, save that of a disinclination to take much trouble over such a simple thing as a photograph, why they should not be done. If photographers would say to themselves, "This scene is as well worthy of my undivided attention and of all my skill as it would be that of a painter who would not hesitate to spend some weeks in painting it," they would probably produce better results. I have never yet been able to see why a photograph should be confined to one exposure for foreground and distance, any more than it should be considered legitimate that an etching should have one biting only. In etching, the artist exposes his plate to the acid a longer time, and bites deeper for the deep shadows than for the lights; if he did not, he would get no variety of light and shade, and his work would be thin and weak. In photographing such a view as the one of Turner's we have taken for illustration, I can see no reason why the foreground should not be obtained in one negative, giving sufficient exposure to bring out the necessary detail in the shadows; and the distance and sky on one or more negatives, suiting the exposure to the effect required. The only technical objection would be, that it would require skill in the printing, which, in the eyes of many photographers, would be an immense advantage, the "fatal facility" of the art for producing rubbish being the great cause why photography as an art has not advanced further than it has done.

Difficulties in art are necessary to its existence. If there was nothing to overcome there would be no incentive to exertion, and art would soon become a mechanical trade. Opie was always of opinion that the internal difficulties of painting were its very best friends, and, in one of his discourses at the Academy related, the following apposite anecdote to prove his statement:—"Two highwaymen (says a certain author), passing once by a gibbet, one of them, with an ill-boding sigh, exclaimed, 'What a fine profession ours would be if there were no gibbets!' 'Oh, you blockhead,' says the other, 'how much you are mistaken! Gibbets are the making of us; for if there had been no gibbets every one would be a highwayman!'"

## ON THE PRINCIPLES OF LIGHTING AND CONSTRUCTING STUDIOS.

BY DR. H. VOGEL.

### CHAPTER II.

In my first chapter I have explained the chief principles of calculating the direct brightness in a glazed room, and pointed out at the same time, by a series of examples, the consequences arising from that calculation, previously neglecting the effect of the light reflected by walls, &c., and the loss of light produced by reflection during the transmission of light through glass.

To those who have followed attentively our explanations it will be of no difficulty at all to determine the amount of

the light which falls on any point in the studio. With small apertures we can very easily calculate the relative amounts of light at different parts of the room; with larger windows, which have some influence on the illumination, the best criterion is afforded by constructing the angle of light. To this purpose the studio (or a piece of it containing the acting glazed surface and the point which must be illuminated) must be drawn on paper, sketch and ground-plan, and the angle of light constructed in the horizontal or vertical direction. These are not yet all the possible or interesting instances; indeed, there could be written a great volume on this subject. In these lines I only propose to write upon the effects of our most important constructions of studios.

In my diagram I suppose a studio with its glazed side

directed northwards. It is 32 feet long and 16 feet broad; there is no interruption in the wall, and the front,  $h g$ , lies northward. At  $a l$  suppose a person at a distance of 5 feet from the glazed wall and of 4 feet from the back wall; the curtains are drawn in the space  $g h$  (28 feet). If we wish to state the effect of the glazed wall,  $g h$ , of 28 feet long, we are obliged to construct the angle of light  $g a h$ . Now suppose, instead of the long glass wall  $g h$ , another,  $g k$ , not directly situated northward, and of a length of 8 feet; the angle  $k a g$  will then be exactly as great as  $h a g$ ; that is to say, this small aperture of only 8 feet long will provide the studio with as much light as the other wall of 28 feet long; nay, even a wall,  $g l$ , of only 5 feet long, would afford the same amount of light to the person at  $a$ , but this would not be quite applicable, because the edge of the wall at  $l$  would conceal a great deal of the field of light to the apparatus at  $A$ .

I have now proved that we could employ an inclined wall of 8 feet long instead of another of 28 feet without decreasing the original amount of light. The same is the case with glass roofs. A straight skylight of 28 feet could be substituted by an inclined one of only 8 feet long.

If I now construct a studio with such a wall and an analogous skylight, I get a room which, as to brightness, totally equals the great studio of 32 feet long. The effect of light would even be much greater with the small glass wall  $g k$  than with  $g h$ , as with the latter the light falls in under a

very great angle, and therefore much more is lost by reflection.

The form of the studio of the above-stated description is to be seen in our diagram. The parts not hatched are glazed, the others dark; the apparatus is to be placed into the dark room, T T, the person, however, at *a* near the glazed wall.

studios—and I have proved that, under the quoted conditions, it is of the same effect for single portraits as a great studio fronting to north. Such a studio would entirely suffice to amateurs and little photographers. The side wall is best fronting to north, because by this means the lateral and chief illumination is kept free from direct sun rays. The roof must be screened by sails. If there is not room enough, the depth may even be smaller than 16 feet.

If such a studio is sufficient for taking single portraits and recommends itself by its great cheapness, it has also its faults, if compared with the great studio fronting north. First of all, the person receives light always from the same side (in our diagram from the right side), whilst in a north studio, according to the position of the sitter, he will receive his light either from the right or from the left side. This fault, however, is not very great. Mr. Reutlinger's excellent portraits, for instance, are all illuminated from the left side.

A greater drawback however arises if the sitter is not placed quite near the glass, but a little further removed from it. Supposing a person at *b*, at double the distance from the glass than *a*, we can judge of the effect of light by drawing the lines *b h* and *b g*, and thus constructing the angles of light *h b g* and *k b g*; in the diagram we instantly perceive that *h b g* is much greater than *k b g*, and consequently that for a point situated at a greater distance from the glass, the amount of light is considerably greater in a studio fronting to north.

In a tunnel studio we must therefore be contented, in our operations, with the room in the direct neighbourhood of the windows, whilst a north studio allows you to extend much more towards the depth, and therefore affords more scope for artistic arrangement, and undoubtedly better illuminates groups which require the whole depth of the studio.

From the physical point of view I now have pointed out the effects of a tunnel studio and of a studio pointing to north. Accordingly to the above-given principles, everybody can easily perceive himself alone how the effect will be changed if the dimensions are altered, as supposed above.

#### NOTES ON DEVELOPMENT.\*

DEVELOPERS which contain a copper salt are sometimes instrumental in causing the negative to be covered with a brownish fog, which, on account of its characteristic colour is easily distinguishable from that generally met with. This fogging may either cover the whole of the picture, or

The depth of the roof is 12 feet. For single portraits it would not only suffice but even be much too great, and only on exceptional occasions it would be used all unveiled. Thus, starting from the principles of the most simple illumination, I arrived at a construction of studio, which, in fact, has already been employed—as, for instance, on the great tunnel

a portion only of the image may be affected by it; but in any case the defect is not superficial, but lies between the glass plate and the film, that part of the negative being most damaged where the collodion layer is thickest. These observations lead to the conclusion that the injury is due to a particular condition of the collodion film, and that this view of the matter is correct was proved by the following experiment:—

Two plates were coated with strongly iodized collodion—such as is generally used—and one of them being placed in the sensitizing bath as long only as was absolutely necessary, while the other remained in the bath a few minutes longer. After exposure in the camera they were both developed with the following compound; viz:—

Sulphate of iron ...	...	...	3 parts
Moist sugar...	...	...	3 "
Sulphate of copper ...	...	...	3 "
Acetic acid ...	...	...	3 "
Water ...	...	...	100 "

The second plate yielded a perfectly clean and pure negative, while the first was totally covered with a thick fog; the reddish brown precipitate lay under the image, and was greater at the end of the plate from which the collodion had been drained than at the other.

From this result we may therefore conclude that in the film of the first plate undecomposed salts of iodine was present, which, combining with the copper of the developer, formed red iodide of copper. The silver reacts slowly upon the iodine salts, being at first prevented from entering into combination with the same by the ether contained in the collodion; it is natural to presume, therefore, that in a thick layer of collodion, undecomposed iodide may still be present, and from this we may deduce the precept that the plate should not be removed from the bath too early, if a copper developer is subsequently to be employed. With thin and porous collodion, obedience to this rule may not be of so much importance as when a material of a thick consistence is used.

The above experiment teaches us one more lesson; viz., that the smooth flowing of the silver solution over the negative on its exit from the bath is no proof that a complete conversion of the soluble iodide salt into iodide of silver has taken place.

In earlier times much discussion took place upon the relative merits of pyrogallie and iron developers for wet plates, and finally it was generally decided that the iron solution was the most energetic developer, and yielded, therefore, quite as soft and detailed a picture, with a short exposure, as the pyrogallie acid did after a longer one. Iron development is now universally employed in conjunction

\* Photographisches Archiv.

with a subsequent intensifying operation with pyrogallie acid.

The solutions in general use of these two materials are of very different strengths, for in employing one part of pyrogallie acid we generally add at least ten times as much water as would be added for one part of sulphate of iron. This hardly seems right, seeing that the iron is already a much more energetic reducing agent.

We have lately been experimenting with a 5 per cent. solution of pyrogallie acid, using, therefore, the latter material in the same degree of concentration as iron is employed, and with this developer we treated a series of portrait negatives. All of the pictures were perfectly free from spots and stains, and so vigorous and intense that it was necessary to proceed rapidly with the operation of washing to prevent the films from becoming too opaque. The period necessary for their treatment was only one-third that required to produce negatives with the iron developer and pyrogallie acid intensifier, and the pictures obtained were quite as soft and delicate as those developed with iron. The only drawback in the method was that the slightest traces of dirt upon the glass caused the deposit of a light metallic precipitate; there can be no doubt, however, that the strong pyrogallie developer brings out the weaker light rays more satisfactorily, and yields, therefore, negatives more harmonious in their character than are obtained by the sulphate of iron solution.

## ON NITROGLUCOSE.

BY M. CAREY LEA.

As nitroglucose has been much less studied than its congeneric nitro-substitution compounds, pyroxyline, xyloiline, and nitroglycerine, a few words on its preparation and properties may not be uninteresting.

The substitution does not take place in sugar with quite the same facility as with cellulose; the acids need to be stronger, and the temperature lower. The sugar, moreover, appears at first to dissolve, and then to separate out again in the form of a greyish paste, which, when thrown into water and freed from the adhering acid, becomes nearly white.

An attempt to prepare nitroglucose by the use of nitre and sulphuric acid, which succeeds so well and so easily in the case of cellulose, failed almost wholly with sugar. Not more than two or three per cent of the weight of the sugar was obtained.

With sulphuric and strong nitric acids, allowed to cool thoroughly after mixing, the reaction takes place easily, and a considerable quantity of nitroglucose is obtained. The nitric acid should be as strong as possible, and, as the acid of the requisite strength is not easily obtained commercially, I have found an advantage in using in part the fuming sulphuric acid. Two fluid ounces of fuming sulphuric acid, 2 of common sulphuric, 2 of strong nitric acid, as near to 1.5 sp. gr. as can be obtained, give good results. The sugar is stirred in, in the form of powder, to a thin paste. The stirring is kept up, and as fast as the nitroglucose separates in doughy masses it is removed with a spatula and thrown into cold water. A further addition of sugar will give more nitroglucose, but considerably less in proportion than the first addition. As soon as possible, the nitroglucose is to be kneaded up with cold water, to get the acid out. In one case, when this was neglected for ten or fifteen minutes, the nitroglucose passed to a greenish colour, and apparently was undergoing a commencing decomposition.

The removal of the adhering acid is much more difficult than in the case of pyroxyline, and is an extremely disagreeable operation. The acid pervades the whole of the doughy mass so fully that the fingers are stained and burned by it, nor can the whole of the acid be removed satisfactorily in this way. The best means I found was to dissolve the

crude nitroglucose in a mixture of alcohol and ether, and then to pour this into a large quantity of cold water with constant stirring, and violent agitation afterward. The method is not altogether satisfactory, and seems to be attended with some loss of material, though why, it is not easy to see.

Prepared in this way nitroglucose is a white, lustrous body, which may either assume the doughy amorphous condition, or the crystalline, and passes from one to the other with extreme ease. When first formed by the mixed acids it always has the doughy form. That which I obtained by the use of nitric and sulphuric acid was crystalline from the first. When precipitated by water from its solution in alcohol and ether, it is doughy and almost liquid, and remains so for a long time, if there is any considerable quantity of it.

The best mode of preserving it appears to be under water. By standing thus it gradually hardens, and passes sometimes to a somewhat hard amorphous mass, and sometimes to a granular crystalline state. It appears to be wholly insoluble in water. A few minute grains of the crystalline form diffused through 15 or 20 ounces of water did not dissolve after many hours standing. In a mixture of alcohol and ether it dissolves as easily as sugar in water, and in such quantity as to make the liquid syrupy.

Its detonating properties are but slight. If it be well dried, and a match be applied, it deflagrates with a feeble flash.

It has been stated by Dr. V. Monckhoven that when dissolved in alcohol and kept some time in a warm place, it undergoes decomposition, as evidenced by the fact that the solution then gives an abundant precipitate with nitrate of silver, which at first it did not do. An experiment made in this direction did not give the result thus indicated. A solution of nitroglucose in alcohol, containing about 40 grains to the ounce, was placed in a stoppered vial, and was kept in the sand-bath at a temperature of about blood heat for nearly a month. But neither it nor a fresh solution gave a precipitate with alcoholic solution of nitrate of silver. It would seem from this that certain conditions of temperature or otherwise are necessary, in order that this decomposition should take place.—*American Journal of Science.*

## Correspondence.

### PHOTOGRAPHIC NOTES ON THE CONTINENT.

[FROM A SPECIAL CORRESPONDENT.]

Nürnberg, 1st August, 1868.

To be transported in forty hours from the hot and noisy Metropolis into the middle of the Thuringian forest, is a change as sudden as it is agreeable. Situated in the centre of Germany, far removed from any town of size or importance, the magnificent scenery of Thuringia with its gigantic forests of beech and pine, stretching out on every side, is little known and rarely visited. And yet the district is one in which Englishmen should feel an interest. The towns of Coburg and Gotha are the principal residences of the Saxe Coburg family, and the palaces of Rosenau and Reichardtbrunn were the birthplace and favourite resort of the late Prince Consort: both of the latter castles are frequently visited by Her Majesty, and are minutely described in "The Early Days of the Prince Consort." Besides these places of interest, Thuringia includes the ancient town of Eisenach, where the princes of Orleans (the descendants and heirs of Louis Philippe) were educated, and the castle of the Wartburg, in which Luther translated the Bible. Thus it would appear that, possessed of both historical and loyal associations, besides being endowed with great natural beauty, the

district requires only to be known to become a place of constant and fashionable resort by the tourists of England.

Eisenach is, perhaps, the most central point of Thuringia, situated on the railway between Frankfort and Leipsic, at the junction of the line from Coburg. Everything in the district is still in a very primitive state, and in the railways one is positively made uncomfortable by the strict regulations posted up in the carriages. You are on no account to lean sideways out of window, nor to press against the door; neither are you to touch the handle of the door, or enter, or descend from, a carriage without the permission of the officers of the Company. Thus when a pretty view strikes you either to the right or the left, the only way of looking at it, if you do not wish to infringe the regulations, is to take a peep out of the corners of your eyes; and as castles, either preserved, or in ruins, surmount almost every hill in a commanding position, the trial to one's feelings is very great indeed.

The universal primitiveness before alluded to is especially noticeable in photography. Neither in Eisenach, Gotha, or Coburg, could I see for sale any pictures taken by the camera of points of interest in the neighbourhood. I wished very much to obtain a picture of the Wartburg, taken, if possible, when I first knew it, some ten years ago, before it had been spoiled (or beautified as the people around call it), for I felt an interest in this remarkable old place, where is still shown, in one of the chambers, the trace on the wall of the ink which Luther threw at the devil. The castle is also the scene of the opera of *Tanhäuser*, and was the residence of the Holy Elizabeth, who, unbeknown to her hard-hearted husband, used to carry up viaticals to the starved out residents in the bourg. On one occasion, when she was caught in the fact by her husband, the latter angrily seized the basket she was carrying and throwing back the cover of the same, discovered nothing more than a cluster of roses; after which, it is said, he never molested her more. In order to purchase a photograph, I entered two or three shops in the town, and on each occasion was shown some three or four dozen prints, but in no single instance were the pictures direct photographs of the objects, but simply copies of engravings. This custom of photographing pictures is one much practised throughout Germany, and is certainly to be deplored, as unskilled purchasers are often misled thereby, the shopkeepers themselves not unfrequently believing in the genuineness of the pictures they sell. It was the same with the pictures of Rosenau and Rheinhardtbrunn; and with panoramas containing series of twenty or thirty sketches of places of interest marked "Photographies de Thuringie," they were all photographs of engravings.

At the town from which I date this letter, photography is practised to a notable extent, but not, in my mind, to the degree it might be done. Nuremberg is *par excellence* a town, noted for its wonderful architecture, its buildings presenting the most varied and beautiful subjects for the camera, and yet of these advantages photographers seem to have availed themselves but partially. The delicate antique stone carving of the various churches and numberless fountains, the frescoes on the public buildings, the quaint gable roofs of the old fashioned houses, together with their overhanging ornamental windows, are subjects essentially suited to photography; and yet, with the exception of some specimens by M. Koenig, of Nuremberg, very few of the beauties of the town are seen produced in the shop windows.

Of the ordinary photographic portraiture produced here I will not speak too critically, as it would be unfair to compare it with that of larger towns, but from the specimens exhibited in the different show-frames, practisers of the art appear to be well represented. No cabinet portraits are to be seen, but some large vignettéd heads exhibited in one or two of the studios are deserving of much praise.

Linz, 3rd August, 1868.

Down the Danube from Passau has been a delightful trip. The scenery although very different to that on the Rhine,

certainly equals, if it does not sometimes surpass the same. True there is not that constant succession of lofty hills, each surmounted by a castle, or ruined bourg, nor are there the green sloping vineyards of Rhineland, but on the Danube the mountain walls on each side are higher and clothed in one dense mass of rich foliage which stretching along the steep slopes dips down to the water's edge on either side. The stream twists and turns continually, and sometimes doubles back so completely that a tower which is first seen at the right hand is afterwards observed on the left. The scene is continually changing, and the views obtained are of the most varied character. It seems very strange that so lovely a district should not be as much visited as the Rhine; on the latter river there are as many as eight or ten large steamers passing up and down every day, whereas here one small steamer per diem suffices for the whole of the traffic. What is wanted is a pioneer in the person of a photographer to depict the beauties of the route and to make them well known. The view from the window of the hotel at Linz, where I am at present writing, is certainly more beautiful and extensive than any that can be seen on the Rhine, and would alone repay the trouble of a visit. If Mr. England will direct his steps in this direction next summer and bring his dry plates with him, I will guarantee him as successful and pleasing campaign as that made by him last year on the Rhine.

I continue my journey down the Danube to day as far as Vienna, and will write again on my arrival in that town.

#### INFORMERS AND PIRACY.—GRAVES v. MERCER.

SIR.—With reference to your report of this case in your valuable Journal, I beg to make a few remarks. It is a significant fact that in a former trial (*Graves v. Ashford*, Mr. Ashford stated just what the defendant in this case states, viz., that the photographs sold by him were of a size differing from the one he was charged with selling, and of which he denied all knowledge.

When evidence is conflicting, probabilities must be considered. At the trial, Mr. Mercer stated that he knew the danger of selling photographs taken from copyright engravings, and had discontinued the practice for some time. He also stated that he knew his customer to be an informer. Under these circumstances it is hardly probable that he would part with a copyright photograph, if he had such a thing in his possession.

The informer, however, must live, and he can only do so by furnishing his employer with the means of obtaining convictions. He therefore buys wherever he can, and when on examining a dealer's stock, he finds no copyrights he solicits the dealer to obtain them for him. Too often the dealer falls into the trap, and is heavily amerced in consequence.

In this case either the informer mistook the identity of the purchase, and planted the photograph amongst those bought, a contingency supposed to be guarded against by having him searched by Cattermole before entering Mr. Mercer's premises.

A man, who to put a dealer off his guard buys hundreds of non-copyright photographs from him, while always asking for illegal goods, is not unlikely to make up a case on finding he cannot otherwise get one.

I do not for a moment suppose that such a proceeding would be approved by the plaintiff, if really committed, but he is open to censure for not clearly ascertaining the *modus operandi* of his staff of informers, and a man who mixes himself up with such men as informers are and must be, notwithstanding their "gentlemanly appearance," must share with them the odium attached to their proceedings, and submit to the rebuke of the Judge and the estimate of the Jury as shown by their verdict.

Dealers not trading in copyrights should know that they have a remedy against informers under the 5th section 11 and 12 Viet. cap. 43, which enacts that any person who shall counsel or procure the commission of any offence punishable on summary conviction shall be liable to be proceeded against and convicted of the same, either together with the principal offender on, before, or after his conviction. Thus informers

counselling the commission of a mis-demeanour render themselves liable to punishment.

Informers are justified in going to a dealer's shop and inspecting what he may have for sale, but on finding that he does not deal in illegal subjects, they have no right to persuade and counsel him to procure and sell such things. In so doing they themselves transgress the law.

Mr. Graves complains of the losses he has sustained by piracy. There is, however, a *per contra* which must act as a partial solatium to him. The heavy fines which have been inflicted have mostly found their way into his pocket, and have to a considerable extent re-imbursed him for his outlay in paying informers.—I remain, sir, yours faithfully, PHOTO.

### PHOTOGRAPHY AND DISEASE.

SIR,—Having through illness in the month of February last omitted to read your excellent Journal, I now find, on reading up, an article headed "Photography and Disease," (see page 98, of February 23th.) in which I read complaints from two brother photographers. I have been a practical photographer about twelve years, manipulating daily for about six years without feeling any ill effects from the process. About six years next August, while returning from business, and to all appearances in my usual good health, I was suddenly attacked with a fit in the street which seized me in the left hand and arm and left me senseless on the pavement. Since that time I have had twenty-one more attacks of the same nature, the last being on the 2nd of January, 1868. I feel the same symptoms as your first correspondent exactly. I have been for six years under some of the cleverest medical men I think in London, and all attribute it to poisoned blood from the use of the chemicals, and each advised me to give up the practice of the art altogether. As I am not adapted for anything else, that to me is impossible as at times I can scarcely stand to develop a plate, so I am compelled to practice the art from necessity. With respect to B. B., your second correspondent, my sincere hope is he will give it up ere too late, my feelings after washing prints are exactly the same as he states, but unfortunately I have lost the use of my left arm on three occasions for about seven days each time. A celebrated physician, whose name I should be happy to send any sufferer, told me three years since I must really give it up. I did so at the time, and went in the country for one month, in which time I got considerably stronger, I improved in appetite, and increased ten pounds in weight in twenty-eight days, but was compelled by circumstances to re-enter this profession. I am sorry for the sake of your correspondents I did not see their letters before, but hope it may not be too late to be of some service.—I beg to remain, dear sir, yours most respectfully.

August 2nd, 1868.

A SEVERE SUFFERER.

### Talk in the Studio.

ROYAL CORNWALL POLYTECHNIC EXHIBITION.—It may be well to remind our readers that pictures intended for competition at the forthcoming Royal Cornwall Polytechnic Exhibition, should be sent in before the 17th of next month. Forms for filling in, and all other particulars relating to the photographic department, may be obtained of Mr. J. C. Stephens, Falmouth. As our readers know, silver medals are offered for the best portrait and the best landscape, and bronze medals for the second best.

THE AMERICAN BROMIDE PATENT.—The great struggle between American photographers and the owners of the bromide patent is concluded, the patentees are defeated, and the restrictions in the United States on the use of bromides in collodion are at an end. The aim of the patentees was to secure a seven years' renewal of an iniquitous monopoly, and they have striven hard to gain that end. The opposition has been conducted energetically and successfully on behalf of American photographers by our friend Mr. E. L. Wilson, editor of the *Philadelphia Photographer*. The treasurer of the opposition finds that the expenses have been in excess of the funds, but, of

course, photographers will quickly contribute to supply the balance out of pocket.

PHOTOGRAPHS IN EVIDENCE.—In a recent trial for murder at Shrewsbury, a photograph of the murdered man was produced in course of the proceedings for the purpose of identifying him as Mr. Zusman, the person stated to have been murdered. It was ascertained, however, that the photograph was a copy of another portrait in a broach belonging to the deceased's widow. In the absence of direct evidence as to the origin of the broach portrait, the copy was regarded as valueless.

CHLORIDE IN BROMIDE OF POTASSIUM. The Paris correspondent of the *Chemical News*, says:—At a meeting of the Société de Pharmacie, M. Baudrimont gave an account of "A Process for Detecting the Presence of Chloride in Commercial Bromide of Potassium." The bromide to be examined is first tested for iodine. For this purpose a small quantity of the salt is dissolved in water in a test-tube, and an equal volume of bisulphide of carbon added. Upon the addition of a few drops of bromine water, the bisulphide of carbon becomes coloured violet, under the influence of iodide, if this be present. When the test shows the presence of iodine it is necessary to remove the whole of this element from the sample. This is effected by dissolving about 10 grammes of the salt in distilled water, adding bromine water until violet vapours are no longer visible upon boiling, and then testing for iodine in the manner first described. Afterwards the solution is evaporated to dryness to remove the excess of bromine, and thus one obtains a bromide of potassium free from iodide, but which may contain chloride. The remainder of the process depends upon the fact that a given weight of chloride of potassium requires a much greater amount of a standard solution of nitrate of silver than the same weight of bromide of potassium; while the bromide for the complete precipitation of 1 gramme requires 1.428 grammes of nitrate of silver, 1 gramme of the chloride requires 2.278 grammes. For the examination of the bromide of potassium, a standard solution of nitrate of silver is first prepared by dissolving, in a litre of water, 10 grammes of the pure salt, each 1-10th c.c. corresponding to 1 milligramme of nitrate of silver. 1 gramme of the bromide to be examined, freed from iodine if necessary, is dissolved in 100 c.c. of distilled water: 10 c.c. of this solution, representing 1 gramme of bromide of potassium, would require, if pure, 14.2 c.c. of the silver solution; chloride of potassium would require 22.7 c.c. M. Baudrimont proposes a method of making the final reaction more delicate by adding a few drops of solution of chromate of potash to the bromide examined; the nitrate of silver added then combines with the whole of the bromine and chlorine in preference, and the complete precipitation is marked by the production of the red precipitate of chromate of silver. It is obvious that the bromide contains more or less chloride, according as the number of burette divisions (divided into 1-10th c.c.) of the silver salt required exceeds 14.2. With a salt containing one-tenth of its weight of chloride of potassium 151 divisions are required, and with a mixture of equal weights of chloride and bromide, 185. The same method may be employed to recognize the degree of purity of several compounds. Operating as before—that is to say, dissolving 1 gramme of the material to be examined in 100 c.c. of distilled water, and taking 10 c.c. of the solution—the following numbers of 1-10th c.c. divisions required will show the purity for at least a considerable number of salts:—102 for pure iodide of potassium, 257 for cyanide of potassium, 246 for dry carbonate of potash, 290 for chloride of sodium, 119 for carbonate of soda + 10 equivalents of water, 47 for phosphate of soda + 24 equivalents of water, and 54 for arseniate of soda + 14 equivalents of water.

THE DUKE OF EDINBURGH.—The London Stereoscopic Company have favoured us with an excellent photograph of his Grace the Duke of Edinburgh, which has the especial interest of being the only one taken since the attempt upon his life. The photograph is very excellent indeed.

PHOTOGRAPHY AND LITERATURE.—The *Athenæum*, in reviewing a book on Lake Scenery illustrated with photographs, is severe on the literary portion of the book but complimentary to photography. It says:—"We turn to the illustrations in photography. Here, as the camera is incapable of slang, the glory of nature is displayed. We hope the photographs are to be procured without the text of this book."

THE BEST PHOTOGRAPHERS, Day and Sun.—*Censor*.

## To Correspondents.

**ALEC.**—As we have not tried the sample of collodio-chloride to which you refer we cannot speak with certainty of the preparation, or give the reason for the lack of vigour in your pictures. We may state, however, that want of vigour in collodio-chloride prints is generally due to one of three causes, either there is insufficient free nitrate of silver, insufficient citric acid (or similar body), or the collodion is too thin. Try first adding a little more citric acid; if that does not give you sufficient vigour, try adding a few drops of a saturated aqueous solution of nitrate of silver; and if that does not give sufficient vigour try adding a little more pyroxyline. You will find in our YEAR-BOOK full instructions for preparing collodio-chloride after a formula which gives us excellent results. In general terms the formula stands thus: the plain collodion should contain about 8 grains to the ounce of pyroxyline made by the formula given on page 79 of our YEAR-BOOK. To each ounce of this collodion should be added 15 drops of a solution of nitrate of silver containing a drachm of the nitrate in a drachm of water; 1 drachm of a chloride solution containing 32 grains of chloride of strontium in 1 ounce of water; and  $\frac{1}{2}$  drachm of a solution containing 32 grains of citric acid in 1 ounce of water. After mixing, the collodio-chloride may be used in from fifteen to thirty minutes. If you do not make collodion, take almost any good plain negative collodion and add the materials as above.

**ENQUIRER.**—Bromide of silver is very sparingly soluble in the nitrate solution. The bromide of silver formed on adding bromide of potassium would be precipitated, and the bulk of it will be filtered out. It is probable that you will not find the solution in any way unsuitable for a negative bath. 2. The thin phantom image you describe is most probably due to the collodion, which you state is of your own make. You should also have stated the formula by which it is made, and we could the better have helped you. Newness in the collodion, if good, is a common cause of thinness of the image. Insufficiency of pyroxyline is a common cause. If you have reason to think that your collodion contains sufficient pyroxyline and sufficient of the sensitizing salts, then modifying the developer may help you. Try the gelatino-iron developer. We remember once trying a sample of collodion which gave the then, poor, blue looking image you describe, and we found that the addition of citric acid (1 or 2 grains per ounce) to the iron developer instead of acetic acid materially improved matters. Let us know the result, and if necessary, state the formula of your collodion. You need not apologize for troubling us. It affords us pleasure to assist our readers.

**A. CANADIAN.**—See answer to ALEC for a formula for preparing collodio-chloride of silver. You will find fuller particulars in our YEAR-BOOK. Any good plain collodion will answer. The nitrate of silver must be added in aqueous solution. A drachm of water will dissolve a drachm of nitrate of silver, and a drop of this solution will contain nearly a grain of nitrate. The chloride and the citric acid are used in alcoholic solution. If you cannot readily procure chloride of strontium, chloride of calcium may be used in its stead. 2. A transparent positive is made in the camera, the image of a negative being made to fall on the sensitive plate instead of an image from an object. You will find instructions in our last YEAR-BOOK on page 73, also in our last volume page 517.

**No. 45.**—The yellow spots on the print forwarded proceed either from imperfect fixation or from nitrate of silver coming into contact with the print before the hypo was fully removed by washing. They are not the results of grease in the paper, nor are they contagious. The probable cause is imperfect fixation from the use of weak or exhausted hypo, or from the prints sticking in the bath. The result is the formation of insoluble hyposulphite of silver, which, being white, is not noticed at first; it is eventually decomposed by light, sometimes in a few hours, sometimes in a few days, and causes brown and yellow spots.

**A SUBSCRIBER (S. Walden).**—You will find full details of the Eburneum process in our YEAR-BOOK for 1866.

**II. E. W.**—We have succeeded with collodio-chloride of silver on many different varieties of paper, our best results having been obtained on the paper prepared with arrowroot for the Wothlytype process. The gelatinized paper of Marion will probably answer well, and we see no reason to doubt the permanency of proofs so produced. The gelatine possibly might, without disadvantage, be rendered insoluble by means of alum. 2. We have used albuminized paper without salt, and obtained good results; but we strongly object to the use of albumen, which, in contact with salts of silver, we believe to be an active cause of instability. To secure any chance of coagulating the albumen on albuminized paper, it

should be floated on boiling water, plain side down; mere immersion will wash off the albumen. 3. Producing collodio-chloride prints on glass, and then transferring them, would doubtless conduce to permanency; and we have obtained some very pleasing results in that way; the chief objection to such a mode would be the trouble involved. We hope shortly to publish some details of operations with some fresh samples of paper.

**C. E. F.**—It is very probable that the lens you mention may answer the purpose; but we cannot speak with certainty. The new rapid rectilinear will also probably answer. 2. It is probable that adding a trace of gelatine to your developer will be of service, as it will aid in securing even flowing of the developer, and also in slightly retarding the rapidity of its action.

**T. H. REDIN.**—Thanks for the solution of hyposulphite of ammonia, which we shall take an early opportunity of trying.

**J. G.**—There is no such memorandum book published. It would probably be found useful. We will make the suggestion to our Publisher.

**W. J. A. G.**—We believe that none of the Abyssinian photographs have as yet been published. We will ascertain and let you know particulars.

**J. H. U. (Sale Green).**—Thanks for the photographs duly received. They are exceedingly fine in all respects. Marion (Soho Square) is the only likely firm that we know. We will make some enquiry as to any other firm, and if we learn will let you know. We do not know of any dry process which would yield better results than yours by the collodio-albumen process; very few, indeed, nearly so good.

**RECEIVED: THE AMATEUR'S MANUAL OF PHOTOGRAPHY.** By Richard Kingham. Fifth edition. Also Specimens of Portraiture by Wm. Notman.

## THE NEW ACT TO REGULATE THE SALE OF POISONS.

An act has just been passed to regulate the sale of poisons and amend the Pharmacy Act of 1852, the provisions of the new Act materially affecting the convenience of photographers and vitally concerning all photographic dealers. By the provisions of the new act it becomes unlawful for any person except a registered pharmaceutical chemist, to retail certain poisons scheduled in the act. The poisons so mentioned, which concern photographers, are cyanide of potassium and other metallic cyanides, corrosive sublimate (bichloride of mercury), oxalic acid, and chloroform, the latter necessarily comprehending amber and other varnishes of which the solvent is chloroform. The penalty incurred by every unqualified person who shall retail any of these poisons is five pounds for each offence.

The qualifications of a pharmaceutical chemist, the examination he must pass, and the registration requisite, are all duly set forth in the present act and in the pharmacy act which is amended by the present enactments, and need not be repeated here, as not concerning the general body of our readers. Pharmaceutical chemists, moreover, may not sell the poisons scheduled except under the most stringent and guarded conditions.

The qualified seller will be liable to penalties unless the box, bottle, vessel, wrapper or cover in which the poison is contained, be distinctly labelled with the name of the article and the word "Poison," and with the name and address of the seller of the poison. In regard to certain poisons the qualified seller must not supply any person unknown to him, unless introduced by some person known to him; and on every sale of any such article the seller must, before delivery, make an entry in a book to be kept for that purpose, stating, in the form provided, the date of the sale, the name and address of the purchaser, the name and quantity of the article sold, and the purpose for which it is stated by the purchaser to be required, the signature of the purchaser and of the person, if any, who introduced him to be affixed to the entry.

The convenience of photographers will be somewhat affected by the act, but photographic dealers are most concerned, not so much, perhaps, by the loss of profits on the articles in question as by the annoyance involved in being unable to complete orders, and the multiplicity of explanations and disappointments involved. Some months ago, during the progress of this bill, we called the attention of those concerned to the possible restrictions on trade which such an act would impose, but, so far as we can learn, the interests of those using various of the articles mentioned for industrial purposes have not been considered. Singularly enough, the makers and vendors of patent medicines are exempted from the operations of the act, and such an excep-

tion having been made, we can scarcely suppose that a similar exemption might not have been secured to vendors for industrial purposes, if the case had been duly represented to the promoters of the bill in committee. As the matter stands the act will have a tendency, probably, to restrict the use, in photography, of cyanide, and also of mercury, neither of which are necessary, and the abolition of which from studios generally will probably do more good than harm.

We append some extracts from the Act which does not come into operation until the 31st of December in the present year, permitting, therefore, plenty of time to photographers who still desire to use such things to lay in a supply, and at the same time allowing the dealers generally to get rid of the stock in hand, which it is desirable they should effect before the date in question. The following are clauses of interest to our readers:—

From and after the thirty-first of December, one thousand eight hundred and sixty-eight, it shall be unlawful for any person to sell or keep open shop for retailing, dispensing, or compounding poisons, or to assume or use the title "chemist and druggist," or chemist or druggist, or pharmacist, or dispensing chemist or druggist, in any part of Great Britain, unless such person shall be a pharmaceutical chemist, or a chemist and druggist within the meaning of this Act, and be registered under this Act, and conform to such regulations as to the keeping, dispensing, and selling of such poisons as may from time to time be prescribed by the Pharmaceutical Society with the consent of the Privy Council.

The several articles named or described in the schedule (A.) shall be deemed to be poisons within the meaning of this act, and the Council of the Pharmaceutical Society of Great Britain (hereinafter referred to as the Pharmaceutical Society) may from time to time, by resolution, declare that any article in such resolution named ought to be deemed a poison within the meaning of this Act; and thereupon the said Society shall submit the same for the approval of the Privy Council, and if such approval shall be given, then such resolution and approval shall be advertised in the *London Gazette*, and on the expiration of one month from such advertisement the article named in such resolution shall be deemed to be a poison within the meaning of this Act.

Several clauses, as the qualification, registration, &c., of pharmaceutical chemists follow, and the Act then proceeds:—

Nothing herein-before contained shall extend to or interfere with the business of any legally qualified apothecary or of any member of the Royal College of Veterinary Surgeons of Great Britain, nor with the making or dealing in patent medicines, nor with the business of wholesale dealers in supplying poisons in the ordinary course of wholesale dealing; and upon the decease of any pharmaceutical chemist, or chemist and druggist actually in business at the time of his death it shall be lawful for any executor, administrator, or trustee of the estate of such pharmaceutical chemist or chemist and druggist to continue such business if and so long only as such business shall be *bona fide* conducted by a duly qualified assistant, and a duly qualified assistant within the meaning of this clause shall be a pharmaceutical chemist or a chemist and druggist registered by the registrar under the Pharmacy Act or this Act; provided always that registration under this Act shall not entitle any person so registered to practise medicine or surgery, or any branch of medicine or surgery.

It shall be unlawful to sell any poison, either by wholesale or by

retail, unless the box, bottle, vessel, wrapper, or cover in which such poison is contained be distinctly labelled with the name of the article and the word poison, and with the name and address of the seller of the poison; and it shall be unlawful to sell any poison of those which are in the first part of Schedule (A.) to this Act, or may hereafter be added thereto under section two of this Act, to any person unknown to the seller, unless introduced by some person known to the seller; and on every sale of any such article the seller shall, before delivery, make or cause to be made an entry in a book to be kept for that purpose, stating, in the form set forth in Schedule (F.) to this Act, the date of the sale, the name and address of the purchaser, the name and quantity of the article sold, and the purpose for which it is stated by the purchaser to be required, to which entry the signature of the purchaser and of the person, if any, who introduced him shall be affixed; and any person selling poison otherwise than is herein provided shall, upon a summary conviction before two justices of the peace in England, or sheriff in Scotland, be liable to a penalty not exceeding five pounds for the first offence, and to a penalty not exceeding ten pounds for the second or any subsequent offence. And for the purposes of this section the person on whose behalf any sale is made by any apprentice or servant shall be deemed to be the seller; but the provisions of this section, which are solely applicable to poisons in the first part of the Schedule (A.) to this Act, or which require that the label shall contain the name and address of the seller, shall not apply to articles to be exported from Great Britain by wholesale dealers, nor to sales by wholesale to retail dealers in the ordinary course of wholesale dealing, nor shall any of the provisions of this section apply to any medicine supplied by a legally qualified apothecary to his patient, nor apply to any article when forming part of the ingredients of any medicine dispensed by a person registered under this Act; provided such medicine be labelled in the manner aforesaid, with the name and address of the seller, and the ingredients thereof be entered, with the name of the person to whom it is sold or delivered, in a book to be kept by the seller for that purpose. And nothing in this Act contained shall repeal or affect any of the provisions of an Act of the session holden in the fourteenth and fifteenth years in the reign of Her present Majesty, intitled An Act to Regulate the Sale of Arsenic.

#### SCHEDULE (A.)—PART I.

Arsenic and its preparations.

Prussic acid.

Cyanides of potassium and all metallic cyanides.

Strychnine and all poisonous vegetable alkaloids and their salts.

Aconite and its preparations.

Emetic tartar.

Corrosive sublimate,

Cantharides.

Savin and its oil.

Ergot of rye and its preparations.

#### PART 2.

Oxalic acid.

Chloroform.

Belladonna and its preparations.

Essential oil of almonds, unless deprived of its prussic acid.

Opium and all preparations of opium or of poppies.

### PHOTOGRAPHY FOR FACSIMILE.

We have had opportunity recently to assist in a somewhat interesting application of photography as a means of aiding in comparison and identification of documents. Many of our readers are aware of the recent discovery of an unprinted poem supposed to be Milton's. Mr. Henry Morley, Professor of English Literature at London University, in the course of compiling a volume of Puritan poems, examined a volume of Milton's minor poems, dated 1645, in the King's Library at the British Museum, written on the fly-leaf of which he found a manuscript poem entitled "An Epitaph," signed J. M., and dated 1647. The style of thought and expression, and the character of the metre, struck him as essentially Miltonic, and he communicated to the *Times* his discovery of what he believed to be an unknown poem by Milton. Straightway a hot controversy arose as to the probability of the poem having been written by Milton. The matter and manner were fiercely attacked and ably defended. The similarity of the handwriting to that of Milton's was denied and re-affirmed, the signature was doubted and defended, and the daily press and the critical weekly press were kept for some weeks in a state of excitement over the discussion.

Any discussion of the literary question would be out of

place in these pages, and we pass by that part of the question by merely remarking that much of the thought and expression are strikingly like, and not unworthy of, Milton. But there is a phase of the question which will interest photographers. Original MSS. in the handwriting of Milton are not plentiful. The authentic examples in the British Museum chiefly consist of fragments or signatures, which do not afford very extensive facility for comparison. Sotheby's *Fac-Similes* afford more scope; but these are, at best, but the imitations of a clever copyist, and, in some instances which we have noticed, fail to reproduce quite accurately the originals. There is, however, in the Library of Trinity College at Cambridge, a fine collection of Milton's original manuscripts, which must manifestly afford the most valuable aids to comparison. But here arises the difficulty: the treasures of Cambridge cannot with propriety leave the Library at Trinity, nor can the British Museum with more propriety permit a rare and valuable book to pass out of its custody. The two manuscripts cannot be brought together, but here photography steps in to solve the difficulty. The authorities of the Museum accorded to Mr. Hain Friswell, the Editor of the "Bayard Series," on which Mr. Morley was engaged, permission to photograph the recently discovered poem, and under this authority an excellent copy of the poem was produced by Mr. Blanchard.

We were entrusted by Mr. Friswell with an early proof of the negative for comparison with the MSS. at Cambridge, and by the courtesy, and with the assistance, of the Master of Trinity, we were enabled to make a careful comparison. It is difficult, perhaps, in a case of this kind to arrive at certainty. Strong probability is as much as can be looked for. Allowing for the somewhat cramped style and diminutive size rendered necessary in completing a given number of lines within the limited space of the blank leaf of a small book, the handwriting in the new poem and that in the Cambridge MSS. was strikingly alike, the resemblance being most marked to poems in the Cambridge MSS. near the date of the recently discovered "Epitaph." The Cambridge MSS. extended over a period of more than twelve years; but the writing in a poem dated 1646, presents the strongest points of similarity, the formation of the figures of the date being precisely the same as the formation of the figures in the date of the "Epitaph." Not only did we find a similarity in the general style of writing, but an absolute identity in many points of distinctive peculiarity in the form of both capitals and small letters, in spelling, and in words of contraction or abbreviation. The capitals, especially in Milton, are unusual in form, and resemble rather the printed italic capitals now in use than the letters with curved and flowing lines of written letters. We have not space here, and it might not interest all of our readers, to enter into minute detail as to the character of individual letters. Suffice it to say, that the experiment proved a strikingly satisfactory illustration of the value of photography for facsimile as superior to any other method which could possibly be adopted.

A photo-lithographic facsimile, produced by Mr. Ayling from Mr. Blanchard's negative, will be published in the volume of poems shortly to be issued, and some notes on the results of the comparison for which facility was afforded by photography.

### THE KINESCOPE.

We have recently received from M. Roman Talbot a pretty little optical toy, in which a curious and interesting application of photography is made. It is practically a miniature illustration of the principle of persistence of vision upon which the effects of moving figures are obtained in the thaumatrope, the zoetrope, &c. The kinescope is in the form of a handsome oval locket with ring to be worn attached to a watch chain. It contains two microscopic transparent photographs, placed opposite a minute Stanhope lens. The two photographs are of the same object in a

different position, and represents two successive phases of one action. On looking through the small aperture at first nothing is seen but a fine magnified image of a transparent photograph. But on pressing a small button the first image disappears and a second fills its place with such rapidity as to produce on the retina the effect of motion in the figure. Thus in the example before us the first photograph gives a group of two figures, a young lady, and a young gentleman leaning over her chair, the lady listening very demurely apparently to the gentleman's conversation. The button is touched, and straightway the gentleman is seen to kiss the lady—respectfully of course, and on the forehead—her head being in turn lifted to receive the kiss. On alternately pressing and releasing the button, the gentleman is seen to repeat the salute with rapidity and *empressment*. This is of course but one effect of many representations of objects in motion which may be produced. The photographs are excellent, and an effect of great solidity is produced. This is another illustration of our recent remarks on the ingenuity with which our continental neighbours are constantly making ingenious, and often, we believe, remunerative, applications of the art.

### THE LATE M. CLAUDET.\*

As a science, and as an art, photography embraces a very wide range of study and experiment, and it has generally happened that its votaries have devoted themselves to some one of the many phases of interest it possesses. To some its especial interest has consisted in the subtle problems it has presented to chemical or optical science, and the stimulus to research in new directions in connection therewith; whilst to others its chief interest has consisted in the facility with which it lent itself to pictorial purposes, and the rare truth and beauty of its results. M. Claudet was singularly complete and universal in his devotion to photography; he was equally enthusiastic in regard to its scientific, mechanical, and artistic developments, some of his most recent experiments having been devoted to the perfection of an ingenious mechanical contrivance, by which he hoped to diffuse definition and secure more artistic qualities in portraiture. His biographer says:—

Yet, whilst we point to Claudet as a philosopher, it would be less than justice not to recognize his ability as an artist, and his great services to the art of photography. He not only himself produced beautiful and perfect works in photography, but was also eminently, by his studies and inventions, the means of enabling others to refine and advance the art. He was, indeed, the champion of photography as an art. When the managers of the Universal Exhibition of 1862 had placed photography in the mechanical department, he emerged from the laboratory into the studio, and, lined in rest, chivalrously proclaimed photography one of the fine arts against all comers. "I am one of those," he says, in one of his printed letters of that date, "who are convinced that photography deserves to be ranked among the fine arts. If photography was only a machine, such as a magic lantern, with which every one can strike pictures on a white screen with the same success, its productions might indeed be exhibited in the mechanical department; but as I find from my own experience, which is as old as photography itself, that nothing is more difficult than to produce photographs deserving to be looked at—that it requires thought, taste, judgment, and refinement to use with success the apparatus and the process—I consider that there is as much art in the result as in any of the so-called fine arts."

Some space is next devoted to recent correspondence between M. Claudet and Sir David Brewster, in regard to the favourite notions of the latter as to the importance of small lenses. Some extracts from his letters to M. Claudet may be interesting here:—

March 22, 1867.—I am persuaded that the great desideratum in photography, whether monocular or binocular, is the *perfection of the picture*, in the camera. I am certain that different cameras, even when the lenses are corrected for colour and aberration, do not give the same likeness.

This imperfection obviously arises from the different apertures of the lens, in a great measure; but I believe, also, from the number and form of the separate lenses.

An infinitely small pin-hole is the most perfect camera, and the nearer we can approach to the smallest and thinnest lens, the nearer do we approach to a perfect portrait.

The extreme sensitiveness of the process enables the photographer to reduce his lens to the size of the human pupil, which is absolutely necessary to produce the portrait of the person whom we actually see, but something also depends on the perfect homogeneity of the glass employed, and of the number and curvature of the refracting surfaces.

No proper experiment has yet been made to ascertain the effect of a single lens of diamond or any other substance. I wish you would enter upon this inquiry. You are the only person I know fitted to do it.

April 18, 1867.—I have no doubt that with your knowledge, theoretical and practical, you will give a new character to photographic portraiture.

I think the two great points to be attended to are: 1. The smallness of the aperture of the lens; and 2. The simplicity of the optical apparatus, the smallest thickness of the refracting material, and the smallest number of refracting surfaces.

I do not think *sharp definition* at all necessary; on the contrary, I think it an evil.

In society I see faces, and every expression upon them with sufficient distinctness, notwithstanding my long-sighted vision. When I put on glasses to have perfect vision, the very distinct picture, even of the youngest and smoothest faces, is disagreeable, while that of middle-aged and old persons is still more so. Beauty, either of form or expression, is injured by sharpness of outline; and the vision of minute parts, and the corrugations and wrinkles of age, and even of middle life, are made doubly disagreeable.

Has it ever occurred to you that a large lens, perfectly achromatic and without spherical aberration, cannot give a correct representation even of a *perfectly flat space*, such as the breadth of a line?

I shall be glad to read the papers you mention, which I hope will soon be published.

June 3, 1867.—I am delighted with the result of the topaz experiment; the portrait is singularly fine. The dispersive power of topaz is 0.024, that of crown glass being 0.033, and that of flint glass 0.048. To have the smallest aberration, the side of the lens with its flatter surface should be next the image, the aberration in this case being 1, and the aberration in the other case 4, so that your excellent effect has been produced *with the largest aberration*. This seems to throw a new light on the subject. The lens had thus a great number of foci, a number increased by the number of chromatic foci, and hence the *excellence of the picture*. It is easy to increase the number of foci by increasing the size of the lens, but then you introduce the error arising from the superposition of different views of the figure, as seen from different points of the lens.

If these views are correct, it would be worth while to try a lens of *flint glass*, with various chromatic and actinic foci, and with the radii of its surface as 1 to 6 (a plano-convex nearly), having its flattest side towards the sitter. It will be curious if we find that the lens which is the worst for the telescope and the microscope should be the best for taking the picture of a solid object, such as the human figure. \* \* \*

I wish you would try some experiments with the largest lens you have in your cameras, and take five pictures of a large statue, one from half an inch of its centre, one from the lowest point, one from the highest part of its circumference, and one from its left and right. This would show clearly the effect produced by the size of the lens.

If the experiment were made upon a living figure, the change of expression would be seen. It would be also very interesting to take a photograph of the same statue with a small pinhole.

August 20, 1867.—I cannot resist thanking you for your interesting letter and its enclosures.

Your portrait by the topaz lens is *perfect*. Nothing can surpass it, and it is hardly necessary for you to try the one-fourth of an inch aperture. It might be worth while to try three-fourths of an inch, which will reduce more than one-half the time of sitting.

It is not necessary here to discuss the question of small lenses of long focus, the adoption of which, even if the results were desirable, would be practically impossible in portraiture. A copy of the portrait by the topaz lens has been kindly promised by Mr. Henry Claudet to each member of the Photographic Society, and many photographers will thus acquire an opportunity of examining the results Sir David Brewster thought so perfect. On the subject of wide apertures, M. Claudet, writing to Sir David, says:—

"In order to prove the defects of operating with large apertures in lenses, I operated in the following manner:—I had a disc of the same size as the lens (5-inch), having on its diameter an aperture of 1 inch, which could at will be turned alternately to the right or left of the horizontal line corresponding with the diameter of the lens. Having taken a portrait with the aperture on one side the diaphragm

\* Continued from p. 373.

was turned so as to present the opening on the other side, and then a second portrait was taken before the sitter had moved."

"The result of this experiment is very conclusive, for the two portraits being examined with a stereoscope, present the strongest stereoscopic effect which can be obtained by the usual mode of operating."

The latter sentence in the paragraph just quoted in reality disposes of Sir David's argument. He believed that a portrait to be correctly delineated should not be produced with an aperture larger than the pupil of the human eye, over-looking, apparently, the fact that two eyes are employed, and that to secure some approximation to the relief and solidity of nature a much larger aperture should be used in the lens, when objects in relief have to be depicted on a flat surface. It is worth noting here, also, that from the letter of Sir David, dated June 3, 1867, it appears to have been a new idea to him that diffusion of definition in rendering solid objects could be obtained by lenses having a series of foci at different planes, or, in other words, by using lenses in which a certain amount of aberration was purposely left uncorrected, a practice the value of which for certain purposes we have pressed upon the attention of our readers for many years.

We conclude by extracting some eloquent paragraphs on the general character and labours of M. Claudet:—

In 1851, Claudet set up a temple to photography after his own heart. Here, in the Hall of Audience, could he be consulted at call from the *adytum sanctum*. Here, surrounded by symbols and examples, the neophyte was impressed with the dignity and beauty of photography; perhaps first learned that photography is an outcome of the labours of philosophers through the ages of civilisation. For he saw, on glancing at the medallion portraits around the cove, names of men now thought of as ancients—Roger Bacon, Porta, Da Vinci, Newton—and was reminded of the honour due to many nearer to his own time, as Davy, Wedgwood, Niepce, Daguerre, Talbot, Wheatstone, Brewster, Arago. He saw described by allegorical paintings the progress of the arts by which natural objects and the human form have been represented from the earliest time—statuary, painting, application of the camera obscura to photography and of photography to the stereoscope, emblems of the discovery of photography and of the means of producing photographic pictures, mural scrolls, chronological records of the inventions and discoveries whereunto photography is indebted; or, looking again, he read inscriptions of the classic testimony of Virgil or Martial: "*Nulla recedunt lux est ingrata*," "*Solem quis dicere fulsum audeat?*" "*Lux est mundi lumen*." All this is to be seen no more. This temple, so characteristic of Claudet's devotion to photography, was burnt a few weeks after its chief priest had quitted it for ever. With it were lost many beautiful works and valuable relics of the master's labours.

But, as we have elsewhere said, that for which Claudet deserves best to be remembered is of such a fabric as fire cannot destroy. He has left his impress upon science—a gap in the ranks. Like all men of original thought, he will be followed, not replaced. Those who haunt the groves of science will miss his familiar form, and listen in vain for his instructive lucubrations. For he was of the order of the Peripatetics. Whether at the Royal Society, or at photographic confederations in England or Scotland, or at universal exhibitions—wheresoever the British Association wandered, there was he seen and heard; or whether in the *Philosophical Transactions*, or in the *Comptes Rendus*, or in photographic journals, or in art journals—wherever photography had to be expounded or vindicated, there would be found the product of his pen. His activity was incessant, his motto that of Pascal: "*Le repos c'est la mort*."

Nor would we conclude a memoir of Claudet without indication of his personal qualities. That he was of a generous temperament, liberal and genial, is indeed partly implied by what has been previously said of his enthusiasm. It was so. He was "one of nature's gentlemen." Unselfish, he allowed the interests of science to overrule all meaner considerations, and with the true sentiment of the philosopher, subdued all things to the purpose of investigating the recalcitrant principles of nature's laws. This was his adoration: "*Est Deus in nobis, est Deus in rebus*." Whatever his toils or his disappointments, he was not discouraged. "He that seeketh to be eminent amongst able men hath a great task," says Bacon, and with such a task Claudet was contented. He was one who had set himself to answer the insatiate Sphinx, not expecting the success of Odipus, willing to die in the encounter. For with him it was truly a "labour of love." Science was the mistress of his heart, a sweet echo ever responsive to his constant call. And so he found solace in—

"Divine philosophy,  
Not harsh and crabbed as dull fools suppose,  
But musical as is Apollo's lute,  
And a perpetual feast of nectared sweets,  
Where no crude surfeit reigns."

The recognition of Claudet's merits in his lifetime was perhaps sufficient to satisfy a man who sought only such honour. He received awards of eleven medals, including the Council Medals of the Universal Exhibition, 1851, besides that on other great occasions, being on juries, he was excluded from the awards. He was elected member of the Royal Society in 1853, and in 1865 he was made a Chevalier of the Legion of Honour. But of such was not his ambition. He was a votary to science, and wrought chiefly to feed her altar-flame. For him that was enough.

"*Recte facti, fecisse merces est.*"

## REDUCTION OF THE SESQUI-SALTS OF IRON TO PROTOSALTS.

Mr. W. J. LAND contributes to our excellent contemporary the *Philadelphia Photographer*, a simple method of converting the persalts of iron to the protosalts by means of nascent hydrogen. As it sometimes happens that large stocks of iron solution become peroxidized, the method may be found useful by photographers. He says:—

"While engaged in the analysis of nitrates by M. Pelonze's method, I find that solutions of persalts of iron are perfectly reduced to protosalts by nascent hydrogen. As I do not remember to have seen a record of such reduction of ferric salts (in solution), I am induced to offer this, hoping that something useful may result from it, either by its application in analysis of iron salts, or to the restoration of developers, &c. The following will serve as an example of the experiment, which may be modified in various ways:— If to a solution of persulphate of iron, a small quantity of sulphuric acid and iron filings are added, an elimination of hydrogen will take place, but the greater part of the gas at the moment of liberation unites with the oxygen of the persalt, and in a short time reduces it to protosulphate, in which no trace of a higher iron-salt can be found. The experiment is best made in a flask with a small neck, loosely stopped; and, if the solution is to be tested for persalt, the flask should be fitted with a valve opening outward. The temperature should be raised that the perfect expulsion of the atmosphere may be affected, the oxygen of which would quickly peroxidize some of the reduced salt. I have experimented upon the mineral acid salts of iron. The organic acid salts would probably undergo like reduction with the proper material for generating hydrogen in their solutions."

## CHLORO-IODIZED COLLODION.

Mr. F. M. Spencer says in the *Philadelphia Photographer*:—"I find the following to make a collodion even more sensitive than any bromized collodion I have ever used. I am indebted to Professor Towler for the idea mainly. I substituted chloride of magnesium for chloride of ammonium, as suggested by him.

Ether and alcohol	...	...	equal parts
Iodide of ammonium	..	...	3 grs. to the oz.
Iodide of cadmium	...	...	2 " " "
Chloride of magnesium	...	...	1 gr. " "
Pyroxyline	...	...	5 to 6 grs. " "

"I dissolve the salts in the alcohol, add the cotton, and then the ether.

"I use a forty-grain silver bath, kept as nearly as possible in harmony with the condition of my collodion—generally neutral, but if my collodion be slightly alkaline, I had rather the bath be so too, than to be the least bit acid. I think any operator who will give this collodion a fair trial, will be pleased with it. I never have to doctor my bath, except when it becomes overcharged with alcohol which I drive off by boiling. Or if I find my bath overcharged with iodide of silver, I add a few drops of a strong solution of cyanuret of potassium. Shake and filter. In short, with a chloro-iodized collodion, I consider the most difficult points in in-door photography to be lighting the subject and managing the development.

## METHOD OF MOUNTING PHOTOGRAPHS AND ENGRAVINGS.

The following method of mounting photographic and other pictures produced upon paper has been patented in America:—

"Take any substance that affords a plain and even surface, and can be enamelled or painted white, whether it be paper, glass, china, or any form of earthenware, wood, stone, or metal, and having made the surface white and smooth, by enamelling, painting, or other process, and cover it with a mixture of clarified beeswax, balsam of fir, and spirits of turpentine, mixed in about equal parts, softened by heat to such consistency that it will readily flow over and off the surface, leaving a thin film remaining. The picture to be mounted, which may be an ordinary photograph, taken and finished in the usual manner, or an engraving, is then rendered translucent, by the application of wax, varnish, or other suitable substance. Before the film of beeswax, balsam, and spirits of turpentine hardens, the picture is placed upon the surface of the film, and pressed gently upon it, or, should it have hardened, it is softened by the heat of a spirit-lamp, and when sufficiently soft, the picture laid upon it, and by the application of an even and gentle pressure, it soon becomes fixed. The picture, after being thus mounted and revarnished, is then ready for colouring, which is done in any of the ordinary methods.

"It is evident that the tint or colour of the background will influence the appearance and tone of the picture, and therefore affords a means of cheaply producing a wide range of artistic and beautiful effects."

## ACTINIC VALUE OF COLOUR IN NEGATIVES.

BY M. CAREY LEA.\*

In working with any sort of dry or preserved plates, we are met by a difficulty which does not occur with wet ones. Instead of the silver-gray colour of the wet plate, we have to do with every possible shade of colour (the expression is not exaggerated, as will presently be seen), and the estimation of the effect of transparency or opacity to the chemical rays of light is a question of vital importance to the photographer. I do not pretend to be able to give rules for its solution, rather feeling disposed to echo the wish of an English photographer for a pair of "actinic spectacles," to enable one to estimate the value of these shades. But even where a satisfactory solution is not to be expected, a survey of the difficulty is always useful.

The colour of the film in a dry plate seems to have very much less to do with its actinic value than could at all be imagined. For example, I have a negative taken by the glycerine process, in which the sky is deep blood red. Such a shade is commonly known as very opaque to the chemical rays, yet the sky "prints through" more than any other negative that I have taken, within my recollection, and more than other negatives with lighter looking skies taken by the same process. It should be mentioned that no part of this negative is very dense, so that the sky printing through cannot be ascribed to anything in the way of a long exposure necessitated by an otherwise dense negative.

On the other hand, some time since I made two negatives, also by the glycerine process. In both the distance consists of trees about a quarter of a mile off. The foliage was dense and dark green, and no sun upon it—the day was overcast with rather thick clouds. The distant foliage in question came out in developing of a well-marked bluish colour. In view of this and of apparent thinness, I expected them to print too black; in place of which, this blue portion proved so opaque that the difficulty was the other way. It should be said that this blue was perfectly so without any tint of green or olive to explain its behaviour.

The opacity to light of the olive colour in many of the

plates developed according to the alkali process is very remarkable. Every one who writes on the subject very properly warns his readers of the danger, and yet I doubt if any one learns the lesson fairly except by experience. Negatives that look beautifully graduated as to colour may print hard and flat for this reason, and considerable experience is required to know when to stop the development, in order to get the best results. Distant trees, if strongly illuminated, may show a strong contrast with the sky when seen with the eye, by holding up to the window, and yet, on printing, these trees may almost shade out into the clouds or sky above.

When negatives by the glycerine process are developed with iron, the most extraordinary diversities of colour result. Sometimes the plates exactly resemble wet plates developed by iron, have the same silver-gray colour and creamy look, and sometimes show well as positives by reflected light. Oftener, especially when the exposure has been long enough to dispense with anything in the way of redevelopment, the image is entirely within the film. Its surface is then hard and glossy, and it is in these cases, especially when there has been a little over-exposure, that the remarkable effects of colour come in.

I have several negatives, in each of which the following triple play of colours comes in:—

First, if they be viewed against a dark background by reflected light, but by diffused reflected light, and not catching the reflection of a sky through a window, then the skies in the negatives are deep blue, very intense—so are their reflections from the surface of water. The grass and foliage is pale-green—so, also, is its reflection in the water, except where the foliage is highly illuminated—in such places its colour is as blue, nearly, as the sky.

If the reflection of the sky, as seen through a window, be caught, these colours disappear, and all the high lights, and even middle tones, have a yellow, brassy, metallic look on a neutral ground.

Held up against the sky, and viewed by transmitted light, the whole negative is brownish-red, except some over-exposed branches of a tree; these are blue by transmitted light.

All this colouration has resisted fixing by hyposulphite of soda, and is easily distinguishable. Although it seems a step towards heliochromy, the effected is simply curious, and not in the least pleasing.

Blue, in glycerine plates, is not at all an uncommon colour, both by reflected and transmitted light. But, it is to be remarked, that the same portion of the plate is never, it would seem, blue by both reflected and transmitted light. The blues, by reflected light are dark brown by transmitted, and the portions that are blue by transmitted light are not so by reflected.

The very same plates that give these varied colours, when developed by iron, give plain black when pyrogallie acid is used for developing. Solarized portions, upon which the light has been too strong, develop red by the iron developer; black, or sometimes dark-olive, with pyrogallie acid.

This suggests the idea that in the study of heliochromy more attention is probably needed to the forms of development, and less to the sensitive agent, than has been given.

## PHOTO-BLOCK PRINTING.

The economic value of a method of producing, by means of photography, surface printing blocks which may be used with ordinary types cannot be over-estimated. Experimentalists have been alive to the value of such a process for many years, and numerous attempts have been made to compass the desired end. The early experiments of M. Paul Pretsch possessed much excellence, but like too many of his efforts in photo-engraving did not meet with the success which their ingenuity and the persevering zeal of the experimentalist deserved. Mr. Dallas, Mr. Hancock, and others have worked

\* *Philadelphia Photographer.*

with considerable success, so far as we can judge from the examples we have seen, in the same direction, but as yet their processes have not received any extended commercial application. Mr. Griggs has worked with some success in the same groove, an example of his work having recently appeared in our pages. We have had for some months in our possession, waiting until we had space to devote to the subject, a fine example of photo-relief engraving by Mr. Swan, and another block, produced by an analogous process, received from Dr. Vogel of Berlin. We hope shortly to find space to place these illustrations of processes before our readers.

A few days ago we were favoured by Mr. D. Fruwirth with some fine examples of photo-lithography and photo-block printing, by processes which he has recently patented. The processes in their general character are, we understand, due to Mr. Courtenay, modifications and improvements only being claimed by Mr. Fruwirth. It is with the block-printing we have to do at present. It is based upon the known re-action of light upon gelatine and a chromic salt, the speciality here depending upon a combination of the glyphotographic process with a photo-engraving process. The operations may be briefly stated as follows:—A good negative is first obtained—always, be it understood, a reproduction of a subject possessing the mechanical gradation of stipple or line—under this negative a plate coated with gelatine and bichromate is exposed, and the insoluble portions are subsequently washed away, leaving the whites of the image in relief. From this relief a cast in plaster is taken, and from the plaster cast another cast in type-metal is obtained. It is here that care is required, and facility for improvements upon old processes arises. It rarely happens that the relief in the gelatine mould is sufficient to yield a good printing block, the recesses not being sufficiently deep. In ordinary press printing the paper is backed by a soft elastic surface, and if the recesses are not deep the paper is pressed into them, and a muddy unclear image is the result. In the glyphotographic processes broad spaces are easily built up on the

usual way. In this stereo cast it will be observed that the lines in relief will form the recesses in an electro block obtained from it, and the mode of treatment we have described will secure, it is understood, sufficient depth in the recesses to permit clean printing. Amongst the examples to which Mr. Fruwirth called our attention were some blocks as large as a page of this Journal. The demands upon our space only permit us, however, to insert here a small illustration, which besides possessing greater delicacy, also permits to many of our readers facility for comparison, being one of Kaulbachs celebrated illustrations to "Reynard the Fox." It is probable that when we have space or occasion we shall place further examples before our readers.

At present we can see no valid reason why processes of photo-block printing for reproduction of engravings or of drawings made in line for the purpose should not receive a much wider economic application than they have yet done; but it is a singular fact, that hitherto almost all attempts to supersede wood-engraving, from photo-engraving down to graphotype, have failed either of commercial or artistic success, or of both. We hope for the method under notice a better issue.

We may add, that besides some very good photo-lithographs in line, Mr. Fruwirth showed us some of the most perfect photo-lithographs in half tone we have yet seen, and possessing very high promise indeed. As the process will be patented, and the specification is not fully entered, we cannot enter into the details of the process at present.

#### PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXIX.

"Nature is always broad; and if you paint her colours in true relations, you will paint them in majestic masses. If you find your work look broken and scattered, it is, in all probability, not only ill composed but untrue."—*Ruskin.*

CHIAROSCURO—(continued).—BREADTH.

WHATEVER arrangement or system of chiaroscuro is employed in a picture it must have breadth of effect, without which the eye will never rest upon it with pleasure. Just as a degree of irritation to the touch arises from uneven surfaces so all lights and shades which are interrupted and scattered are more irritating than those which are broad and continued. It must not be supposed from this that extreme contrast of light and shade in the proper quantity, and in the right place, is not agreeable, for upon contrast and opposition, as I have already shown, much of pictorial effect depends, but it is the flickering lights and perpetually shifting glare of ill-managed chiaroscuro that keep the eye in a state of constant irritation, and distracts the attention from the subject of the picture. The effect to be avoided is that which Milton described before his weak and easily affected eyes had lost their light, when he wrote—

"Hide me from day's garish eye,  
When the sun begins to fling  
His flaming beams."

In an endeavour to explain the cause of the beautiful effect of breadth as seen in twilight, an admirable writer says:—"It may, perhaps, be said that the imagination, from a few imperfect hints, often forms beauties which have no existence, and that indifference may naturally arise from those phantoms not being realized. I am far from denying the power of partial concealment and obscurity on the imagination, but in these cases the set of objects when seen by twilight is beautiful as a picture, and would appear highly so if exactly represented on the canvas; but in full daylight, the sun, as it were, decomposes what had been so happily mixed together, and separates a striking whole into detached unimpressive parts."

It is always of service to the artist to examine the same

mould with wax to prevent this result; but the close spaces between finer lines are more difficult to deal with. Mr. Fruwirth having obtained his stereo intaglio, applies a thick coating of a suitable varnish or ink to the whole of the surface, besides building up the broad spaces with wax in the

scenes at different times of the day and under different effects. He then has an opportunity of speculating on the cause of the beautiful appearance at one time, and of the commonplace look most scenes have at other times.

Objects, which in themselves possess no interest, are frequently made to delight the eye, from their being productive of breadth. This cause seems to account for the pleasure we receive from many massive, heavy objects, which, without this charm, and considered singly, are positively ugly. Some pictures, though bad in every other respect, but possessed of breadth, attract and arrest the attention of the cultivated eye; while others, admirable in detail and colour, but where the harmonizing principle is wanting, will

often be passed over as uninteresting. But breadth must not be carried out to effeminacy; the most healthy system requires a tonic sometimes, and too much sweetness and breadth become sickly. Illustrations of pictorial art are often to be derived from music. It is so here. The first effect of mere breadth of light and shadow is to the eye that which mere harmony is to the ear, both produce a pleasing repose, which, if not relieved, becomes dull and wearisome. The eye requires to be awakened occasionally, for it must be remembered, however delightful repose is, repose leads to sleep and sleep to death. But as harmony and design must be preserved in the wildest music, so must breadth be observed in the most complicated scenes.

The illustration to this chapter, the original of which is a fine example of breadth of effect, is taken from Turner's "Liber Studiorum," and was used by Mr. Lake Price in his articles on a similar subject to the present one in the PHOTOGRAPHIC NEWS some years ago. Its excellence as an example of breadth must be my excuse for introducing it again. Mr. Lake Price observes in reference to it:—"The fine subject of 'Norham Castle' is a masterly example of this management, [breadth of effect]. Here the dark mass of the castle occupies the centre of the picture, and is the focus of shadow, diminishing thence to the edges of the subject; the principal light of the sky being brought into immediate contact with the strong dark, the qualities of increased brilliancy and great breadth are simultaneously attained. The beautiful and poetic effect of this subject should animate some of our landscape photographers to endeavour to emulate similar effects from nature. The student will gain considerable knowledge of the capabilities of chiaroscuro, in its application to landscape, by repeated and careful examination of the broad, varied, and masterly effects to be seen in Turner's 'Liber Studiorum,' which is in itself a compendium of light and shade applied to landscape composition."

Painters have found it difficult to unite breadth with detail, but it has been attained, in the works of some great masters, in great perfection, showing that breadth is not inimical to finish as insisted by some writers and painters, and by one photographer. The microscopically finished works of Gerard Dow are never wanting in breadth, and the well-known pictures of Meissonier, highly elaborated as they are, are remarkable for the very qualities which it has been supposed high finish would destroy. But the photographer is not so much troubled as the painter with this fear of detail destroying breadth. The utmost extreme of definition is quite compatible with the most tender atmospheric gradations. The detail of nature need never be sacrificed for the sake of representing atmosphere. If definition and atmosphere

exist together in the subject to be photographed they should appear in the picture, or something is wrong. Either the chemicals are out of order, the exposure is not well timed, the development or intensification ill-judged, or the photographer has attempted to do on one plate that to which he should have devoted two or three, and combination printing.

Nothing, perhaps, is more pleasing or more flattering to the vanity and indolence of artistic mankind than the being able to produce an agreeable general effect with little labour and less study; this they call "artistry," and think clever, but it is not the intention of painting which should represent nature, and not an abstract idea of it. Mere sketches of breadth no more represent nature than do the "tone" pictures of some modern artists, in which the changes are rung on all the gradations, from the very limited scale of lavender to white, represent colour. These pictures, in which the painters probably endeavour to "snatch a grace beyond the reach of art," are very clever as far as they go, but they, like sketches that show only breadth, do not go beyond A or B in the alphabet of art.

#### ON THE MEASUREMENT OF THE LUMINOUS INTENSITY OF LIGHT.

BY WILLIAM CROOKES, F.R.S., ETC.\*

THE measure of the amount of free polarization present in the disc  $c d$ , will give the relative photometric intensities of D and C.

The letter I represents a diaphragm with a circular hole in the centre, just large enough to allow the compound disc  $c d$  to be seen, but cutting off from view the side discs  $c' d'$ . In front of the aperture in I is placed a piece of selenite of appropriate thickness for it to give a strongly-contrasting red and green image under the influence of polarized light. K is a doubly refracting prism, similar in all respects to H, placed at such a

\* Continued from p. 370.

distance from the aperture in I that the two discs into which I appears to be split up are separated from each other, as at *g r*. If the disc *c d* contains no polarized light, the images *g r* will be white, consisting of oppositely polarized rays of white light; but if there is a trace of polarized light in *c d*, the two discs *g r* will be coloured complementarily; the contrast between the green and red being stronger in proportion to the quantity of polarized light in *c d*.

The action of this arrangement will be readily evident. Let it be supposed, in the first place, that the two sources of light, D and C, are exactly equal. They will each be divided by II into two discs, *d' d* and *c' c*, and the two

polarized rays of which *c d* is compounded will also be absolutely equal in intensity and will neutralize each other and form common light, no trace of free polarization being present. In this case the two discs of light, *g r*, will be colourless. Let it now be supposed that one source of light (D, for instance) is stronger than the other (C). It follows that the two images *d' d* will be more luminous than the two images *c' c*, and that the vertically polarized ray *d* will be stronger than the horizontally polarized ray *c*. The compound disc *c d* will therefore shine with partially polarized light, the amount of free polarization being in exact ratio with the photometric intensity of D over C. In this case the image of the

Fig. 2.

selenite plate in front of the aperture I will be divided by K into a red and a green disc.

Fig. 3.

lect the rays from D B C (fig. 2), and throw the image into the proper part of the tube. At M is another lens, so adjusted as to give a sharp image of the two discs into which I is divided by the prism K. The part N is an adaptation

Fig. 2 shows the instrument fitted up. A is the eye-piece (shown in enlarged section at fig. 3). G B is a brass tube, blacked inside, having a piece, shown separate at D C, slipping into the end B. The sloping sides, D B, B C, are covered with a white reflecting surface (white paper or finely-ground porcelain), so that when D C is pushed into the end B, one white surface, D B, may be illuminated (as in fig. 2) by the candle, and the other surface, B C, by the lamp. If the eye-piece A is removed, the observer, looking down the tube G B, will see at the end a luminous white disc divided vertically into two parts, one half being illuminated by the candle E, and the other half by the lamp F. By moving the candle E, for instance, along the scale, the illumination of the half D B can be varied at will, the illumination of the other half remaining stationary.

The eye-piece A (shown enlarged at fig. 3) will be understood by reference to fig. 1, the same letters representing similar parts. At L is a lens to collect the rays from D B C (fig. 2), and throw the image into the proper part of the tube. At M is another lens, so adjusted as to give a sharp image of the two discs into which I is divided by the prism K. The part N is an adaptation

of Arago's polarimeter; it consists of a series of thin plates of glass, capable of moving round the axis of the tube, and furnished with a pointer and graduated arc (shown at A G, fig. 2). By means of this pile it is possible to partially polarize the rays coming from the illuminated discs in one or the other direction, and thus bring to the neutral state the partially polarized beam *c d* (fig. 1) so as to get the images *g r* free from colour. It is so adjusted that when at the zero point it produces an equal effect on both discs.

The action of the instrument is as follows:—The standard lamp being placed on one of the supporting pillars which slide along the graduated stem (fig. 2), it is adjusted to the proper height, and moved along the bar to a convenient distance, depending on the intensity of the light to be measured; the whole length being a little over four feet, each light can be placed at a distance of twenty-four inches from the disc. The flame is then sheltered from the currents of air by black screens placed round, and the light to be compared is fixed in a similar way on the other side of the instrument. The whole should be placed in a dark room, or surrounded with non-reflecting screens; and the eye must also be protected from direct rays from the two lights. On looking through the eye-piece two bright discs will be seen, probably of different colours. Supposing E represents the standard flame, and F the light to be compared with it, the latter must now be slid along the scale until the two discs of light, seen through the eye-piece, are about equal in tint. Equality of illumination is easily obtained; for, as the eye is observing two adjacent discs of light, which pass rapidly from red-green to green-red, through a neutral point of no colour, there is no difficulty in hitting this point with great precision. It has been found most convenient not to attempt to get absolute equality in this manner, but to move the flame to the nearest inch on one side or the other of equality. The final adjustment is now effected at the eye-end, by turning the polarimeter one way or the other up to 45°, until the images are seen without any trace of colour. This will be found more accurate than the plan of relying entirely on the alteration of the distance of the flame along the scale; and by a series of experimental adjustments the value of every angle through which the bundle of plates is rotated can be ascertained once for all, when the future calculations

will present no difficulty. Squaring the number of inches between the flames and the centre will give their approximate ratios; and the number of degrees the eye-piece rotates will give the number to be added or subtracted in order to obtain the necessary accuracy.

The delicacy of the instrument is very great. With two lamps, each about twenty-four inches from the centre, it is easy to distinguish a movement of one of them to the extent of 1-10th of an inch to or fro; and by using the polarimeter, an accuracy considerably exceeding that can be attained.

The employment of a photometer of this kind enables us to compare lights of different colours with one another, and leads to the solution of a problem which, from the nature of their construction, would be beyond the powers of the instruments in general use. So long as the observer, by the eye alone, has to compare the relative intensities of two surfaces respectively illuminated by the lights under trial, it is evident that unless they are of the same tint it is impossible to obtain that absolute equality of illumination in the instrument which is requisite for a comparison. By the unaided eye one cannot tell which is the brighter half of a paper disc illuminated on one side with a reddish and on the other by a yellowish light; but by using the above-described photometer the problem becomes practicable. For instance, on reference to fig. 1, suppose the disc D were illuminated with light of a reddish colour, and the disc C with greenish light, the polarized discs *d d* would be reddish, and the discs *c c'* greenish, the central disc *c d* being of the tint formed by the union of the two shades. The analysing prism K and the selenite disc I will detect free polarization in the disc *c d*, if it be coloured, as readily as if it were white; the only difference being that the two discs of light *g r* cannot be brought to a uniform white colour when the lights from D and C are equal in intensity, but will assume a tint similar to that of *c d*. When the contrasts of colour between D and C are very strong—when, for instance, one is a bright green and the other scarlet—there is some difficulty in estimating the exact point of neutrality; but this only diminishes the accuracy of the comparison, and does not render it impossible, as it would be according to other systems.

No attempt has been made in these experiments to ascertain the exact value of the standard spirit-flame in terms of the parliamentary sperm candle. Difficulty was experienced in getting two lots of candles yielding light of equal intensities, and when their flames were compared between themselves and with the spirit-flame, variations of as much as 10 per cent. were sometimes observed in the light they gave. Two standard spirit-flames, on the other hand, seldom showed a variation of 1 per cent., and had they been more carefully made, they would not have varied 0.1 per cent.

This plan of photometry is capable of far more accuracy than the present instrument will give. It can scarcely be expected that the first instrument of the kind, roughly made by an amateur workman, should possess equal sensitiveness with one in which all the parts have been skilfully made with special adaptation to the end in view.—*Quarterly Journal of Science*.

## ON SOME NEW EXPERIMENTS ON LIGHT.

BY J. H. GLADSTONE, PH.D., F.R.S.

THE *Chemical News* reports a lecture at the Royal Institute, by Dr. Gladstone, from which we make some extracts.

The speaker commenced by referring to the fact that we are constantly making new experiments or observations on light: in fact, all seeing is but a comparison of different degrees of light and shade, and the contrast of colours. Most of the rays that meet our eyes from surrounding objects are reflected rays, but some of the commonest things, such as the water-bottles and tumblers of cut-glass on our dining tables, exhibit beautifully the bending, the magnifying, the diminishing, and the production of coloured fringes, due to refraction. The purpose of this discourse was to rise from the simplest phenomena of this kind to a consideration of refraction-equivalents, and to describe the state of our present knowledge in regard to them.

By means of the electric lamp it was shown that a piece of glass, or other transparent body, will throw a perfectly black shadow if the two surfaces through which the ray passes be not parallel; that the light is then bent on one side, and at the same time spread out into its component colours; that this bending (refraction) varies with the amount of inclination

of the two surfaces to one another, but in such a way that the sine of the angle of refraction bears a constant ratio to the sine of the angle of incidence; that this constant number, termed the index of refraction, or  $\mu$ , belongs only to the one substance, each solid, liquid, or gas, having its own index; that there is no necessary connection between the amount of refraction and the length of the spectrum (dispersion) caused by different substances, whether gaseous, liquid, or solid—for instance, a solution of an iodide always disperses more than a solution of the chloride of the same metal, even though it be diluted to the same amount of refraction.

This index of refraction is affected by change of temperature. In liquids, and probably in all gases, the bending decreases as the thermometer rises; in solids, on the contrary, as lately shown by Fizeau, the change is in the opposite direction, crown glass always remaining the same, and fluor spar being the only case where he observed a diminution. This was experimentally demonstrated in regard to liquids. Thus a yellow sodium ray, which had passed through a hollow prism filled with oil of nutmeg, and thence through another filled with bisulphide of carbon, moved some inches along the screen when the nutmeg oil was warmed a few degrees by stirring it with heated iron wire. This index of refraction is still more materially affected when a body passes from the solid to the liquid, or from the liquid to the gaseous condition: a fact that was illustrated by the visibility of the water melted in crystalline spaces in the middle of a block of ice.

The index of refraction of a mixture is moreover not always the mean of the indices of its constituents. Thus a ray passed successively through two hollow prisms filled with equal quantities of alcohol and water respectively, fell on the screen in a certain position; but when the two liquids were mixed together, and divided between the two prisms, the ray was visibly refracted to a greater distance.

These changes depend on the alterations of volume which the substances undergo; and the speaker, in conjunction with the Rev. T. Pelham Dale, had observed in liquids that the index of refraction, minus unity, divided by the density (in symbolic

language  $\frac{\mu-1}{d}$ ) is constant for all temperatures, and for all mix-

tures, or rather that the coincidence is very close, but not quite perfect, on account of some other law not yet understood. This conclusion has been abundantly verified by Landolt of Bonn, Ketteler, and Wüllner, and the former experimenter has founded upon it a method of analysing mixtures of liquids.

This unchangeable number was termed the "specific refractive energy" of the substance, and it seemed to hold good, notwithstanding a change from the solid to the liquid or the gaseous condition. It was early observed that the specific refractive energy of a compound bore a close resemblance to the mean of the specific refractive energies of its components. Landolt, by multiplying this number by the chemical equivalent, facilitated the calculation greatly. He termed this new

number the "refraction-equivalent,"  $P = \frac{\mu-1}{d}$ , and proofs have

rapidly accumulated that the number is little affected, not only by temperature, change of aggregate condition, mixture, or solution, but even by strong chemical combination.

Thus diamond, which is crystallized carbon, has the refraction-equivalent 5.0; sulphur has 16.0. Bisulphide of carbon,  $CS_2$ , which is nearly the most refractive liquid known, should therefore be represented by  $5 + 2 \times 16$ , that is, 37.0. The experimental number is 37.3. But the diamond will burn in oxygen, and is thus converted into carbonic anhydride, while it is possible to reduce this gas into another containing only half the amount of oxygen, namely, carbonic oxide. The refraction-equivalents of these gases, as deduced from Dulong's observations, are respectively 10.03 and 7.53; but the difference between  $CO_2$  and CO is one equivalent of oxygen, and the difference between the above numbers is 2.5. This, then, may be taken as the refraction-equivalent of oxygen, and subtracting it from  $CO=7.53$  we have remaining  $C=5.03$ , practically the same number as that obtained directly from crystallized carbon. Similarly, but generally by more indirect methods, it has been determined that this element, whether pure, as diamond, or combined with other elements, to form gases, as the above-mentioned, coal-gas, or cyanogen; or liquids, as chloride of carbon, benzole, oil of turpentine, alcohol, or ether; or solids, as paraffin, sugar, or camphor, is still exerting the

same influence on the rays of light that set its particles in motion, an influence that we can express by the number 5.0. Again, to revert to sulphur, the two salts, sulphocyanide and cyanide of potassium (K S Cy and K Cy) differ by one equivalent of this element, and their refraction-equivalents as determined from their aqueous solutions are respectively 33.4 and 17.1, numbers differing by 16.3, a number almost identical with that reckoned from molten sulphur. In this way the refraction-equivalents of a large number of the elements have been determined, and the following table comprises what seem the most probable numbers among those that have been hitherto published by Landolt, Haagen, and Schrauf, as well as the speaker:—

	Atomic-weight.	Refraction-equivalent.
Hydrogen ...	1.0	1.3
Chlorine ...	35.5	9.8
Bromine ...	80.0	15.7
Iodine ...	127.0	24.4
Oxygen ...	16.0	3.0
Sulphur ...	32.0	16.0
Carbon ...	12.0	5.0
Silicium ...	28.0	6.2
Nitrogen ...	14.0	4.1
Phosphorus ...	31.0	18.5
Arsenic ...	75.0	16.0
Antimony ...	122.0	25.7
Vanadium ...	51.4	25.4
Sodium ...	23.0	4.9
Tin ...	118.0	15.2
Copper ...	63.4	11.2
Mercury ...	200.0	21.6

The above numbers are reckoned for the red ray. Most of them as yet claim to be considered only as approximative; and it seems certain that some elements, as oxygen and sulphur, have more than one refraction-equivalent.

Vanadium, though included in the above table, has only just been determined, and that from the oxytrichloride which Professor Roscoe exhibited a few weeks before. It is interesting, as it supports his theory of the close analogy of phosphorus and vanadium, for these two bodies, with sulphur, exceed all others in refraction, and especially in dispersion.

The speaker stated that he was now engaged in examining the effect of salts in solution on the rays of light, and that he hoped to determine in this way the refraction-equivalents, not only of a multitude of salts, but of the metallic elements themselves.

## Proceedings of Societies.

### PHOTOGRAPHIC SOCIETY OF MARSEILLES.

THE usual monthly meeting was held on the 8th ult., Mr. A. TAYLOR in the chair.

The minutes of a previous meeting having been adopted,

M. COCHET presented to the Society a number of fine proofs of the monuments of Nîmes, some of which were of large size, and stated that they were produced by the Triple and Rectilinear lens of Dallmeyer, upon the perfection of which instruments he spoke in high terms, and stated that from the contracted space it would have been impossible to obtain them without a lens of wide-angle yielding straight lines.

After some conversation on the Woodbury process,

Mr. TAYLOR (the Chairman) exhibited some specimens of Swan's Carbon Process, and also Mr. Wharton Simpson's work on Carbon Printing. The specimen excited much admiration.

M. VIDAL said if such beautiful and stable results could be obtained by this process, and they had before seen some of equal excellence, it was surprising that such comparative indifference to the process continued to exist in France, and hoped that they would soon imitate the example of their foreign confreres.

Mr. TAYLOR said he had recently visited England, where he saw many fine specimens of carbon printing, and understood that it was being tolerably generally adopted. He had had the pleasure of seeing and conversing with Mr. Wharton Simpson, who, in speaking of the various new processes, had mentioned, as a means of overcoming the difficulties of using ordinary gelatine in hot weather, the probable advantage of employing

a vegetable gelatine which did not readily become fluid, even at a high temperature. This gelatine was used for culinary purposes in Java, and retained its solid gelatinous form in very hot weather.

M. VIDAL, who had made trial of this vegetable gelatine, believed that in addition to the advantage named it would give still more delicate results than the ordinary gelatine, and hoped to communicate some further results at the next meeting of the Society.

The COMMITTEE charged with the examination of the *Sel Clement* stated the results of experiments. It was, they said, more economical than the ordinary nitrate of silver, as the inventor had affirmed, and that was an essential point of superiority. The proofs required, they thought, a little longer exposure, but they came out very well and very regularly. By using twenty per cent of *Sel Clement* some time was gained as regarded the exposure, and there was still a notable economy compared with the ordinary nitrate employed at fifteen per cent. As regarded the preservation of whiteness in the paper, there was also an advantage, as the paper prepared by the Committee continued white for five or six days without any especial means taken for the purpose, while those examples which were kept enclosed showed no alteration at present, after a lapse of more than fifteen days. The Committee, therefore, did not hesitate to advise the use of that salt as really advantageous, and they recognized the truth of the assertion made by M. Clement in support of his invention. Without occupying themselves with the matter on a chemical question, it was more important to ascertain whether it was practical, if there was economy in it, and, as to the paper, whether it preserved its whiteness. On these two points the Committee had concluded in the affirmative.

M. VIDAL placed upon the table some specimens of the *Carrier* paper, sensitized and unalterable. He was happy to state that M. Carrier had arranged for the manufacture of his sensitive paper. He hoped that until the carbon process became more general that paper would render great service to the art of photography. It was to be desired that local depôts should be established, in order that when a few sheets were required they need not have to send to Paris for them. For the negative photometer, and for the photometer used in carbon printing, those sheets would prove valuable auxiliaries, because they preserved their whiteness for years. M. Vidal was pleased to testify that the specimens which he had in his possession for a long period remained without the least alteration, either in their colour or in the sensitiveness. When used for printing proofs, the paper gave fine blue blacks in a bath thus composed:—

Water ...	700 cub. centimetres
Chloride of gold ...	1 gramme
Water ...	500 cub. centimetres
Sulphocyanide of ammonia	100 grammes

Mix these two solutions in equal parts for whatever quantity may be required. If too much chloride of gold be used the image becomes too blue. It is necessary to print deep in the pressure frame.

The proceedings then terminated.

## Correspondence.

### PHOTOGRAPHIC NOTES ON THE CONTINENT.

[FROM A SPECIAL CORRESPONDENT.]

Vienna, 6th August, 1868.

Down the Danube, from Linz to Vienna, the country is very different to that about Passau. Instead of the forest scenery and densely-wooded slopes which shut in the river on both sides above Linz, the banks of the stream are studded with thriving villages, large well-built convents, and picturesque ruins. The panorama is certainly as fine, and, perhaps, more varied than that of the upper Danube, where the banks are not so much cultivated nor so populous inhabited. At one part, about midway between Linz and Vienna, called the Donau Wirbel, there is a very strong rapid, and here the view is particularly beautiful. On approaching Vienna the village and convents assume a more Eastern aspect, and the spires and steeples of the larger

buildings are ornamented with the peculiar Turkish or Russian domes and cupolas.

The Danube does not actually flow through the city of Vienna, or "Emperor town," as it is called in Germany, but passengers on entering the Austrian metropolis by water are conveyed thither by a canal leading from the river. The town is just now in holiday garb, for the *Schützen Fest* is being held here, and the streets are full of riflemen in their picturesque shooting coats faced with green. Flags are planted along the principal thoroughfares, military bands are continually parading the streets, and *fêtes* of all kinds are going on. Fifteen thousand foreign riflemen are said to have assembled from the different European countries and America, and the *Schützen-halle*, or shooting hall, which I visited on Monday last to hear some of Strauss' far famed music, is probably one of the finest and largest temporary buildings that was ever erected.

Passing to matters photographic, I may mention that I have visited several of the studios in the town. M. Ludwig Angerer, the royal photographer, whose charming group pictures are well known in England, possesses three studios in the town, one of which, viz., that specially employed for taking carte and cabinet pictures, I had the pleasure of visiting. It is situated in the Johann Gasse, in the busiest part of the town, plenty of side and top light being available, and the greater portion of the glass room being furnished with blue glass. The dressing-rooms are very conveniently situated on the same floor as the studio—just behind the screens—so that the sitter has but a very short distance to come. Cabinet portraits seem most in demand, and M. Angerer disposes of them at the very reasonable rate of ten shillings the half dozen. I saw several portraits taken, mostly of riflemen, all managed in a very prompt and skilful manner. The printing, mounting and similar manipulations are not carried on in this studio, but are confined to another building devoted specially to that class of work. The lenses used by M. Angerer are mostly those of Dallmeyer and Voigtländer.

The studio of M.M. Rabening and Monkhoven I was likewise permitted to visit; and here, again, I found the favourite style of portraiture to be the cabinet, excepting, of course, the enlargements, which are a speciality of this firm. For the last description of photographs a laboratory has been fitted up, in which the manipulation of large sheets of paper is proceeded with. One of the tanks used for developing, toning and fixing measured  $4\frac{1}{2}$  by  $6\frac{1}{2}$  feet, and there were besides, several other baths of somewhat smaller dimensions. All the collodion employed, as likewise all the chemical preparations used by the firm, are compounded on the premises, and by this means an exceedingly regular system of working is insured. The glass room possesses but little side-light, but is provided with illumination mostly from the top. The portion of the room in which the camera is placed, and where the operator stands, is almost in utter darkness; in fact, so much so, that the plate may be sensitized or developed in the dark-room leading from this part of the studio without the door of the laboratory being closed. The dark room is always kept at an even temperature, a stream of cold water being allowed to flow into the room during hot weather, and artificial heat employed in the winter months. The horizontal bath is used for the sensitizing, and the vertical bath for the fixing of plates. It is the custom to intensify after fixing, and finally to fix again, whereby the negatives are said to gain in brilliancy and transparency. No other lenses but those of Dallmeyer are used.

I was shown Dr. Van Monckhoven's enlarging apparatus in working order, magnifying a carte-de-visite picture upon a screen three feet long. The pictures are produced direct, and not by development, except in very bad weather, hard pictures being produced upon nitroglucose paper, and soft ones upon salted paper. With a good light, an enlargement is produced in a quarter of an hour, without having recourse to any accelerating process, such as the use of ammonia vapour, &c. The original carte negative, from which

the enlargement is taken, is left unvarnished, and is never intensified.

The show of photographic portraiture in the streets is remarkably fine, and certainly equal to that of Paris. The specimens exhibited by Dr. Heid, M.M. Mahlknecht, Luckhardt, Lowy, Adele, and others too numerous to mention, are certainly very superior, and the prices asked in most cases are remarkably reasonable. Of the minor class of photographers there appear to be but few in Vienna.

Ischl, 8th August, 1868.

Beautiful Ischl, situated in the middle of the most sublime scenery of the Salzkammergut, is the spot from which I write these lines. As it is the most fashionable watering place of Austria, and the favourite resort of the Empress, I was in the hopes that, in common with our own Spas, the town would contain one or two photographers of note whom I might pick up a few stray hints. As I have not, however, yet seen anything worthy of mention, I shall defer any further remarks until I reach Salzburg.

## Talk in the Studio.

**NORTH LONDON PRESENTATION PRINT.**—The North London Committee appointed to select the presentation print, have been enabled, through the liberal terms at which the most suitable prints were offered by the producers, to offer to the members the two best prints submitted for competition. One is a magnificent 12 by 10 figure subject, by Mr. Lake Price, entitled "The Falconer," and the other a 16 by 12 landscape, with wondrously fine clouds, by Mr. N. K. Cherrill. It is hoped that the prints will be ready for distribution at the first meeting of the Session in October next.

**THE FORTHCOMING ECLIPSE.**—As our readers know a total eclipse of the sun, of a very remarkable character, will take place on the 18th, not visible, however, in this country as the central line will pass just south of Arabia, across India and the northern part of Borneo to the northern limit of Australia. The central eclipse begins at half-past three in the morning of Tuesday. This eclipse possesses unusual features of interest. The greatest possible radius of the circular shadow of the moon thrown on the earth careful computation gives as 174 miles. An eclipse of this extent cannot happen once in many thousands of years, nor can one happen often which approaches even closely to the conditions required to make the duration of total darkness the greatest possible. In the great eclipse of the next week nearly all the conditions which tend to increase the moon's shadow are nearly fulfilled. At the place which is most favourably situated the total eclipse will last six minutes fifty seconds. The exact position of this spot is in longitude east from Greenwich 102 deg. 50 min. 6 sec., and north latitude 11 deg. 35 min. 7 sec. As our readers know several observing expeditions will visit the best points of observation. Two expeditions, well provided with instruments, have proceeded from this country to India for the purpose of observing this great eclipse. The first, organized by Major Tennent, has been sent out under the auspices of the Royal Astronomical Society. The second has been sent out by the Royal Society, under Lieutenant John Herschell, son of Sir John Herschell. Mr. Pogson, superintendent of the Madras Observatory, will head a third expedition. France has sent out M. Jansen at the head of a well-appointed expedition. Prussia has sent Dr. Vogel and others to Aden; and the Pope sends out the Jesuit priest and astronomer, Father Secchi.

**M. BRAUN'S REPRODUCTIONS.**—The excellent photographic reproductions of the art treasures of Continental galleries by M. Braun, are well-known, and it is stated that he contemplates a visit to England for the purpose of reproducing the rare works comparatively buried in this country. English photographers should look to it that the laurels be not shorn on their own ground. The *Journal of the Society of Arts* speaks in high terms of a highly-interesting portfolio of photographic reproductions in pigment printing of designs by the old masters, belonging to the various museums in Europe. The work includes nine hundred designs from the Louvre, eleven hundred pieces from the Albertine of Vienna, one hundred and fifty pages from the collection of the Grand Duke of Saxe Weimar, and several hundred drawings from the little-known Uffizi collection, at Florence. M. Braun, it states, has lately pro-

duced, at Milan, copies of the Ambrosienne entire, with the eighty drawings by Leonardo de Vinci, and the cartoon of Raphael's "School of Athens;" at Venice he has reproduced more than three hundred of the designs in the Academy of the Beaux Arts; at Florence he has photographed the most remarkable examples of sculpture, ancient and modern.

**TRANSPARENT METAL.**—From one of our German exchanges we copy a statement that a transparent metal has been discovered, the component parts of which are water-glass and copper: "It is of a deep orange hue, can be melted and cast, wrought under the hammer, and rolled. Files will not scratch it; it is translucent, and capable of being wrought into ornaments of rare beauty." Evidently a chemical canard, unworthy of serious notice.—*Scientific American*.

**OPAQUE GLUE.**—Dr. Vander Weyde, writing to the *Scientific American* says:—"I see a recipe of a correspondent for making opaque glue, which is as injurious to the glue as the bone dust proposed for that purpose in a former number. Bone dust being gritty and not mixing with the glue spoils it entirely. I find by analyzing a specimen of very white opaque glue of excellent quality, that the white substance is nothing but carbonate of lime very finely divided, probably introduced in the form of the so-called Paris white. I find in trying the mixture of this substance with glue, that it has two effects beneficial to the manufacturer: first, in giving a dark coloured glue a lighter shade and thus presenting an appearance of a higher priced article, and, second, in adding to the weight of the glue by the addition of a substance only about one tenth of its value. The beauty of this adulteration is that the sticking qualities—which are of course the only ones the consumer cares for—are not in the least deteriorated, but, on the contrary, seem improved."

## To Correspondents.

**HENRY BERLON.**—Herr Grasshoff's address is 51, Behren Strasse, Berlin. We should think Mr. Trubner would order the work for you. Herr Grasshoff is an artist, and himself retouches negatives. Herr Lindner produced and retouched the negative a print from which was issued in a recent number of Dr. Vogel's *Mittheilungen*.

**REV. J. H. JOHNSON.**—We will submit the queries to Mr. Bovey. For our own part, we prefer the use of a little carbonate of lime when the gold salt shows any trace of acidity. As a rule, however, when the double chloride of gold and sodium is used there need be no excess of acid at all.

**HENRY WILLIAMS.**—We believe that collodio-chloride of silver is supplied by most dealers. Messrs. Mawson and Swan, Huggon and Co., and some others prepare it. You will find instructions for making and using it in our YEAR-BOOK. 2. We do not know of any agent for Obernetter's paper in this country.

**MORPHINE.**—There is a special form of printing-frame made for printing transparencies on dry plates from uncut negatives, permitting the necessary movement of the plate. A very good one was devised by Mr. Smith, of Negretti and Zambra's, and may doubtless be obtained of that firm. If you print on wet collodion in the camera no cutting is necessary, as the requisite transposition of the images is necessarily made in the camera, by each half being practically turned round on its own axis. 2. We are not in possession of the information in reference to Cook's apparatus which you require.

**W. J. A. G.**—It is illegal to make copies, for your own amusement, of copyright pictures. The fact that a sale is generally proved in order to secure conviction arises from two circumstances: first, it is generally the easiest mode of proving delinquency; and, second, because the actual producers are rarely caught; the dealers only, as a rule, come within reach of detection. Very few proprietors of copyright would, we apprehend, take the trouble to prosecute an amateur whose copies were *bona fide* for his own amusement only. But the terms of the Act are stringent. It enacts that if any person not being the owner of a copyright shall, without consent of the owner, "repeat, copy, colourably imitate, or otherwise multiply for sale, hire, exhibition, or distribution," he shall forfeit a sum not exceeding ten pounds for each offence. 2. A mixture of glycerine and water may be used instead of golden syrup and water.

**HENRY WILCOX.**—All the manipulations in Mr. Gordon's gum process, as described in our YEAR-BOOK, remain precisely the same, except the use of the iron developer instead of that at first prescribed. 2. Drain upright on clean blotting-paper. 3. A changing box for 12 by 10 plates would be costly, and perhaps a little difficult to manage. Double backs would be best; or a changing bag might be managed possibly. 4. The rapid rectilinear lens is not intended for studio work, but would probably be as rapid as the single wide angle for landscape work. 5. For enlarging, your No. 1 will answer well, and will be most convenient. 6. No. 1 in answering our correspondents, we have undertaken a duty which a very lengthened experimental and practical acquaintance with

almost every branch of photography has rendered easy and pleasant to us, and we do not, therefore, get tired of what you term the "eternal interrogatories" put to us.

**J. BARRATT.**—Registration will protect a design or shape, but it will not protect a principle, nor will it protect anything dependent on the working together of parts. A patent is required for such protection. Whether registration will serve your purpose or not we have not data before us to determine. The protection of registration can only extend for three years. It is of course much cheaper than a patent, only costing three or four pounds.

**SPECULA.**—Your concentrated nitrate of silver solution having been in the sun during the hot months which have elapsed since Mr. McLachlan's communication ought now to be ready. The next step is to proceed exactly in accordance with his instructions as to iodizing, dilution, and rest for a few days, until any excess of iodide of silver is re-precipitated. The only modification in which you can do justice to the author of any process is to follow implicitly his own directions.

**D. W. S.**—Unless you have some skill in colouring you will scarcely succeed in colouring glass transparencies for the magic lantern; and if you have any skill you will succeed best with the medium to which you are most accustomed, whether oil or water. If you wish to use aniline colours you will find it best first to give the transparencies a varnish of dilute albumen, about 1 part white of egg and 4 parts water. This varnish will also aid you in using ordinary water colours.

**ENGINEER.**—The article in our YEAR-BOOK practically contains all the information which has been published on Mr. England's dry process. On p. 187 of our last Volume you will find his communication to the Photographic Society on the subject; and in the early part of the same Volume many communications and comments from other contributors, but we do not remember that any of these contain more details than Mr. England himself has communicated. The trustworthiness of the process is best avouched by the fact that Mr. England brought home from his last summer's tour 300 perfect negatives.

**T. F.**—We have once met with a similar case to that in the spotted example you enclose. It arose on that occasion from prints being left a long time in water without movement or agitation. The prints which had floated to the top of the water looked spotted with dust, and on sponging the surface it was found to be covered with spots in which the albumen was removed, as in the example forwarded. It was clear that the long soaking with, possibly, the action of lime salts in the water, possibly some atmospheric deposit from the operating room, had induced a decomposition of the albumen surface, dissolving it at the points of contact; but the precise cause we are unable to indicate. The yellow stain on the print is due to imperfect fixation, probably from the print sticking to another print or to the side of the dish in fixing.

**PHOTO-LITHO.**—Your specimens are very good for a young hand; but they possess the defects most common to photo-lithography; that is, a certain rottenness in the fine lines and a want of rich depth in the blacks. What is the nature of the process you employ? We shall be glad to hear of your progress and see more of your work.

**R. T. S.**—You will find the description in question on p. 38 of our Fourth Volume. The principle involved preserves the water and the print constantly in motion, and keeps a fresh supply of water constantly running in, whilst the old water is emptied by a siphon.

**DR. P. LIESEGANG.**—Many thanks. We will write soon. We have not received the last number of the *Archiv* containing the formula you mention. The last which has reached us is No. 137. Will you kindly forward us the number in question.

**T. JONES.**—We are not aware of any agent for the Obernetter paper in England.

**ELECTRO.**—The journal styled the "Electrician" has, we understand, been discontinued for some years.

**Q.**—The statement is not true. The resolution was passed without a single dissentient. Neither of the gentlemen named either moved or seconded the resolution. 2. Yes; your conjecture is probably correct; imaginary existences; but we cannot go into the matter here.

**IGNORAMUS.**—The back of the plates is to be painted after the preparation is complete, and before exposing of course. It is because the sensitive film is very transparent, and therefore the plates are liable to the defect which has been erroneously styled "blurring."

2. The paint is of course washed off after exposure. If the alkaline developer is used, the image is brought out by the combined action of pyro and ammonia; but if you consult Mr. Gordon's recent article you will find that he recommends iron development. Your letter was not in time for an answer in our last.

**DR. PHIPSON.**—Received: "Sur l'application de certaines propriétés optiques des corps à analyse Chimique des substances minérales et des substances organiques, par M. le Docteur Phipson." Many thanks.

**G.**—An angle of 45° answers well; but a little modification is not of importance. It is important to secure a good pitch to throw the water off in wet weather, and prevent a tendency to leakage.

**ANXIOUS.**—You do not state on what point you require an opinion. The negative appears to have been taken in a dull light, and is thin and lacking in vigour, partly from bad light and partly, probably, from the quality of the collodion.

Pictorial Effect in Photography. By H. P. Robinson.....	402		

### MONS. ADAM-SALOMON IN LONDON.

MONS. ADAM-SALOMON has just returned to Paris, after a week or two spent in London, and we have had the pleasure of spending a good deal of time in his company, listening to his remarks on the art and practice of photography. We have also had the good fortune to receive further examples of his charming portraiture, some of which exceed, if possible, any of the wondrous pictures which we have before noticed, and which some of our readers have had opportunity of examining.

Here we have a portrait of a noble little fellow, in a half-sitting, half-reclining position, the treatment of which was suggested, M. Salomon informs us, by a picture by Sir Thomas Lawrence—probably the portrait of Master Lambert. Every part of the picture seems literally perfection. Whilst the general effect is one of extreme vigour, richness, and relief, on examining the details every part is found full of the most exquisitely delicate half-tone and modelling. A fair child, with profusion of light hair, a light dress, large white collar, white cuffs, and white stockings, there is nevertheless not a point so large as a pin's head of pure white in the picture, fine half-tone marking the gradations of every white object, the texture and colour of each being rendered by tones very distinct from those of the fair flesh, every portion of which is most perfectly modelled. The grace, ease, simplicity, and naturalness with which the child rests his fine head on a pretty hand, and the sweet unconsciousness of his expression, cannot be well described, but they are such as satisfactorily illustrate the fitness of photography, under favourable circumstances and in capable hands, for producing the highest art results in this direction. The composition and chiaroscuro of the picture seem simply faultless.

Another picture, of a totally different subject, is also a fine example of a similar kind of treatment, securing perfect gradation of tone, detail, texture, and modelling in light materials, without a single patch of white. This is a portrait of a lady, a brunette, with dark eyes and hair, in a white dress of tulle trimmed with white satin. Every undulation of every fold; every thread, in fact, in the light, soft, flowing drapery is perfectly rendered; every play of light and reflected light in the satin trimmings perfectly registered; but everything is full of tone: except a glancing light here and there, no patch of white is present much larger than the sparkling point of brightness on the pearls on the lady's bracelet. All this is secured without any sacrifice of perfect detail and richness in the dark hair and the dark accessories in the picture, the whole being singularly harmonious. We have not often seen a photograph which so thoroughly illustrated the possibility of a degree of perfect lighting rarely attained. On examining every part of this picture, it would seem as if the light had been especially arranged to secure relief in that part. The delicate

white arm which rests against the white dress is a perfect study of modelling and roundness, so nearly like the dress in colour, yet so different in texture, and so boldly in relief, it would seem, on examining it, as if the light had been arranged for that effect alone; yet further examination proves every other part of the picture as perfectly lighted and effectively rendered in its kind.

It is not a little singular that whilst great brilliancy is the first quality which strikes an observer in M. Salomon's pictures, yet the study of tone and harmony is that which mostly engages his attention. In speaking of tone here we do not mean tint or colour, but of fullness of gradation throughout the picture. No degree of vigour or of mis-called brilliancy obtained by great contrasts of black and white could compensate, in his estimation, for the absence of harmony. We were strongly reminded, in a conversation with him, of some remarks of Mr. Rejlander's on the same subject. If, by any chance, he remarked, it was necessary to print from a hard negative, he would prefer to expose the paper to the light for a minute or two, in order to degrade the tint, and so reduce the scale of tones, rather than have a picture with crude contrasts of black and white not united by proper gradations of half-tone.

Whilst maintaining and so admirably proving the capabilities of photography for art expression, M. Salomon, in common with most men possessed of the faculty of creative art, feels deeply the tyrannical conditions and unplastic character which belong to photography. The photographer, he remarked, in endeavouring to produce a picture, is a slave to his light, his lens, his chemicals, his sitter; the perverseness or imperfection of any of these may defeat all his efforts to realize an idea and produce a work of art; and often, when exhausted and disappointed, he has retired for relief, rest, and tranquillity, to his sculptural atelier, where the modelling clay answered to every touch; no rigidly awkward muscles or perverse expression, no movement, no limited range of focus, no chemicals yielding only results out of all harmony with the aim of the artist, or giving negatives full of spots, streaks, or pinholes. Nevertheless, photography, with all its difficulties, is the subject of his intense enthusiasm, and its conditions, chemical and mechanical, are carefully studied, with a view to coax from it its most willing service to art purposes. He prepares his own collodion, and, in answer to a question as to the proportion of bromides and iodides he employs, we learn that he thinks it worth while to use constant variety to suit varying conditions of subject and of light. So also with his developer and with other controllable preparations. His most usual formula for developing is, however, as follows:—

Ammonia sulphate of iron	...	75 grains
Glacial acetic acid	...	75 minims
Sulphate of copper	...	7 grains
Water	...	3 ounces.

He is deeply interested in conversation with a company of photographers who surround him, and is readily communicative on all subjects connected with his experience in the art.

In printing, it is his practice to produce one impression from a negative himself, as a guide or pattern for his printer. If the negative require it, some portions are masked during printing with cotton wool, or sometimes with ground glass; small portions at the back of the negative are stopped out with transparent water colours, to retard in given degree the passage of light. Spots and pinholes are touched out, and occasionally, also, strongly-marked freckles; but beyond that there is no retouching on the negative.

*Apropos* of this question of retouching, an amusing incident occurred during his visit. A photographer of considerable position having heard that M. Salomon was in London, called upon him to pay a visit of courtesy and express appreciation of his pictures. In course of conversation he remarked that, of course, the pictures were retouched, and that much of their beauty was dependent on this fact, adding, "Of course I know it is said that this is not so, but strictly in confidence, and *entre nous*, touching is the great secret, is it not?" In reply to this, M. Salomon called for a sponge, and asked his visitor to take the print in immediate question—the Duke of Hamilton, we believe—to wash the print thoroughly, and remove the touching. This having been done without altering the character of the picture, the visitor expressed his conviction that the touching was upon the negatives. This M. Salomon assured him was not the case; with the exception of the stopping out little defects, his negatives were untouched. Where a print required it, such touching as might be desirable was, of course, applied, but that in no case were they worked up so as to change the character of the picture. Satisfied from his experiment that it was not to retouching the excellence of the print was due, the visitor hit on a very brilliant idea: he had discovered, he thought, the secret of success. Each print was the product of two negatives identical in contour, &c., but varying in intensity; one being taken for the delicate lights, and the other for the deep shadows. A print was then carefully produced by printing from the two negatives in succession! The idea is undoubtedly ingenious; but M. Salomon had not tried it; he thought it would be difficult, if not impossible, to succeed satisfactorily, and assured his visitor that his results were produced by ordinary appliances without intricate or secret dodges.

M. Salomon had the pleasure of meeting in London, by his especial desire, Mr. Williams, Mr. Robinson, Mr. Rejlander, Mr. Blanchard, Mr. Mayland, and some others whose work he knew and admired. To Mr. Williams he sat for a portrait, being the first photograph for which he had ever sat. Messrs. Lock and Whitfield also obtained a negative of him, a print from which we have not yet seen.

More than one photographer in London courteously offered to M. Salomon the use of studios during his visit, should he desire to produce photographs; but, with the exception of a day spent at Tinnbridge Wells experimenting in conjunction with Mr. Robinson, M. Salomon did not attempt photography in this country. Mr. Robinson obtained several fine large negatives of his visitor.

To the method of finishing the print with an eucastic paste M. Salomon attaches considerable importance. For that employed on his pictures he has promised to send us the precise formula, which we shall have pleasure in giving to our readers, as it varies in some respects from the recipes hitherto published. Some other communications from M. Salomon, to whose kindly and genial communications we are much indebted, we hope also to place before our readers shortly.

We shall be happy to show the new specimens to any of our readers who may call at our residence, and we have obtained M. Salomon's promise to send some further examples to the exhibition meeting of the Society in November next.

### THE AMERICAN BROMIDE PATENT.

A fortnight ago we announced that the application for a renewal of the bromide patent in the United States had been refused, and congratulated our American brethren on their final emancipation from a tax so irritating and iniquitous. A thirty-two page supplement to the *Philadelphia Photographer* puts us in possession of all the details of the case, both for the patentee and for the opposition, the latter having been chiefly managed by our friend Mr. E. L. Wilson, editor of the *Photographer*. As the matter possesses historic interest, a brief summary of the case will probably interest our readers.

The notorious bromide patent was obtained in America by Mr. James A. Cutting, of Boston, in 1854, and is dated July 11 of that year. The special claims in the specification are for two things: first, the displacing by alcohol of the water remaining in pyroxyline after it is washed, the collodion being, it is stated, more sensitive when the cotton is quickly dried; and, second, the use of bromide of potassium in collodion; the proportion given being  $2\frac{1}{2}$  grains of the bromide and  $2\frac{1}{2}$  grains of iodide of potassium, dissolved in a little water, to one ounce of collodion. It is worth noting that at the same time Mr. Cutting obtained two other patents for so-called improvements in photography: one for the addition of camphor to collodion, an addition, in our experience, rather injurious than otherwise; and another for cementing a glass over photographs by means of Canada balsam, an operation for which Mr. Ross had received the medal of the Society of Arts in this country years before. And it is further worthy of note that Mr. Cutting obtained a patent in England, on the 26th of the same month, in which was included the means of removing moisture from soluble cotton by means of alcohol, the use of camphor in collodion, and the cementing of glass over photographs by means of Canada balsam; but, oddly enough, in this patent there is no mention whatever of bromide, a circumstance which is very suggestive of some knowledge that at that time the value of bromides in collodion was too generally known in England to permit of the slightest chance of obtaining a patent for their use. Certain it is that in this country the use of bromides in collodion by some photographers was coeval with the discovery of the collodion process. The action of bromine in the Daguerreotype process and the effect of bromides in paper processes had been so well known for many years that it would scarcely have been possible to overlook their probable value in collodion. In the first treatises on the collodion process bromide is mentioned and recommended, and in the third number of the first photographic journal published in this country we find the use of bromides in collodion referred to, not as a novelty, but as a matter-of-course fact. At a meeting on the 5th of April, 1853, negatives were exhibited, in the production of which bromide of ammonium was employed, and the details were published; nevertheless, in America, in July, 1854, Mr. Cutting obtained a patent for the use of bromide of potassium, which has since been construed to mean any bromide.

This patent has been in operation during the last fourteen years, and enormous sums have been paid by American photographers for its use. One photographer alone, it appears, paid Cutting 10,000 dollars, and we find mention of the payment of various other sums amounting to upwards of 15,000 dollars. Cutting eventually parted with the bulk of his interest in the patent, finding great difficulty in enforcing it and in obtaining licence fees. The ultimate possessor, a Mr. Hubbard, has enforced it with much perseverance and shrewdness. The question of the validity of the patent has on several occasions come before the courts, but the cases have generally been compromised. The application for a renewal of the patent has been made by the executor of Mr. Cutting, who died in comparative poverty, it is stated, some time ago. He appears to have been a versatile genius, having latterly carried out to a large extent the "aquarial-garden business." He built and owned a boat

called the "Ambrotype," in which he used to make aquatic excursions to supply his garden with pickerel, horn-pouts, and whales; at one time he "ran" a Western saw-mill. He had various other patents: one for a beehive, one for a spark arrester, and one for a photo-lithographic process. The ground of the application for an extension was that Cutting had not derived sufficient remuneration for his invention.

The evidence by which the originality of the invention was sustained appears to have been weak and insufficient in the last degree, and it seems clear that if the case had ever been fairly brought to trial before that, the patent must necessarily have been proved invalid. The evidence of the opponents was very strong. One witness stated that he saw Cutting experimenting in 1853, and saw him refer to a book in which a bromide formula was published. Dr. Langdell, who was a partner with Cutting in 1853, gave evidence that at that date Cutting had not tried a bromide in collodion, and that he (Langdell) made the first trial, and communicated the result to Cutting. Dr. Cresson, of Philadelphia, a gentleman of high reputation as a chemist and expert, gave evidence of the use of bromides in 1852, pictures produced by their aid having been shown at the Franklin Institute at that date. A curious piece of evidence was introduced by this gentleman: he produced a bottle with its original label as follows:—

No. 10. Mo. 4—18, 1852.

Collodion	...	...	...	oz. j.
Iod. potassæ	...	...	...	gr. viij.
Brom. potass.	...	...	...	gr. IV.
Chlorid. sod.	...	...	...	gr. IV.
Water	...	...	...	m. 30
Absolute alcohol	...	...	...	m. 30

There is one piece of evidence for the opposition which is a little puzzling. Mr. F. Langenheim, an old photographer in Philadelphia, stated that in 1849 he used collodion, and employed salts of bromine in preparing it. As the recognized discovery of the collodion process by Archer was not published until 1851, this allegation by Mr. Langenheim requires some explanation or corroboration.

One of the most interesting documents connected with the case is the Report of Chief Examiner in the Fine Arts Department of the Patent Office, Mr. T. R. Peale. The original application for a patent was passed by this gentleman; but now, in the presence of fuller evidence, he distinctly states that Mr. Cutting was not the originator of the use of bromide in collodion, nor was he entitled to a patent for its use; and, further, that an extension of such a patent could not be granted without great injustice to the public.

After hearing the evidence, the character of which we have briefly indicated, it is not surprising that the Acting Commissioner of Patents refused the application for an extension, and American photographers will no longer be harassed by constant but irregular demands for payments of "room rights," demands which, being enforced by threats of legal proceedings, have often been paid simply to avoid the harass, risk, and loss of time inevitable in such suits. Without organization it is almost impossible to resist an imposition of this kind, and we congratulate our American friends on having secured a combination to defeat the attempt to extend an irritating impost, and on the able leadership under which this organization has been so successfully carried out.

### Critical Notices.

**HISTORICAL AND ARCHITECTURAL NOTES** on the Parish Churches in and around Peterborough. By the Rev. W. D. SWEETING, M.A. Illustrated with Photographs by WILLIAM BALL. (London: Whittaker and Co.; Peterborough: E. T. Hamblin.)

THE value of photography is rarely better illustrated than when it is employed in delineating architectural and archaeological subjects, for which its literal and minute truthfulness

so especially fit it. Mr. Ball's photographs in the volume before us give the work, we have no hesitation in saying—and without any underrating of the laborious care with which the text has been written—its especial value and interest in the estimation of readers, the actual pictured representation of each church before the eyes investing written description and parochial records alike with a degree of interest which must otherwise have been wanting.

There are few districts in England more rich in parish churches of historic interest than the Eastern Counties, and the Master of King's College School at Peterborough has done good service in furnishing a valuable contribution to archaeology and to local history in writing these notes, and in collecting and arranging the records before us. The volume is a handsome one, well printed and well got up.

### THE AMATEUR'S MANUAL OF PHOTOGRAPHY.

Edited by RICHARD KINGHAM. Fifth Edition. (London: Thomas Kingham.)

WE have before noticed this excellent manual in favourable terms. The fifth edition, now before us, is, we are informed, a reprint of the previous edition, no change or improvement of sufficient importance for notice having been made in photography since the issue of the fourth edition, fifteen months ago. The manual is a useful one throughout, and its value is much increased by the possession of several chapters on various subjects by Mr. Valentine Blanchard. The editor scarcely does his work full justice, by the way, in neglecting to append Mr. Blanchard's name to his articles where they appear in the text; with this exception we have nothing to say but commendation.

### PHOTOGRAPHIC PORTRAITS, By WILLIAM NOTMAN, of Montreal, Canada.

WE have been favoured by Mr. Notman with some further examples of large portraiture, treated in the manner known as characteristic of the portraits by M. Adam-Salomon. In most respects these pictures are very admirable; they are brilliant, forcible, and well modelled; rich, deep, and warm in tone; and fine in composition. The chief fault we have to find is the presence in some of a few chalky and spotty lights. M. Salomon, we may observe, saw them, and expressed considerable approval.

### PHOTOGRAPHIC PRINTING IN SILVER, THEORETICAL AND PRACTICAL.

By W. T. ROVEY.

#### ACTINISM: ITS VARYING CONDITION AND INFLUENCE ON TONING ACTION, ETC.

IN the experiences of photographers who have submitted to practical tests the formula presented with my last communication, discrepancies have, I am not in any way surprised to learn, occurred in the results arrived at; and I was quite prepared, when I invited communications on the subject, to find sceptics denouncing "new-fangled innovations," and pointing out the virtues possessed by the "bleaching solutions" whenever they chance to work aright, which being, as they prove, matters of uncertainty, afford evidence that their constitution is allied to empiricism; their principles are open to a fuller investigation. My readers will probably admit that the apparent novelty of my views on toning matters places me in a position of some considerable difficulty, as I am arrayed, single-handed, against matured ideas, deep-rooted prejudices, and, added to these, the published opinions of many very able experimentalists, who are justly regarded as authorities in all matters pertaining to photographic science. I have accepted the conditions freely, not in a spirit of bravado, but with a full consciousness of the purity of my motives, which aim to accomplish some amount

of good by ridding an art of the elements of uncertainty in at least one direction. Having anticipated some objections, I am prepared to encounter others, and am desirous that the theories I have already advanced, together with others I am about to offer, may be fully and exhaustively discussed, for I hold that he who aims at truth should cling to no pet dogmas that are found to be based on error; his mind should be ever open to conviction, and, if assailed by error, he may find comfort in the thought that an infant truth is at all times surrounded by a net-work of misconception—that a wise and natural law has so designed it.

If we trace the history of civilization as far back as the pen of the historian has spanned, we perceive the course pursued by progress impeded with ifs, buts, sophistry, and scepticism, and these retarding influences, seen as things to be wept over, until the mind embraces a wider field of vision, when it is directly perceived that the improved results justify every retarding cause, and make visible the link which connects each impediment with the grand scheme of progression, a scheme that finds in each adverse influence a wisely ordered power, devised to separate the chaff from the wheat, by upholding error until truth has undergone a searching scrutiny to remove every cause of doubt that would dim the luster of final victory. If the human mind was more credulous, less conservative, less prone to cavilling, less inclined to doubting and disputations, progress would admit of a wide definition and muddle; anomalies, wisdom, and folly would each in their turn afford the interpretation. But I am turning into the "sidings" of digression, so will embrace a starting point that will lead to new arguments and observations in connection with the subject of gold toning.

From the numerous communications I have received, having reference to the method of toning I recently explained, I presume the subject has been more or less studied; and where success has been attained, some amount of curiosity has been felt to ascertain why so small an amount of gold should work so effectively with comparatively so large a bulk of water; and, seeking the results so nearly resembling the products of an acetate bath when in its best "form," some have been prompted to speculate on the reason why of the coincidence. The tale is briefly told. My chloride of gold and sodium bath embraces the actual motive principles possessed by the acetate, carbonate, and every other form of soda baths where sulphur forms no part of the compound. That such is a fact is clearly shown by the arguments advanced in my last communication; and the real advantage possessed by the toning method I advocate is simply an entire absence of every retarding influence which exists in all other kinds of toning solutions, by reason of the excess of acetate, carbonate, or other compound of soda provided in their construction; an excess which not only occasions an immense waste of gold, but adds a greater evil in the elements of uncertainty it provides. But we need not dwell further on this point, as we have to enter at length on subjects of greater importance, and the first to be considered is described in the heading to this paper; viz., "Actinism: its varying conditions and influence on toning action."

Photographers who are engaged regularly, or at intervals, in printing operations must have observed the perplexing differences that occur in the quality of the prints they produce; sometimes rich and full of vigour, at other times poor, flat, and unpromising; sometimes printing a fine violet tint, at other times a briske red. Not unfrequently the prints seem to fly up "overdone" with surprising rapidity; more frequent still the printing proceeds tardily, and the resultant prints prove unsatisfactory, notwithstanding the light is brilliant and the weather promising. These changes are, as a rule, attributed to the paper, which is supposed to have been mixed by the dealer, and he is consequently condemned, whilst the true cause remains unsuspected. I have paid much attention to this subject during the present year, and my intimate knowledge of the paper I

use has assisted me in arriving at, I believe, a correct conclusion, viz., that the variety of results described are due to meteorological influences. More than this, I believe—and the belief is founded on careful and continuous observation—that the actinic condition of the atmosphere exercises no small amount of influence on the human body, especially when the nervous organization belongs to the sensitive order. When the chemical force is applied in fits and starts, like magnetic storms, the printing proceeds with irregular rapidity, and the prints are violet-colour, full of vigour, and behave in a peculiar manner in the toning bath, as I shall by-and-by describe. Under the conditions alluded to, a nervously organized individual experiences a strange irritation, and his or her temper is for the time being none of the sweetest. On the other hand, when the prints move slowly, and a bright light is present, our nervous friend experiences a lassitude, and is inclined to dejection; but when the printing moves comfortably fast, no matter what light, and the prints assume the depth and hue which portray a successful day's work, our friend is in good spirits and feels remarkably well. These observations on a person unconnected with photography convince me that actinism is electricity under another name. It is, doubtless, hidden from the most sensitive of electrometers, but may exist, nevertheless, in a latent form; just as latent heat causes no change on the thermometer, was concealed from philosophers until the splendid researches and discoveries of Dr Black were made known.\* The opinion I have formed is further strengthened by the behaviour of the toning bath when the batches of prints taken under the several conditions described are submitted to the action of my toning bath. The prints secured during the season of intermittent yet violent actinism tone with rapidity, and, except activity and care are observed, a case of over-toning ensues.

Mem.—To add a minimum quantity of gold when strengthening the bath. The condition of printing having at the proper time been observed, when the prints have been procured in the dragging manner before alluded to, toning action is slow. Mem.—To add a full amount of gold (3 to 4 grains, not over-dosed with hot water) to the solution. When the prints are in first-rate condition, and the bath not too strong with accumulated gold, the least given quantity of gold to be added to the bath, a full dose of boiling water to be applied. The remarks on prints of slow production apply to pictures printed in the direct sun; also to those printed when the atmosphere is excessively dry and hot, such as we have amply experienced during the present summer; for, be it remembered, the hygrometric condition of the atmosphere exercises a vast modifying influence on the character of the prints, over dryth being more injurious than over dampness, a proof of which is shown if we remove a piece of paper from a calcium drying-box and at once place it in the frame. I have found great advantage, when the paper was too dry, by placing it in an ordinary fuming-box, such as I described about three years ago, and placing damp sheets of blotting-paper at the bottom of the box in lieu of ammonia.

From the above remarks it will be perceived that to secure undeviating good results in printing operations the eyes of the printer must be kept wide open, and the conditions under which his day's work is executed should be keenly observed; and if he is of a philosophical temperament and able to accumulate information by the sense of touch as well as sight, let him note well the touch of his prints as they leave the toning bath. Your slowly produced batch of prints (when a bright but yellow light prevails) feel smooth and soft, but the quicker produced prints have a touch singularly different.

In the spring of this year, when I was first led to investigate the influence of actinism on the toning of the prints, I was guided by the strange sensation experienced at my finger ends when handling prints that had been produced

"I regard actinism as electricity in its primary condition, chemically active, but insensible to ordinary tests that detect free electricity."

with marvellous rapidity, and the toning flew up at a jump; the sensation was similar to that experienced when a weak galvanic circuit is completed between the body and a vessel of water and the tips of the fingers are applied to the water. Struck by the phenomenon, I cogitated again and again over the matter, and I at length felt convinced that a toning bath was, after all, a simple affair, and that toning prints was only another name for electrotyping; and if the construction of my toning bath is considered, we have an electro bath pure and simple, minus the electro power as usually applied by a battery. This last difficulty is, however, set aside if we regard the silver print as the primary motive power; and this remark leads us into the theory of toning action, which we describe briefly as follows:—

Our gold bath consists of gold, chlorine, and sodium in combination, water, free chloride of sodium, and a trace of free acid all being diffused through a volume of water; so far we have a non-actinic solution. Introduce the prints. What follows? With the gold solutions usually employed chlorine, strong and active by concentration, pitches into the silver surfaces, and, finding no free silver to gratify its appetite, nowise particular, it turns on the reduced silver, and half devours it before a sufficient layer of gold is deposited to arrest its voracious, destructive propensities. In some instances a little bleaching is advisable when extremes of contrast in the negative cause the darker portions of the print to become bronzed and buried ere the lighter are finished; but with a real good negative the slightest amount of bleaching the better. I need not here enlarge on the disadvantages found in toning with a small quantity of concentrated solution a large number of prints when each batch is toned under conditions different from those which preceded. Having had my say on this matter on a former occasion in the pages of the *Year-Book*, suffice it that I return to my toning solution to show up its more consistent behaviour. The prints are introduced, a small amount of free nitrate adhering to each print. The chlorine, proving powerless to attack the reduced silver, is content to form an alliance with the trace of free silver; the liberated gold is deposited on the print, toning action is set up and continued until the whole silver surface receives a deposit, when, if the solution is properly constructed, further toning action ceases, and the print may be removed. The minute trace of salt added with the gold serves to keep the silver in check that is introduced in the washing water or is roaming at large in the solution; it grasps the intruder, and my batch is not slow in showing that chloride of silver is only awaiting your absence to change its to-and-fro career into a drive towards the bottom of the vessel.

In concluding this paper, I would just add, that wild as some of the statements here offered might appear, they are no less facts; and facts called freaks which nature works, though true, yet seem wild fiction to those who, having eyes, think they see, yet see not through lack of searching observation.

#### DIRECT ANSWERS TO CORRESPONDENTS.

1. The chloride of gold I employ is that known as non-deliquescent, prepared by Johnson and Matthey.
2. It matters but little if the solution discolour.
3. When a bath is fresh made and refuses to tone, do not throw away the solution, but add gold treated with hot water until the bath *will* tone; no difficulty will be afterwards experienced.

Other enquiries will be answered in my next, and the value of free silver in the toning bath further illustrated.

#### SKETCHES OF TRAVEL FROM A SUN-PAINTER'S PORTFOLIO.

BY STEPHEN THOMPSON.

##### No. 3.—THE LAND OF BURNS.

To wander amidst the natural scenery that a great poet has enshrined in verse is like a posthumous visit to the studio; a peep into the workshop; a turning over of the draperies and

materials which he has grouped and worked up into his pictures; the bricks and mortar with which he reared the edifice we all know so well; the dry bones which he has made to live; the background of his subjects, and the side-scenes; the “setting” of the pearl of thought—but the setting only, the framework, so to speak—that he has grouped and wreathed around his gems. The Banks O'Doon, though pretty enough, furnish but the materialities which clothe, not inspire his songs. Many another stream that flows through deep-flowered meadows, sparkling in the golden sunlight by day,—

“And to the sleeping woods all night  
Singeth a quiet tune,”

would have served his purpose equally well. That sensibility which made him so alive to the beauties of external nature, at once a source of exalted pleasure and of exalted pain, would have found materials almost anywhere; the power of expression which accompanied it is a faculty for which we must seek explanation elsewhere.

In an evening walk by the banks and braes of the winding Doon, past Alloway's auld hamlet kirk and the Brig O'Doon's keystone arch, you will see many of those things which have been filtered through the mind of Burns into his verse—lassies “wi' lint-white locks,” youngsters paddling i'the burn, the Castle O'Montgomery, and, may be, “the bouny blink” of some Mary's e'e, to which Burns was but too susceptible. You may see the rose and woodbine twine, hear the mavis pour its melodious song, and stroll where the milk-white thorn scents the evening gale. Cottars' “wee bit ingles” stand beneath the shadow of their appropriate tree, and were the traveller to enter one he would see the “big ha' Bible” reposing on its shelf. The hymn of praise is still Dundee's “wild warbling measure,” “plaintive Martyrs,” or “noble Elgin.”

Burns was a true artist in his own particular walk. He knew well how to arrange his materials,—

“And rustic life and poverty  
Grew beautiful beneath his touch.”

His pictures are generally good in composition, nor do they lack breadth and contrast. He was very fond of the use of particular accessories—the burn, the hawthorn, the mavis notably, and the silvery birch, or “birk” (Scottish) he used inordinately, and introduces it at every opportunity. He is as much addicted to its use as Reynolds to the use of carmine and the fugitive lakes, or Turner to the use of the scarlet shadow. Nor was he wrong. The “Lady of the Woods,” as Coleridge named it, lends herself gracefully to the limner—though, by the way, from its tremulousness, a very difficult tree to photograph—and for beauty and graceful delicacy well deserves the lake-poet's appellation.

Like many great poets, Burns' smaller pieces were the best. His *little* birds sang sweetest! But he could set up his easel and attack a larger canvas successfully, and *close* on his subject with no feeble grip. See his “Tam O'Shanter,” and his “Cottars' Saturday Night.” At the same time he was as unequal to the sustained effort of the *Idylls* or *Enoch Arden* as to the “*Iliad*” of Homer. Yet he seldom affected the sonnet—those little cabinet pictures that in Milton and Wordsworth's hands sparkled like mosaics—“the key with which Shakespeare unlocked his heart,” Spenser's “glow-worm lamp,” Dante's “myrtle leaf,” and Petrarch's lute; and which, as Keats has sung, should consist of one idea well worked out,—

“The sonnet swelling loudly  
Up to its climax, and then dying proudly.”

Burns had an eye for colour: he tipped his wee modest daisies with crimson, and hung upon every green blade a pearl of dew. But his colour is always laid on judiciously, and every touch of the pencil tells. And what a lofty ideal he had of the inborn worth of man as man, and what a withering scorn of the selfish worldling and the pharisaical

bigot! When he worked on such subjects he dipped his brush in the "primaries," and his manipulation was terribly vigorous. He made his *bath* very acid, and got hard pictures. There was more of Gainsborough in him than of the courtly Reynolds, and with a strong dash of George Morland. But the greatest charm which haunts these banks O'Doon is that subtle sense running like an under-current through the mind wherever you tread, that Burns also trod these paths, "with his ploughman's stoop and genius flaming eye."

All this seems, perhaps, to have little to do with photography, but it serves to show that in poetry and art (in which photography may be included), although the genius of the operator is new and distinct, he has to work on the same old materials. The circling year brings seasons presenting the same types of beauty that they did in ages past. The woods and trees blossom and decay in pretty much the same way they did of yore. All nature's stock-in-trade is of the same old pattern, because incomparable from the beginning; and the human face divine, we may be sure, always presented—allowing for varieties in the dress or "setting"—much the same types of expression, because it is the passions and emotions that mould or modify its outward form and contour, and *human nature* (which, as Mr. Squeers observed, is a "rum-un") has always been animated by pretty much the same desires and propensities, virtues and vices.

But all artistic workers work in the same spirit, poet or artist, ancient or modern. There is in all the same love of beauty of form, and grace, and symmetry *for its own sake*. And photography—to make a personification of it—is a young fellow of perfectly new and original genius, but, like the rest, he has to work upon old materials and old stock subjects. His range is limited, and some things he cannot do at all, not even badly. Perhaps it is a pity that others with no more eye for colour, and as little ideality or imagination, were not under the same restrictions. But what is within his range he can do inimitably well. And, moreover, he has not yet fully cultivated all the gifts he has. When he has done so will be time enough to deplore the want of others. Perhaps by that time, as the powers that be are said to add their gifts as a reward to those who have faithfully cultivated the gifts they already possess, sister Science may add a little more plasticity, remove some of his youthful restraints, grant a longer tether, and, perhaps, above all, a little more sensibility to the harmonies of colour. Ruskin says, colour should always be sterily withheld until all other technicalities are mastered, and then made the student's reward for all the uphill, preliminary labour. Perhaps if photography had that gift prematurely, greater crudities and incongruities would be perpetrated than are now laid to his charge. We know not what latent powers may reside in certain substances under certain conditions, as unknown and unsuspected as those which lay dormant for centuries in the substance known as horn-silver, that blackened on exposure to light, but which the alchemists of old could make nothing of, handling the fact as a monkey does a watch—examining it, peering into it, and finally laying it down with a puzzled air.

Burns' land is very accessible ground from Glasgow for the tourist. The subjects are well together, and are lighted at different periods of the day, so that he may be certain of some of them. "Alloway's auld haunted kirk" is a morning subject, and requires a lens of very wide angle, the kirkyard is so small. "Burns' monument" is due about noon or later. The "Auld Brig O'Doon" makes an excellent subject, both from the river-side and the new brig, but requires a lens of long focus. It is good from 3 p.m. until sundown. "Burns' Cottage" is half a mile from the other subjects, and is due in the morning later than Alloway kirk. There are some pretty bits farther up the Doon, but it requires some thoughtful prospecting as to composition, &c., which should be done on the day or evening before.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XXX.

"With respect to the conduct necessary to be pursued in obtaining this advantageous distribution of the lights and darks in a picture, there is little now can be said upon it, as our neighbours on the Continent have long since developed the principles of practice adopted by the great chiaroscuro-ists."—*Barry*.

CHIAROSCURO—(continued).—PORTRAITURE.

In portraiture the chiaroscuro is to a very considerable extent under the control of the artist; there is, therefore, not so much excuse for imperfect and faulty lighting as there is in landscape photography.

The tendency of the lighting in photographic portraiture has been to harsh patches of black and white, or to miserable softness, full, it is true, of delicacy and half tone, but insipid and without character. Neither of these varieties possess what could be strictly called chiaroscuro, which term implies some notion of the arrangement and management of light and shade. The extreme popularity of M. Adam-Salomon's pictures in the Paris Exhibition seems to have made photographers alive to the fact that there is something more in light and shade than what is shown in the modelling of a face. It is this last subject, however, that we will first consider.

The object to be attained in lighting a head, considered as a head only, without reference to the general effect of the picture, is roundness and a certain degree of relief, not the relief attained by the stereoscope, but that degree of projection which is seen in all good pictures. How to obtain this relief shall be our next consideration. It will first be necessary to say a few words on the studio in which the portrait is produced. The general details of a glass house have been so often explained that for my present purpose it is sufficient to say that in these remarks I refer to a ridge-roof studio, one side (the south) of which, up to the ridge, is opaque, the other half glass to within a few feet of the floor. I make no reference to tunnels, in which I do not believe, and which are only available in the hands of men who will make good pictures in spite of, and not because of, the difficulties with which they have to contend.

The glass side of the roof may be blocked up permanently for five feet from each end; the remaining space of glass should be divided into four widths, covered with white blinds on spring rollers, pulling down from the top. I do not think blue or black blinds in addition of any consequence; they only produce complication and disorder. The side, also, if the studio is so situated that it receives light through it direct from the sky, should have corresponding blinds; but if the light reflected from buildings only is admitted, then the blinds are not necessary, this kind of light being very weak and ineffective in comparison with that from the sky.

We will suppose the south wall to be papered or coloured with a middle tint of a grey or greenish-grey colour—the studio will then be ready for making experiments in light and shade on the face. To assist further description, I give

Fig. 1.

a plan of the roof, premising that the size of the floor is 28 feet by 14 feet.

Place a sitter in the usual position; or, perhaps, a marble

bust will be better, because you can look it more steadily in the face, and it will not tire with your prolonged study and observation. Turn the face to the light, and let all the blinds be up, so that it may fall full upon it. The consequence will be that the features will appear faint and indistinct, or very much in the condition Queen Elizabeth would have preferred to have been taken, without shadow. If the head is now turned away from the light until it presents a three-quarter view to an observer standing where the camera is usually placed, the off-side of the face will appear in agreeable shadow, and the nose and other features will stand out in relief. But the best effect is not yet obtained. Although the light is broad, and relief is got, the light is too broad and flat, and there is not sufficient subtlety or delicacy in the gradations in the lights, and not enough transparency in the shadows; the photograph would consequently have a harsh black-and-white effect. If all the white blinds are drawn down about one-third of the roof space, the shadowed side of the face will appear softer and more in harmony with the light. We have now to produce the greatest amount of gradations in the lights. This is done by drawing down the two curtains (1 and 2) farthest from the sitter. It will now be found that the shining lights down the nose, on the forehead, and other parts, are produced to perfection, and that all gradations, from opacity to bare glass, to speak photographically, are to be seen on the bust, and that the whole face receives its proper projection and relief.

It will be thought by some that to exclude light in the manner described will prolong exposure, but experience teaches that the truth lies the other way. A properly lighted head does not take a longer exposure than one on which the fullest light attainable in the studio is thrown, and the results are not to be compared.

If it is considered desirable to take the head more inclining to profile, or if the sitter has features that project very considerably, the shadowed side will be found to be too dark. In this case reflectors are sometimes employed. This I think an objectionable proceeding. Any reflection giving more light than the natural reflection from the grey wall I have described will produce a second spark of light in the eye, which has a very disagreeable effect. A much better method is to work diagonally across the studio, as shown in fig. 2.

Fig. 2.

In this arrangement the background (a) is placed aslant; the sitter (b) is seen from the camera (c) in a fuller light, but still with a three-quarter view; the shadows of the nose will be stronger, but confined to a less space, and the shadowed side of the face will be lighter. This arrangement is also very suitable for an exact profile, or one showing a glimpse of the off eye.

In a photograph of a well-lighted head will be seen the extremes of white and black in small quantity united by masses of ever-varying gradation. The extreme value of black and white in minute but visible quantity was never better stated than by Ruskin in the following passage, which, although it refers to colour, states the case as regards light and shade equally well:—

"Next, respecting general tone. I said just now, that, for the sake of students, my tax should not be laid on black and white pigments; but if you mean to be a colourist, you must lay a tax on them yourself when you begin to use

true colour; that is to say, you must use them little, and make of them much. There is no better test of your colour tones being good than your having made the white in your picture precious, and the black conspicuous.

"I say, first, the white precious. I do not mean merely glittering or brilliant; it is easy to scratch white sea-gulls out of black clouds, and dot clumsy foliage with chalky dew; but when white is well managed, it ought to be strangely delicious—tender as well as bright—like inlaid mother-of-pearl or white roses washed in milk. The eye ought to seek it for rest, brilliant though it may be, and not to feel it as a space of strange, heavenly paleness in the midst of the flashing of the colours. This effect you can only reach by general depth of middle tint, by absolutely refusing to allow any white to exist except where you need it, and by keeping the white itself subdued with grey, except at a few points of chief lustre.

"Secondly, you must make the black conspicuous. However small a point of black may be, it ought to catch the eye, otherwise your work is too heavy in the shadow. All the ordinary shadows should be of some colour, never black nor approaching black; they should be evidently and always of a luminous nature, and the black should look strange among them; never occurring except in a black object, or in small points indicative of intense shade in the very centre of masses of shadow.

#### LIKENESS IN PORTRAITURE—LIABILITY OF SITTERS.

A CASE of considerable interest to professional photographers is reported in the *Sussex Express*, as having been recently tried in Westminster County Court:—

An action was brought by Messrs. Manll and Polyblank, photographers, of Piccadilly and Fulham Road, Brompton, to recover the sum of £8 17s. 6d., being the price of an enlarged photographic portrait of Mr. Rhodes, the defendant, who is a gentleman of some property, well known in Brighton, which they had painted in oil. Mr. Minton appeared for the plaintiffs; Mr. E. C. Willoughby, instructed by Mr. Robert Warren, of Golden Square, London, represented the defendant.

It appeared from the evidence of a number of witnesses called by the plaintiffs, that the order for the picture in question was given some time in August, 1866; that, on its being sent home, the defendant was dissatisfied with it, chiefly on account of the high colour on the face, and what he considered a cynical expression.

The artist was called, and stated he took the portrait from a smaller photograph, which was enlarged and then painted in oil. He could not say that he gave the subject a sitting prior to the complaints made, and in explanation of the variation of the colouring of the hair and whiskers in the portrait from the original, he stated he received general instructions to soften and tone down the ravages of age, and that the final sitting was important to give a "pleasant touch up," in other words, to put a pleasing expression on the face of the sitter. All the witnesses agreed in the opinion the likeness was a flattering and an agreeable one, and was done in a workmanlike manner.

After several attempts at alteration the defendant returned it as not being a proper likeness, and hence these proceedings.

Mr. E. C. Willoughby, on behalf of the defendant, stated he did not dispute either that the picture was a good one as a work of art, or that it was worth the money. The sole question was whether it was a likeness or not. The learned counsel suggested that the law was the same in this as in every case where the buyer relies upon the seller's judgment and skill; the latter impliedly warrants the article furnished shall be reasonably fit and proper for the purpose for which it is required. So here, an artist who agrees to paint a likeness is bound by his contract to supply what is a *likeness*—not a resemblance or a caricature. He then cited two cases; one where Sir Edwin Landseer had returned to his tailor a dress-coat because it did not fit him, being so humpy at the shoulders as to make him (if he had worn it) an object of ridicule at the Royal Academy dinner; and another where Madlle. Pictiens, the celebrated singer, had refused a statuette, as it was an indifferent likeness. In both cases the learned judge told the

jury that where persons paid a good price for an article, relying on the seller's skill and judgment, they had a right to expect their money's worth, and he left it to the jury to say whether the contract had been fulfilled. In both the verdict was for the defendant. So here, what with the flattering alterations and the "pleasant touch up," the real character of the features was departed from, and though an excellent work was produced, yet it was not a likeness of the defendant, but what one sees in the Academy at this season, "a portrait of a gentleman unknown."

Mr. Rhodes, who is a fine and good-looking man, was called as a witness, and was carefully scrutinized by the learned judge, who compared his features with those on the smaller photograph, and the oil painting. Mr. Rhodes stated that the portrait was required for his mother, and was rejected by his family on the sole ground that it was not a likeness. He sat several times after to the artist for the purpose of alterations, but finding it was no better, but rather worse, he declined to accept the picture. He distinctly denied he ever told the artist to give him a "pleasant touch up," denouncing this expression as photographic slang.

The learned judge, in giving judgment, said this was a very important case, and he was rather sorry he was left alone to decide it. He quite agreed with many of the observations for the defence. It really was a very narrow issue. Was the oil-painting a likeness of the defendant or a good copy of the small *carte-de-visite*? The *carte-de-visite* was an excellent likeness; it was admitted that the oil portrait was to follow this. It seemed to him it did not do so; none of the features were preserved in their integrity; and, in fact, he could barely identify a single one. Under these circumstances he could not say it was a likeness, or the contract carried out, and in his opinion the defendant was not bound to receive it. His judgment would be for the defendant.

## A CHAPTER IN THE EARLY HISTORY OF PHOTOGRAPHY.

Our excellent Philadelphia contemporary recently contained a report of a meeting of the photographic section of the American Institute, at which the early history of photographic portraiture came under attention. As there appears to be considerable disagreement in the statement of facts by different authorities, and exactitude in the history of every step in our art is matter of interest, it seems desirable, if possible, that the state of the case should be ascertained whilst many of the actors in the scenes are still alive to tell the story. The origin of this discussion is as follows:—A short time ago a letter addressed to Mr. Peter Le Neve Foster was published, and this letter was read at this meeting of the Institute in question. Upon this Mr. J. Johnson, a gentleman intimately associated with the early history of the art, made a statement in which he takes exception to Mr. Claudet's facts in terms of somewhat scant courtesy. The letter which follows was sent in reply to a letter from Mr. Foster congratulating Mr. Claudet on the receipt of a second honour:—

MY DEAR FOSTER,—Immediately on the discovery of Daguerre, I went to Paris, saw him, and bought from him the first licence to work out his process under the patent he had taken in England. I came back, brought all the specimens I could procure—made by his pupils, for he was attending once a week at the *Conservatoire des Arts et Metiers*—to instruct all the adepts and give them the information they wanted to master the process. I sent to the Royal Society's soirées the best specimens, after having submitted a collection of them to the Queen, who kept the best of them.

At that time, and without any authority from the patentee, the Polytechnic Institution took up the subject as an advantageous one to give lectures upon; and Mr. Goddard, a chemist in the employment of the Institution, explained every day the process to visitors, illustrating it by taking Daguerreotype pictures of a white bust before the audience.

Then, without a licence, and in defiance of the patentee, Mr. Beard, having bought an American invention by which, substituting a large concave mirror for the object-glass of Daguerre, found it was possible to operate upon a very small plate placed in the focus of the mirror, with a greater rapidity than by Daguerre's plan. Beard was allowed by the Polytechnic Institution to erect on the top of the building a glass room, and he began to take portraits by the said American photographic process. He intentionally dropped

the name "Daguerreotype." You recollect the success and popularity of the process.

In the meantime, wishing to work out my license, I treated with the proprietors of the Adelaide Gallery, and I erected on the top of the building a glass room and all that was necessary; but I could not use the patented mirror, so that I was obliged to do the best I could with Daguerre's slow object-glass. I went on so during 1840.

Early in 1841 I communicated to the Royal Society my discovery that chloride of iodine and chloride of bromine, added to the preparation of Daguerre (iodide of silver), was capable of rendering the original process one hundred times more sensitive, and from that moment I obtained instantaneous Daguerreotype pictures—as much so as with the present process of photography. My discovery made a great sensation in France, and every one took up the process, for which I had not taken out a patent.

But I must not omit to state that Goddard had made some experiments on the application of bromine, and that before my paper was read at the Royal Society it appears he had sent to the Royal Society a sealed paper, in which he had described the accelerative property of bromine. I believe that it was so; but my discovery was the only one (being published and public) by which the photographic world could practise a very quick process; and, in publishing fit to the Royal Society, I gave all the information and directions necessary to practise it.

Not long after Beard had taken up the American photographic process, Daguerre instructed his agent in London to find a buyer for his English patent. By my license he was bound to give me the option of refusal. My partner, not understanding the future of photography, would not consent to our buying the whole patent for £800, which was the price asked by Daguerre. I was obliged to decline the offer; and Daguerre's agent having made known to Beard the terms of the purchase of the patent, the latter wide-awake speculator was too glad to accept the offer, particularly, thinking that in buying the patent he could withdraw my license. This gave rise to a very long and expensive action in Chancery, which was at last decided in my favour, and Beard had to pay the whole expense.

During the year after Beard had bought the patent, he sold licenses to all country towns to the amount of £36,000!! This I know as certain from Johnson, who was interested with Beard, having sold him part of his patent for the concave mirror, of which Johnson was the inventor. I have told you more than you probably wanted, but I could not help giving you the whole story.

A. CLAUDET.

Mr. John Johnson, of Saco, Maine, being present at the meeting, stated that this contribution to the "History of Photography" contained statements so wide from and at variance with the truth, it might not be out of place to endeavour to show wherein A. Claudet is unreliable, historically.

At the suggestion of John Johnson, in New York, United States, in October, 1839, Alexander S. Woolcott joined him to prosecute the Daguerrean art. In this month and year the first Daguerrean portrait from nature was taken by Woolcott and Johnson.

On the 3rd of February, 1840, William S. Johnson (the father of John) sailed for London, and reached there about the close of the month, and immediately thereafter had an interview with Richard Beard, Esq., and with whom an agreement was entered into for the patenting of the mirror camera (the invention of Woolcott) in England.

The issue of this patent was opposed by Daguerre's agent in London; the opposition to the issuing of the patent for the mirror was withdrawn on Beard and Johnson agreeing to pay Daguerre £150 per annum for the right to employ and use all pertaining to the Daguerrean art, chemically, patented by Daguerre.

Mr. Claudet undoubtedly went to Paris; he was the first to obtain a licence from Daguerre (through an agent); his licence was for the use of three cameras anywhere in England, paying the sum of £200 therefor. It was thought the British Government would purchase the entire patent of Daguerre; if not, Claudet should have the first right to purchase the entire patent for £900 more. On the other hand, if any other party (Claudet not becoming the purchaser within the time prescribed) purchased the entire remaining interest, Claudet was bound in honour to receive his purchase money, and to deed to Richard Beard (for himself and Johnson) the license he held; but he thought differently, and an expensive Chancery suit was instituted; the subsequent failure of Beard doubtless terminated the litigation, leaving Claudet, without doubt, to foot the bills.

Richard Beard, Esq., paid £200 and expenses for one-half of the American invention; the remaining half, with all profits, he purchased for £7,000 at twelve months from the issuing of the American patent in London.

John Goddard, before being in the employ of Richard Beard and William S. Johnson, was an employé of the Adelaide Gallery Association as a lecturer in the department of light, demonstrating, with the aid of the magic-lantern, the physical proportion of light; he was in no sense a chemist, and did not profess to be.

In March, 1840, Wolcott and Johnson opened in New York city the first Daguerrean portrait gallery of the world.

In October, 1840, John Johnson (the speaker), at the solicitation of Richard Beard and William S. Johnson, sailed for and arrived in London about the middle of October, for the purpose of aiding to upbuild the English enterprise.

Wolcott and John Johnson, from the time of the departure of Mr. William S. Johnson, conveyed by letter, &c., to Beard and Johnson, in London, every detail of experiments, arrangement of light, discoveries, applications, and improvements.

John Johnson, it will be seen, had been engaged a twelve-month in the art before sailing for Europe—seven months at practical portrait taking in the gallery at New York.

The high latitude of London, and the shortness of the days, with the feeble actinic power, even in October, there made it apparent, in an eminent degree, to a New Yorker, that a renewed effort should, if possible, develop by chemical means a shorter sitting.

To this end I worked diligently, succeeding, by the discovery and application of chloride of iodine, in effecting the desired result, toward the close of November or early in December, 1840; Dimond and Co. (per Mr. Turner), of Holborn Bars, London, preparing whatever was ordered for my use.

In March, 1841, Richard Beard opened his Daguerrean gallery at the Polytechnic Institute. By reference to the publications of that date, it will be seen that the enterprise was no longer a doubtful one, my chloride of iodine producing results highly satisfactory, as it had months before in New York City, I having communicated the discovery to Mr. Wolcott, then in New York.

John Goddard, of London, was in the employ of Beard and Johnson, at Holborn Bars, and at the Polytechnic, and claimed to have made a discovery in the application and use of chemicals to the Daguerreotype.

For several months he and I worked in the same gallery, each using their own preparation of chemicals; his was marked "A. and B." The nature of his, as conveyed to me by himself, consisted in adding iodus and iodic acid to iodine.

If Mr. Goddard ever used bromine with iodine, he failed in its application as an accelerator, for in no instance did he ever produce results more speedy—using the same camera with myself—than those pictures produced by myself with chloride of iodine.

In the early part of 1841 much of my personal time was devoted to the planning and constructing of the operating room and building at the Polytechnic Institute, London, and looking after the blue plate glass for its skylight, in plate-glass works in Lancashire, &c.

After months of working in London, I was despatched to other cities and towns to aid in opening other galleries, William S. Johnson taking general charge of the manufactory, and assisting generally in all that pertained to this art and enterprise.

In October, 1841, John Johnson returned to the United States, and soon thereafter discovered and used chloride of bromine, and at once forwarded the formula to A. S. Wolcott (who had, in the previous July, gone to London to take charge of the optical, chemical, and mechanical details). Mr. Wolcott manufactured chloride of bromine in London, and it was sold and distributed throughout England as "Wolcott's Mixture," and it prevailed as a successful and needed chemical.

Claudet reports that "Johnson" had told him that Beard had sold licenses to the amount of £36,000, and adds: "This I know as certain, from Johnson, who was interested with Beard, having sold part of his patent for the concave mirror, of which Johnson was the inventor." Wolcott invented the concave mirror in its application to the Daguerreotype, and I am certain that "Johnson" never informed Claudet or reported that £36,000 were received, for no such sum was ever received from licenses and sales.

Months after Beard opened the rooms at the Polytechnic Institute, he, with the consent and wish of both Johnsons, purchased all Daguerre's interest in his patent, and was assured, on paying £200 to the agent, that Claudet would deed to him (Beard) all his right by paying £200 therefor. Claudet, how-

ever declined; legal proceedings were had, resulting as before stated.

A brief summary, then, would show that Johnson and Wolcott took the first Daguerrean portraits from life, established the first public gallery in the United States, and subsequently, through their labours, opened the first one in England; that John Johnson, in 1840, discovered, used, and applied chloride of iodine in England; that Wolcott soon thereafter made it public in America; that Claudet opened a gallery at the Adelaide Institute in 1841, months after Beard had been in full work. Claudet's "instantaneous" pictures were myths; instantaneous pictures could not be had by those sent to sit for them. Beard worked not "without a licence, and in defiance of the patentee!" but with one granted months in advance of any real need of its use.

John Goddard was a lecturer, not a chemist, at the Adelaide Gallery, before being employed by Beard and Johnson.

The process introduced by Beard and Johnson was always considered as substantially that of Daguerre, and his name was never "intentionally dropped."

If Claudet worked at all in 1840, it was not for the public; the records should prove when he opened his gallery, and the time of a sitting, and as to the time of the application of both chloride of iodine and chloride of bromine.

Goddard was sent to France to obtain the great secret and possess himself of the required chemicals that had been heralded as "instantaneous;" on returning, however, he brought with him a camera possessing the wonderful property of instantly producing the work!!

Goddard's bromine combination—if, indeed, he ever used it—failed to produce faster action than that of chloride of iodine, discovered and used by John Johnson.

Had Claudet acted in good faith, there would have been no Chancery suit. Daguerre complied with the terms of his agreement, either that Claudet should purchase the entire patent, or yield to that other who should the licence he held, by being refunded the purchase money; and, finally, to prove to the British public his far-seeing, Mr. Claudet greatly magnifies the sum Mr. Beard had received, and endeavours to qualify it by answering his "Dear Reader" that Johnson, "the inventor of the concave mirror" (of which he was not the inventor), had so informed him; it not being true: Johnson did not so inform Claudet.

"The whole story" is too jumbled a mass to pass for history of "great interest," or contribution to the "History of Photography."

## Correspondence.

### PHOTOGRAPHIC NOTES ON THE CONTINENT.

[FROM A SPECIAL CORRESPONDENT.]

*Heiligenblut, 13th August, 1868.*

I HAD intended to have written from Salzburg, but wishing to join a party of pedestrians who were contemplating a knapsack tour through the Tyrol, I was compelled to leave that town rather earlier than I had expected. I am now writing from a small village in the Puster Valley, at the foot of the *Grosse Glockner*, known as the Chamounix of the Tyrol, and as we are just now awaiting the dispersion of hazy weather before we can ascend to the glaciers, I seize the opportunity of sending you a few notes made since I left Vienna.

In a previous letter I mentioned the practice which obtained very greatly in some parts of Germany, of selling photographs of engravings, of landscapes, &c., as original photographs. When I made this statement I imagined the custom was confined to smaller towns and out-of-the-way places only, and I was very much astonished indeed to find that at Vienna and Salzburg, both of which towns are especially noted for their good photography, these spurious articles were largely sold. At Vienna, where I was very anxious to obtain some pictures of the Danube and other localities of interest, it may be stated that at the shops of the largest photographic dealers fully one-half of the smaller pictures were reproductions of engravings. There is, of course, no harm in selling a photograph of a wood-cut

or engraving if the same is sold as such to the public, but in most cases the latter believe the print to be really a genuine picture taken direct by the camera from nature.

The landscape photographs exhibited at Salzburg are decidedly superior to those shown at Vienna. In the last-named town, with the exception of a few pictures, of mediocre quality, of various places of interest in the vicinity, there was nothing whatever to be seen; all photographic talent was concentrated upon portraiture (certainly with great success), and landscape work overlooked altogether. In Salzburg, however, some very fine pictures may be seen of the Salzkammergut and Tyrol, taken mostly by MM. Baldi and Wurthle. A photograph of the *Koenig See*, and another of the principal square at Salzburg, were particularly good. No scenes on the Danube were, however, to be obtained, and it certainly seems passing strange that while the Rhine has been worn out and done to death by photographers, none of the clever followers of the art who live actually upon its shores or in its immediate vicinity should have deemed it worth their while to have reproduced some of the many beautiful spots which adorn the greatest, if not the finest, of European rivers.

Bad Gastein, through which I passed on my way here, seems very much in the same position as Ischl as regards photography. It is one of the most fashionable and expensive spas in Austria, and yet I did not actually see one photographic studio in the place. Views of the mountains, waterfalls, and points of interest in the neighbourhood were exhibited for sale in the bazaar and at the shops, but where one photograph was to be seen, twenty of the old tinted exaggerated pictures were shown.

With regard to the prices charged at Salzburg and Vienna for cabinet and card pictures, they are certainly very low. The highest price quoted for cabinets was ten florins for half a dozen, while the general price at first-rate artists was but six florins (a florin being equal to about one shilling and ninepence). Carte-de-visite pictures varied from twelve and eight florins per dozen downwards, articles of a very good description indeed being obtainable at six and five florins per dozen.

In Salzburg the specimens exhibited in the show-cases betrayed, in more than one instance, unmistakable signs of fading and yellowness. Some of them had been so imperfectly washed, that not only were the whites utterly destroyed, but the pictures themselves were rapidly disappearing. From this it would seem that our neighbours on this side of the Channel were not more fortunate than ourselves in producing durable and imperishable silver prints. No specimens of the carbon process or of photo-lithography did I see in any of the establishments that I visited.

The scenery in this part of the country is truly magnificent, and the extensive views to be obtained in making one's way here from Gastein, over two mountain passes 9,000 feet above the sea, and a glacier more than two miles broad, are among the most beautiful I have ever seen. The landscape is very wild and uncultivated, and the neighbourhood thinly populated. On the paths at every half mile, or thereabouts, are erected small chapels or crucifixes (the people are Catholics), and these of the most crude description. Some of them are indeed so imperfect as to remind one very much of the photographs recently taken in Abyssinia of pictures from native bibles. Besides the religious erections before mentioned, the roads are plentifully studded with rude paintings of fatal accidents which have happened in the vicinity, such as a man falling from a precipice or into a stream, or perishing in the snow. These productions are quite peculiar to the district, and are so numerous (for many of them date fifty years back) that I have counted as many as thirteen in one day's journey.

I must not conclude this letter before mentioning two very beautiful optical effects which I witnessed a day or two ago. The first was the formation of a perfect rainbow in the spray of a large waterfall, which could be seen, so our guide informed us, only between six and eight o'clock in

the morning, when the sun's rays fell upon the fall in a certain direction. All the colours were very clearly rendered, the violet band being very marked indeed.

The other optical spectacle was even more striking. A swift stream ran between two mountain walls of considerable height, which at one time bent round so as to form a right angle. A narrow path had been cut into the side of the rock at some distance above the stream, whence the rapid current might be seen foaming and chafing below. The sunlight fell direct upon the water until the latter turned the angle, when it came under the deep shadow of the rock. The current, however, carried the sunlight with it beyond the angle into the more sombre portion of the chasm, where it appeared like a stream of molten silver flowing from a furnace and illuminating the objects in its immediate vicinity.

#### WHITE PIGMENT IN CARBON PRINTING.

SIR,—I understand that Mr. Blair has just invented a new carbon process which, a friend assures me, is to supersede all processes at present in existence. The new process consists, I understand, in the use of a white pigment on a black ground, instead of a black pigment on a white ground. If I am not much mistaken, such a process was proposed by some one in your own pages some years ago, and condemned subsequently by Mr. Carey Lea as impracticable, because almost any white pigment which could be used would be likely to decompose the sensitive salts. If such a process be practical, the credit of the suggestion is due to your original correspondent, whose name I forget. My chief object in writing now is to suggest that, whilst many white pigments—such as oxide of zinc, carbonate of lime, &c.—might decompose the chromic salt, it seems likely that kaolin might have no such action, and would probably form a good pigment for the purpose.

By the way, did not Mr. Blair propose the method of exposing carbon prints at the back after some person else had published precisely the same thing? Is he in the habit of making, as "original," suggestions which others have already published?—Very truly,  
Z.

[The suggestion to which you refer was made by Mr. Frank Eliot in our issue for June 17, 1864, in an article entitled "Suggestions for a New Pigment Process." Mr. Carey Lea has recently referred to the same idea as worth consideration, having doubtless thought better of the matter since 1864. Mr. Eliot's suggestion was to use a white pigment on black paper, employing M. Poitevin's process with gelatine, perchloride of iron, and tartaric acid. You will find it noted in our recently published work. Mr. Burnett was the first person to definitely point out the necessity of exposing a carbon print on one side and washing away at the other, although it had been somewhat indefinitely referred to by the Abbé Laborde. Mr. Blair published shortly after Mr. Burnett, and, as we have no doubt, without any knowledge that the idea had already been published. Mr. Blair has been, we believe, a hard-working and conscientious experimentalist in carbon; that he has occasionally made suggestions which had already been published is probably due to insufficient familiarity with the current photographic literature, which would keep him informed on the progress of the art.—Ed.]

#### Talk in the Studio.

KEEPING QUALITIES OF GUM PLATES.—In a letter just received from Mr. Russell Manners Gordon, who is in North Wales, he observes, in relation to some of the gum plates he has been trying, that they keep perfectly for six months (and how much longer requires to be ascertained) after exposure and before development. The only change (if any) is the improvement in quality. We do not know any other dry plate of which such a statement can be made.

**NEW PRESERVATIVE FOR COLLODIO-BROMIDE PLATES.**—The new preservative, the results of which were recently described at a meeting of the Liverpool Amateur Society by Mr. Bolton, consists of quassia and sugar. One ounce of quassia chips and 200 grains of sugar are macerated for a few hours in water, which is poured over them in a boiling state. The solution is then strained, and is ready for application to the collodio-bromide plate. The addition of albumen to this solution, in the proportion of a drachm to a pint, Mr. Bolton thinks an improvement. The advantage of the new preservative is increased sensitiveness. It is probable that the preservative might be applied with advantage to plates prepared with bromo-iodized collodion, and excited in the usual way.

**FULMINATING SILVER.**—M. Couvreur recently addressed a letter to the French Photographic Society, stating that in evaporating a bath of nitrate of silver in which a portion of the water had been replaced by alcohol, he noticed a white light precipitate, and hastily removing the capsule from the fire he recognized in the filtrate fulminate of silver. He fortunately removed it from the fire in time to prevent an explosion.

**INFORMERS AND PIRATES.**—We find various comments expressed on the subject. Whilst all persons sympathize with Mr. Graves in regard to the deep wrong he has suffered from photographic pirates, almost all regret that questionable means should be used to serve a right cause. The *Stationer* says:—"In reference to the spy system, it occurs to us as very peculiar that the persons who have been heretofore prosecuted have not thought of the Act 11 and 12 Vic., cap. 43, sec. 5, which recites that "every person who shall counsel or procure the commission of any offence punishable on summary conviction shall be liable to be proceeded against and convicted of the same, either together with the principal offender, or before or after his conviction." In the case of the hawkers, it is worthy of note that the fine was inflicted for an offence committed at Portsmouth so long ago as the 27th December last! When the Act of Parliament was passed which required process to be issued within six months after the commission of an offence, it surely was never intended that delinquents should be subjected to the law for that period after the discovery of the fraud? Mr. Graves, as we have said in prior issues, is quite right to protect his own interests, but we strongly object to his delaying the prosecutions for so long a period as six months. In all other criminal indictments it is considered incorrect unless a prosecutor takes immediate process. And such a feeling is correct, because, were it otherwise, it would hold out a premium for persecution, and enable malicious persons to practise the *lex talionis* in a manner that could not fail to produce injurious social effects.

**PRECIPITATE OF CHLORIDE OF SILVER.**—Dr. Vogel says:—"Not long ago we had a discussion in our Photographic Society on a proper method to facilitate the precipitations of chloride of silver from the waste water containing silver salt in solution. It is curious that sometimes days, and even weeks, will elapse before all the chloride of silver has been precipitated, and particularly is this the case in those printing establishments where the pictures are pasted with gum arabic to the negatives; the gum finds its way into the water and retards precipitation. Other organic substances have a similar retarding influence. The best practical remedy appears to be, to mix a couple of pounds of nitric acid with the waste water, or some hot water."

**FIVE HUNDRED DOLLARS PRIZE.**—A medical journal in Philadelphia says that a correspondent has authorized the editor to offer a prize of 500 dollars for an improvement in photo-micrography. He says:—"To advance science, facilitate research, further our knowledge of diseases, at the meeting of the American Medical Association, in 1869, through the award of a committee, I will tender a prize of five hundred dollars for an improvement on the micro-spectroscope. I am anxious to have invented and perfected a micro-photographic apparatus for scientific purposes—a compound microscope, with an attachment so arranged that it will afford the investigator a complete photographic representation, or spectrum, of all microscopical bodies placed within the field of vision. Such an instrument would be an achievement in science; we could read direct from the type true pathology. It would be obvious to all. It would reveal many of the mysteries of nature in morbid agency. It would aid us in etiology and histology. It would afford advantages in the study of organic and inorganic chemistry. We could observe the changes produced by a diathesis—determine the faults in rheumatism and gout. We could also mark the developments and progress of pyogenic,

septic, and zymotic diseases. I want an instrument simplified, with power sufficient to print animality, from the larger animalcula down to the minute microphite. The micro-photographs thus taken could be readily magnified if desired. The premium should be open to all competitors, at home or abroad. Without invidiousness, I respectfully nominate Professors Joseph H. Leidy, University of Pennsylvania; Christopher Johnston, University of Maryland; and Austin Flint, Jr., Bellevue Hospital Medical College, New York, as the committee to determine the award to the inventor of the best instrument."

**RELIEF IN ART.**—A daily contemporary, in noticing some paintings in which the artist had endeavoured to secure unusual roundness and relief in his pictures, emulating in some degree the effect of the stereoscope, says: "But grave authorities on art matters have decided that this perfection of imitation is not the true aim of painting; but, on the contrary, that the pencil should be taught to reject minor details, which detract from the great whole which a composition should always assume; that the painter should depict what he beholds in the mirror of the imagination, rather than make a minute transcript of objects as they appear to keen critical eyes. Painting is a creative art. Genius will often realize, by a few strokes of the pencil, ideas and effects full of pathos and dramatic power, which the more imitator could not rival by excessive labour. It must always be understood that a Demoor-like fidelity and a stereoscopic-like relief are not regarded as beauties by those who have thought much and written much about the great art of painting."

**ANTIDOTE TO VEGETABLE POISONS.**—The Coroner stated, at a recent inquest, that if powdered charcoal were administered, it would often prove an antidote to irritant vegetable poisons like aconite.

## To Correspondents.

**A YOUNG PHOTOGRAPHER.**—The lower part of your negative being fogged whilst the top part is quite clear and clean suggests that the defect is due to diffused light entering the dark slide through the aperture at the top when the shutter is drawn up. The light in such case would fog the bottom part of the negative, which, whilst in the dark slide, is of course uppermost. In taking a portrait in a sitting-room the window should not be opposite your lens. The best mode of proceeding is to place the sitter with his side-face to the window, the front-face, perhaps, a little inclining towards it. The sitter should be placed about three feet from the window. The camera, then, being placed as close as possible to the wall in which the window is pierced, will be slightly directed from the light rather than towards it.

**PURGEON.**—First cleanse the brass-work thoroughly, then apply what is called "chemical bronze." It consists of a solution of bi-chloride of platinum 4 drachms, and nitrate of silver 1 grain, in 6 ounces of water. Apply with a camel-hair pencil. When the requisite blackness is obtained, wash the brass with water, and, after drying, polish with blacklead. A preparation made of old Daguerrotype plates, consisting of silver and copper, dissolved in dilute nitric acid, and applied to the brass, which should first be cleaned and made very hot, is said to give a good black to brass. 2. The black precipitate in your toning bath is probably reduced gold. Filter it out, and preserve it with your gold residues, to be reconverted into chloride of gold. More than ten sheets of paper ought certainly to be toned with 15 grains of chloride of gold.

**T. W. M.**—The general form of your studio seems good, and it ought to give good results; but you have less light than we should think desirable, especially as it seems divided into narrow panes, the sash-frames in such case interrupting the passage of a good deal of the light which should reach the sitter. We should prefer four feet more at the top on the north side, and a couple of feet more side-light at the north. This will probably enable you to illumine your shadows better.

**H. R. S.**—The card group is not bad, but it might have been better. It would have been better, in a group of three figures, to have avoided giving the full-face of each; if one had been in profile, or nearly so, the effect would have been more pleasing. Neither should every face have been looking into the camera. If the little one now sitting on the floor had been kneeling and reclining against its sister the result would have been better, we think. The chemical qualities are not bad, but there is a little tendency to hardness and chalkiness. On examining the group, and thinking over these suggestions, you will agree with them.

**W. L. S.**—We have not met with a paper giving those singular transparent, greasy-looking spots when wet. We should think the defect was in the original paper. Can you let us have a sample

- of the unsensitized paper in which it occurs? Have you noticed the defect in the paper before printing?
- J. H. M. (Exeter).—The Copyright Act forbids "copying" copyright pictures as well as selling them. We do not suppose that the owner of any copyright would take proceedings against an amateur copying for his own use; but he could do it. 2. A trace of iodine in an iron developer will tend to check fog. Such a check would not be required with the gelatino-iron developer, as the gelatine generally effectually prevents fog. 3. The stain to which you refer is, if we rightly understand you, a matt silver stain, and is, in the case described, probably due to contact with the inner frame, from which some particles, having a reducing action, have been drawn on to the surface of the plate by capillary attraction. 4. The prints enclosed lack a little vigour, but whether this is due to a weak bath or a thin negative we cannot say. The lighting of the figures is good. As prints, a little more warmth and vigour would be an improvement. Thanks for the design, which we shall carefully consider. We shall be glad to hear anything further regarding it.
- DAVID THOMAS.—Marion's transparent pellicle, to which we referred some time ago as having the characteristics of flexible glass, is perfectly smooth, polished, and transparent, like glass.
- A. TAYLOR.—When a collodion is sold as prepared for iron development, it is meant that the iron development should be employed in the wet process. If the collodion be employed in a dry process, then the most suitable development for the process must be employed, and in Mr. England's process you must, of course, adopt the kind of development he recommends. The collodion you mention may be used for his process; but it will be better for the purpose if you add 1 grain per ounce of bromide of cadmium.
- J. R. WAITE.—We have despatched the letter. Mr. Hingley's address now is 10A, Great Portland Street.
- F. W.—Thanks for the interest you express. We do not, however, agree with you as to the necessity for answering the attacks. In the first place, the game is not worth the candle, and few people are deceived by persons notorious for mis-statement; in the next place, we have more important uses for our space, and having fully discussed the matter once, we are content to rest in the verdict of all whose opinion is worth consideration. You will find the matter fully answered on pages 380 and 402 of our last Volume. To your categorical questions we may reply that we never acknowledged that the collodio-chloride process was not ours, or claimed modifications. The statement that we did so is a simple falsehood. The process had no existence until we published it in 1864. M. Gaudin never claimed the process; but, in the course of some remarks on it soon after our first publication, said that, during his experiments with iodide and bromide of silver in collodion, he had with the chloride "experimented very little," and did not proceed because he was convinced "that there was no possibility of succeeding." 3. M. Gaudin's experiments with haloid salts of silver in collodion were published in 1861; we experimented in the same direction at a date anterior to the publication of M. Claudet's experiments; and we exhibited negatives produced without a nitrate bath at the North London Society. For fuller details see articles already referred to, if you are sufficiently interested in the question. For ourselves, we feel small concern in the matter. Nothing so thoroughly induces indifference to calumny as supreme contempt for the calumniator.
- W. J. A. G.—We think it probable that you may apply without disadvantage a spirit varnish to a negative which has been varnished with amber varnish, but as we have not tried it we cannot speak with certainty. We should recommend trying the experiment on a worthless negative, and if all goes right you may then treat valuable negatives the same way with advantage.
- J. PALETHORPE.—The material used in Marion's preservative cases is chloride of calcium. It may be obtained of most chemists.
- E. D.—We have no doubt that the marks are the result of the action of hypo coming into contact in some way with the prints before fixing. The most probable cause which we can suggest is washing the prints in the same dishes before fixing in which some prints have been placed after fixing. We have known very similar-looking stains from such a cause. Some slight traces of hypo probably cling round the vessel in which the prints are washed before fixing, and probably before toning, and this will be sufficient to produce these slight irregular-shaped yellow stains.
- NOVICE.—Your discoloured silver bath will not do any harm so long as it does not cause any permanent discoloured tint on the prints. The addition of a little of a solution of chloride of sodium (common salt) generally clears a bath well, causing a precipitate of chloride of silver, which carries down with it the particles of discoloured matter.
- H. S.—So far as we can see, you have made the best of the means of lighting you possess, and, without the facility for obtaining more side-light, we do not see how improvement can be made. Send us a head of about an inch, lighted in the studio, and we can possibly offer some suggestion. We do not know of any capable person who could advise you professionally on such a matter.
- J. C. S.—We shall be glad to receive a bottle of the collodion in question for examination. Thanks.
- T. H. REDIN.—The prints duly received. Nothing can be better than their appearance. We hope to have time, soon, to make some experiments as to probable stability. Thanks.
- J. W. H. A.—Albuminized paper excited and blackened by exposure, but unfixed, is an excellent thing for masks. Tinfoil has the disadvantage of frequently causing spots and stains. Thick orange paper also answers well.
- R. R. TAYLOR.—For interiors, nothing could be better than the lens you inquire about; it will work much more rapidly than that you have been trying, and will give straighter lines. For groups, heads, &c., in the open air, it will answer well; but it is scarcely rapid enough for studio work. If you wish to combine fitness for studio work with suitability for interiors, the group lens of the same maker will answer better.
- L'OUVRIER.—You cannot alter your lens to make it work quicker. If you work it with open aperture you get all the rapidity of which it is capable, unless it happen to be dirty, and require cleaning, which might, of course, make it a little more rapid. For what kind of object, and under what circumstances, do you give a thirty minutes' exposure? 2. *Sel Clement* is a preparation of nitrate of silver for printing, which is stated to be more economical than the ordinary nitrate.
- NATURAL.—Several articles on double printing, for introducing natural backgrounds to portraits, have appeared in the PHOTOGRAPHIC NEWS this year; and a few weeks ago we published an article on the production of double negatives for the same purpose. There is no work devoted to double printing; but our YEAR-BOOK for 1864 contains a full article on the subject by Mr. H. P. Robinson.
- LYTLE'S STUDIO.—If the reticulation in your collodion film is present before varnishing, it is due to the presence of too much water in the collodion—that is, the alcohol has not been sufficiently highly rectified; but if, as its appearance indicates, the cracking appears after varnishing, it is due to a slight tendency in the film to dissolve under the varnish, which may arise from the use of very strong alcohol in the varnish, or from the quality of the pyroxyline. A weak solution of gum poured over the negative before it is dried would prevent this. If you explain more fully we can more fully advise you. A negative packed in a box is not treated as a book parcel, and eightpence additional postage had to be paid at our office.
- A. X.—The microscopic photographs to which you refer were produced by M. Dagron in Paris. We do not know of any English house which supplies them commercially, nor do we remember any detailed account of M. Dagron's mode of working. The kind of paper, proportion of salt and albumen, &c., all affect the colour of the print in the printing-frame. A highly albuminized *Rice* paper will, as a rule, print of the foxy colour you ask for.
- T.—To rectify alcohol it should be distilled over carbonate of potash. Agitating with carbonate of potash and decanting would remove water, but there is a risk of a little water holding the potash salt in solution remaining. The iodized collodion remaining colourless might be due to such a cause, but it may also be due to the presence of methyl, which combines with free iodine and prevents the colouration of the collodion. The proportion and strength of the solvents are satisfactory. There is a patent method of purifying methylated spirit, but we believe its use has been declared illegal. The addition of alcoholic solution of iodine will produce a similar effect to that produced by the liberation of iodine; but at first the iodine added will probably be absorbed, and the collodion remain colourless. A collodion for copying prints should be made with a cotton giving intensity, should have plenty of the cotton, should be chiefly iodized with salts of potassium, and contain no more bromide than is necessary to clean working—less than half a grain per ounce. The object of using strong acids and adding water is to gain an increase of temperature by the mixture of water with the sulphuric acid.
- G. G. (Stockton).—It is difficult to say why you should get fog in performing precisely the same operations which, in other hands, succeed well and yield good results, unless the condition of your chemicals is in some way imperfect. Let us know whose collodion you used, and condition of bath; also how long you left plate in the bath first time, and how long in the distilled water. The plate does not require long immersion in either before exposure. Was your distilled water pure?
- DR. LIESEGANG.—The chloride of lithium received safe. Thanks. Several Correspondents in our next.

### THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE thirty-eighth meeting of the British Association for the Advancement of Science was commenced in Norwich on Wednesday, the 19th instant, under the presidency of Dr. Hooker, Director of the Royal Gardens at Kew. The presidential address, not so profound or so brilliant as those of some preceding years, was able, comprehensive, and practical. The most interesting part of the address related to recent researches among the indigenous populations of India. It would, he said, surprise many of his hearers to learn that within three hundred miles of the British capital of India there existed a tribe of semi-savages which habitually erected dolmens, menhirs, cists, and cromlechs, almost as gigantic in their proportions, and very similar in appearance and construction, to the so-called Druidical remains of Western Europe. In dealing with this subject he paid a passing tribute to the importance of photography in such investigations, and stated that the efforts of the Indian Government in obtaining photographs of the native Indian tribes had been eminently successful, the high value of the photographs rendering all the more disappointing some literary matter which had been published in connection with them. Some excellent remarks followed on the government and use of museums of natural history, in which Dr. Hooker enforced the importance of giving them a specifically educational character, by the suitable classification of the contents, and demonstrations to be given by the curator of each museum. Passing on to his own especial subject, botany, the speaker paid a high tribute to Darwin and his theory of the origin of species. The speaker concluded by some remarks on religion and science, pointing out that a positive, earnest, conscientious investigation was the proper attitude of man in relation to both questions. "Science," he said, "has never in this search hindered the religious aspirations of good and earnest men; nor have pulpit cautions, which are but ill-disguised deterrents, ever turned inquiring minds from the revelations of science." To search out his "whence and whither" must ever be an unquenchable instinct with man. "But," he added:—

"A sea of time spreads its waters between that period to which the earliest traditions of our ancestors point, and that far earlier period, when man first appeared upon the globe. For his track upon that sea man vainly questions his spiritual teachers. Along its hither shore, if not across it, science now offers to pilot him. Each fresh discovery concerning pre-historic man is as a pier built on some rock its tide has exposed, and from these piers arches will one day spring, that will carry him further and further across its depth. Science, it is true, may never sound the depths of that sea, may never buoy its shallows, or span its narrowest creeks, but she will still build on every tide-washed rock, nor will she deem her mission fulfilled till she has sounded its profoundest depths and reached its further shore, or proved the one to be unfathomable and the other unattainable, upon

evidence not yet revealed to mankind. And if in his track he bears in mind that it is a common object of religion and of science to seek to understand the infancy of his existence—that the laws of mind are not yet relegated to the domain of the teachers of physical science, and that the laws of matter are not within the religious teacher's province—these may then work together in harmony and with good will."

On Thursday the business of the Association commenced with the Report of the Kew Committee. It recorded, amongst other things, that a self-recording magnetograph for the photographic registration of magnetic changes had been supplied to the Colaba Observatory in Bombay, together with a complete equipment of photographic apparatus and material. The photographic department at Kew, under the charge of Mr. Page, was stated to work satisfactorily. The Kew photo-heliograph, in charge of Mr. De la Rue, continued to be worked in a satisfactory manner. During the past year 224 negatives had been taken on 140 days. Ninety pictures of the Pagoda in Kew Gardens had likewise been taken, in the hope of being able, by this means, to determine accurately the angular diameter of the sun.

In Section A, devoted to mathematical and physical science, Professor Tyndall presided, and opened the proceedings with an eloquent address, pointing out the purpose and especial advantages of the British Association. Quoting Fichte, in his "Vocation of the Scholar," to the effect that the culture of a student should not be one-sided, but all-sided, in order that his intellectual nature might expand spherically, and not in a single direction, he proceeded:—

Fichte's idea is, to some extent, illustrated by the constitution and the labours of the British Association. We have here a body of men engaged in the pursuit of natural knowledge, but variously engaged. While sympathising with each of its departments, and supplementing his culture by knowledge drawn from all of them, each student amongst us selects one subject for the exercise of his own original faculty—one line along which he can carry the light of his private intelligence a little way into the darkness by which all knowledge is surrounded. Thus the geologist faces the rocks; the biologist fronts the conditions and phenomena of life; the astronomer, stellar masses and motions; the mathematician, the properties of space and number; the chemist pursues his atoms; while the physical investigator has his own large field in optical, thermal, electrical, acoustical, and other phenomena. The British Association, then, faces nature on all sides, and pushes knowledge centrifugally outwards, while, through circumstance or natural bent, each of its working members takes up a certain line of research in which he aspires to be an original producer, being content in all other directions to accept instruction from his fellow-men. The sum of our labours constitutes what Fichte might call the *sphere* of natural knowledge. In the meetings of the Association it is found necessary to resolve this sphere into its component parts, which take concrete form under the respective letters of our Sections.

His concluding remarks are pregnant, and worth quoting:—

The process of things upon this earth has been one of amelioration. It is a long way from the *Iguanodon* and his contemporaries

to the President and Members of the British Association. And whether we regard the improvement from the scientific or from the theological point of view, as the result of progressive development or as the result of successive exhibitions of creative energy, neither view entitles us to assume that man's present faculties end the series—that the process of amelioration stops at him. A time may therefore come when this ultra-scientific region by which we are now enfolded may offer itself to terrestrial, if not to human investigation. Two-thirds of the rays emitted by the sun fail to arouse in the eye the sense of vision. The rays exist, but the visual organ requisite for their translation into light does not exist. And so from this region of darkness and mystery which surrounds us, rays may now be darting which require but the development of the proper intellectual organs to translate them into knowledge as far surpassing ours as ours does that of the wallowing reptiles which once held possession of this planet. Meanwhile the mystery is not without its uses. It certainly may be made a power in the human soul; but it is a power which has feeling, not knowledge, for its base. It may be, and will be, and we hope is, turned to account, both in steadying and strengthening the intellect, and in rescuing man from that littleness to which, in the struggle for existence, or for preëminence in the world, he is continually prone.

In the Chemical Section the first paper of interest to photographers was one by Dr. Plipson on Sulphocyanide of Ammonium, which, although more relating to its uses in agriculture than in photography, possesses sufficient interest for reprinting, and will be found on another page.

In the evening a soiree was held in St. Andrew's Hall, at which fewer objects of scientific interest than we have ever seen on a similar occasion were exhibited: a display of models of artillery, &c., and of photographs of cannon, and the effects of shot at Shoeburyness and elsewhere, all under the charge of Mr. Spiller, together with some fine photographs by Mr. Sawyer, formed the chief feature of the display.

On Friday, in the midst of sectional business, a telegram from India was read, to the effect that the observation of the solar eclipse had been mainly successful, although there had been some light clouds. Subsequently a telegram was received by the President of the Astronomical Society from Dr. Jaussen, of Paris, as follows:—"Eclipse observed. Protuberances' spectrum very remarkable and unexpected. Protuberances of a gaseous nature."

In the Section A, on Friday, Col. Strange read an important paper on the importance of Government aid in securing the progress of science, upon which we shall have something more to say hereafter. A paper on Actinometry, by Mr. L. Bing, was also read: it will be found on another page. A valuable report was presented by Mr. Catton on his Synthetical Researches on Organic Acids. In the evening Professor Fergusson lectured on Ancient Buddhist Remains, using as illustrations some enlarged drawings from photographs.

On Monday a paper was read by Professor Morren on a Peculiar Action of Light on Salts of Silver, pointing out that if moist chloride of silver be blackened by light in a sealed tube, and then placed in the dark, the chlorine still present will again attack the reduced silver, and reproduce chloride. We reprint the paper on another page.

In the limited space at our disposal we can only notice such part of the extensive proceedings of the Association as may be interesting to our readers as photographers. Although not directly bearing on their art, we may mention a curious contribution by Dr. Richardson, on the Transmission of Light through Animal Substances. He exhibited a magnesium lamp, made for him by Mr. Solomon, by which he was able to transmit light through the semi-transparent substance forming the bodies of living men. The structure the most diaphanous was the skin; after that, and singularly enough, bone; then thick membranes; next, thin superficial muscles, lung tissue, fat, and the dense tissues of the liver and the kidney. Various lights had been tried—viz., the electric, the oxy-hydrogen, the lime light, and the magnesium. For all practical purposes the magnesium light was the best; it was the most convenient to use, and the light had the advantage of penetrating deeply. In the lantern which Dr. Richardson exhibited the light was also unattended with heat at the

point of observation, so that the hand could be put in at the brightest illuminating point. The structure to be examined was placed in a groove provided enclosed between two discs of perforated wood, and the object was surveyed from the further end of the tube. A thick piece of bone, the flat rib of an ox, was placed in the lantern, and light was distinctly transmitted through it by way of illustration. Animals whose tissues were thin, such as fish, could be placed in the lantern, and the condition of their circulation and respiration could be carefully studied under the action of various agents. In the human subject, especially in the young, with fragile tissues, the thinner parts of the body could be distinctly rendered transparent; and in a child, the bones, with a somewhat subdued light, could be seen in the arm and wrist. A fracture in a bone could, in fact, be easily made out, or growth from bone in these parts. In a very thin, young subject the movements and outline of the heart could also be faintly seen in the chest, but the light he had as yet employed had not been sufficiently powerful to render this demonstration all he could desire. It would be possible, lastly, to see through some diseased structures, so as to ascertain whether, within a cavity, there was a fluid or a solid body.

On Monday, in the Department of Zoology and Botany of Section D, Dr. Karl Koch read a paper in which he called attention to the necessity of having photographs as aids to the systematic comparison of living plants, for after some were dried they gave a very imperfect idea of the physiognomy whilst growing. He was making such a collection of photographs of the plants in the Botanic Gardens at Berlin, and he invited possessors of gardens and green-houses to produce photographs of their contents, and so aid to form complete collections. In the same Section, and in some others, photographs were largely used to illustrate the papers of the contributors.

On Tuesday evening, Dr. Odling delivered an interesting lecture on "Reverse Chemical Action," and a second soiree was held in St. Andrew's Hall. A somewhat better collection of photographs was exhibited on the occasion. In addition to the fine photographs by Mr. Sawyer, there were some fine examples of the Eburneum process and other photographs by Mr. Burgess. Mr. Henderson, of London, sent down a frame of enamels by the process he has recently worked out with so much skill and energy, the details of which, however, are unknown. Many of the specimens were exceedingly perfect, and left little to desire. There were also some examples of Mr. Woodbury's process, and some examples of the value of clouds in photographic landscapes.

The Association was, as a whole, a less brilliant success than it has been on some occasions, the total number of members and associates present falling short of 2,000, whilst on recent occasions it has exceeded that number by some hundreds. There were fewer objects of interest at the soirees, and generally less enthusiasm than we have seen at many recent meetings. The photographic contributions were fewer and of less interest than on many occasions. One well-known face was missed in sections A and B, always associated with one or more photographic papers at these annual gatherings; we refer to M. Claudet. Mr. Joseph Ellis's memoir of him, reprinted as a pamphlet from the *Scientific Review*, was delivered amongst the members.

The next meeting will be held at Exeter, under the presidency of Professor Stokes.

## VISITS TO NOTEWORTHY STUDIOS.

### MR. BURGESS'S STUDIO AT NORWICH.

THE pilgrim visiting photographic shrines meets with an experience in England which is somewhat diverse from that he encounters in most other countries. In France, for instance, whilst he may occasionally meet in large provincial towns with fine examples of work, it is in Paris he will find the concentration of excellence: photographs of the

highest qualities in the greatest profusion, and in the greatest variety, spread broadcast over the city. Visitors are apt to regard Parisian photography as typical of French photography, a great mistake. In this, as in many other respects, Paris absorbs the refinement of France. The same fact, in relation to photography at least, is true of most parts of Continental Europe. In America the visitor's experience will not be far different. The highest excellence will be found concentrated in metropolitan towns, such as Boston, New York, Philadelphia, Baltimore, Chicago, &c., whilst in provincial towns will be found men whose chief business still consists of the collodion positive or "Ambrotype."

All this may seem very simple and very natural; probably it is so; but the noticeable fact is, that it is not so in England. Probably in no city in the world is there so much commonplace and relatively bad photography produced as in London. There are, of course, first-rate photographers in the metropolis, a few of unsurpassed excellence in their line, and a few more of high average excellence; but it is scarcely an exaggeration to say that the number of portraitists of really first-class ability, photographic and artistic, might be counted on the fingers of one hand. Foreigners for the first time visiting England notice this fact; provincial photographers visiting London are struck with it. But on travelling through the provinces the experience is reversed: the observant traveller is perpetually meeting in country towns with the works of some modest photographer possessing photographic excellence and art qualities far beyond the average. This is not unfrequently the case in some comparatively unknown provincial town; more frequently in a city of some fashionable or commercial importance. We might easily, if it would not be invidious, mention a score of illustrations of our position. The reader will, however, readily recall to mind the multitude of names distinguished in photography, whose reputation belongs to the provinces and not to the metropolis.

We are led to these reflections by a brief sojourn in the picturesque and ancient, but somewhat unprogressive, city of Norwich, where we visited two studios: that of Mr. Sawycr, and that of Mr. Burgess,\* the latter a gentleman whose name is known to our readers as the inventor of the Eburneum process, and as the author of various ingenious and useful suggestions which have appeared in our pages. We propose to describe the studio of Mr. Burgess first.

As might have been anticipated, Eburneum pictures form the speciality of his establishment, a good collection of excellent examples being displayed in his specimen room. These admirably illustrate the value of the process. Here, from one negative, are half-a-dozen sizes of one portrait, showing the effect of various gradations of enlargement, from a card size to a whole-plate or ten by eight picture; and the fact we have before mentioned was very noteworthy here, that owing to the exquisite delicacy of the material, everything like coarseness, commonly characteristic of enlargements, was entirely absent, and, further, that in some of the enlargements an amount of detail and gradation was present altogether wanting or imperceptible in a paper print from the original negative. Amongst the specimens we find some illustrations of the fitness of Eburneum prints for colouring, the effect being scarcely distinguishable from that of an ivory miniature, the similarity to genuine ivory in tint and transparency, of the fictile material, being of especial value for colouring purposes.

Whilst we are examining the specimens we ask Mr. Burgess's opinion as to the question of stability as based upon the four years' experience he has had. There are two possible sources of change in the materials of the finished picture, in regard to which we are anxious to obtain the results of experience. The possible elements of change are, first, the presence of a trace of chloride of silver, formed

when touting a silver print by means of chloride of gold; and, second, the known tendency of gelatine to become darker in colour. Mr. Burgess answered our question by placing in our hands a most charming whole-plate Eburneum portrait of a child, which had been for upwards of a twelvemonth in his window exposed to a blaze of light, often to direct sunlight. The picture was faultless in colour: the lights were of a delicate warm-toned white, peculiarly satisfying and pleasant to the eye; the half-tints were warm and rosy, and the deep shadows a rich deep neutral black. He then informed us that on removing the picture from the mount, after the long exposure to light, he found that the blacks and half-tones were a little deeper in the exposed portions than in those under the mount. The minute traces of chloride of silver formed had doubtless been reduced; but this only served to give a slight increase of force to the picture. The lights containing no silver were unaltered; but the various gradations of black had become, in just an appreciable degree, more strongly marked. In some cases, after long exposure to light, the whites acquire a slight tone, approximating to a delicate cream tint; but Mr. Burgess has not in his experience met with any change which involves deterioration.

In answer to questions as to the stability of the gelatine itself, and its susceptibility to change from heat and moisture, Mr. Burgess stated that if prints were kept carelessly in a very moist place, and then changed to a very hot or dry place, they would certainly manifest a tendency to curl and cockle; but with the ordinary care due to a work of art, and which a water-colour drawing, say, would receive, he had never had any trouble in preserving the pictures in perfectly good condition.

Beside Eburneum pictures, we find in the reception room a variety of excellent examples of paper portraiture, and notably a fine collection of views of Norwich. A very charming twelve by ten view of the Cathedral, seen through a clear opening in foliage in the foreground, composing admirably, is pointed out to us as an excellent example of what may be done by using the front combination of the rectilinear lens as a single landscape lens, just the requisite amount of angle being secured, he stated, which he could not readily have obtained with any other lens in his possession. Another view of the Cathedral alone is an admirable photograph, and, by the printing-in of clouds from a second suitable negative, it becomes a charming picture.

We will now ascend to the studio, which possesses many capital properties, and furnishes an excellent example of making the best of existing facilities. It is not a glass-room built for the purpose, but is what may be termed a converted studio. At the top of the building, which was suitable for business, Mr. Burgess found a large room, 38 feet long by 17 feet wide, with a low ceiling less than 9 feet high. On removing a portion of the ceiling, the ridge of the outer roof is found to be very lofty. Accordingly, Mr. Burgess had a portion of the ceiling removed, commencing with 5 or 6 feet of one end of the room and extending laterally about 12 feet. Into the roof thus laid bare he had two large sky-lights placed, each sloping from the ridge about 15 feet high, to the eaves about 9 feet high, forming on each side a space of glass about 12 feet square, placed at an angle of about 45 degrees. These lights face north and south, the latter, except for occasional purposes, being covered by blinds. In the north side wall are two or three small windows, of about 3 feet square, which for certain effects are available in lighting, but for most purposes are ignored and often covered up. The light of the room, it will be seen, is derived, in fact, from a skylight; but is in effect, from the steep pitch of the roof and the great width of the room, a high side light. A large reflecting screen of tinfoil in the frame-work of a pier-glass is made available in various effects of lighting. It will be seen that the lighted portion of the studio forms a room about 17 feet square, with a couple of lofty skylights. Beyond is the portion of

\* The name of the firm is Burgess and Grimwood, but we did not ascertain that Mr. Burgess's partner took any active part in the business.

the original room with its low roof, and no light beyond what might be admitted through a couple of very small windows on one side: the windows are kept covered, however, by blinds, this portion of the room providing the obscurity for the photographer and the camera which is sought by some in dark tunnels.

The studio is well supplied with good accessories: there is a variety of tables and chairs of good design; a rustic stile, rails, and some similar properties; a couple of shallow trays, about 7 feet long, 20 inches wide, and 3 inches deep, containing mould planted with natural foreground consisting of weeds, flowers, and ferns, amongst which we may mention, by-the-way, that the common nettle seemed most hardy. There is a variety of backgrounds, of which the favourite one appears to be one of a greenish-blue cloth, which, instead of being stretched on a frame or roller, is simply suspended by rings on a cord or wire stretched across the room, and kept stretched by two or three rings at the bottom attached to hooks on the floor. There is a capital contrivance for producing gradations of light and shadow on the background. It consists of a light-covered frame 7 or 8 feet long and 3 or 4 feet wide. This is suspended by a centre at each end of the frame, just above the background, and between it and the skylight. A cord attached to one side runs through loops along the ceiling, and hangs down beside the camera, within reach of the operator's hand. By pulling this cord the hanging screen can be placed in any position, and may be made, by reflection, to throw an extra portion of light on the background, or by intervening entirely, to cut off much of the light and produce tolerably deep shade.

That Mr. Burgess is an art student his work renders apparent, and we find on a table in his studio the quaint old quarto of Gerald de Lairese. In the surroundings, generally, an artistic feeling is manifest. In his mode of operating and dealing with his sitter the same quality is apparent—a fine taste, and quiet, unobtrusive demeanour, an absence of fidgetty uncertainty in making his arrangements, all conducing to a satisfactory result in portraiture.

We had the pleasure of watching the simple, certain, and rapid manipulations in producing fine prints by the Eburneum process, some further observations upon which, in relation to points of practice, we must defer for a future number.

## PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN

COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXXI.

"The same principles of uniformity and variety or variegated unity which must be previously pursued in so arranging and constructing the figures and general forms of a picture that they may serve as a proper substratum for that chiaroscuro which brings them to the sight as an harmonious totality—these same principles, and these *only*, are the constituents of all similar agreeable effects."—BARRY.

### CHIAROSCURO—PORTRAITURE—(continued).

SINCE the last chapter was in the hands of the printer I have had the pleasure of receiving a visit from M. Adam-Salomon, the great master of photographic chiaroscuro, whose name and works I have had occasion to mention frequently, and we enjoyed a day's work together in the studio. It was gratifying to me to find that the direction that I gave in Chap. XXX. for lighting a head very closely resembled the arrangements employed by this famous photographer. The secret of success depends not so much on any given formula for the adjustment of blinds and backgrounds as upon a proper appreciation of what treatment is required to give character and individuality to heads that differ so much from one another as those which come under the consideration of professional photographers; but it will be found in practice that the four white blinds described, and the use of the studio diagonally, will give a very wide range of effects.

It was an instruction from Queen Elizabeth to Zucchero, when he was about to paint her portrait, that he should put

no shadow into her face. A similar story is told by Catlin of some Red Indians whom he painted. The Queen of England—in that period which has been called the Augustan age, when Shakespeare, Ben Jonson, and Spencer wrote—and the noble savages were equally ignorant of art and its requirements. The portrait photographer of the present day will occasionally hear his sitter say, "One-half my face is not black." This is, no doubt, sometimes said, after the fashion of the virgin queen, through ignorance; but it will be more often found that the lighting of the head is in fault, that the light has been too violent, the exposure too short, or the intensification carried too far; and because of these causes the gradations in the shadows, as well as the lights, are lost, and there is no transparency in the shadows, or balance of light and shade.

The light that illuminates the head will, of course, be that which lights the figure; it therefore follows—the light being fixed—that the only other means of modifying the chiaroscuro of a portrait is by the colour of the dress of the sitter and accessories, and by the background. Of the light and shade of the background I have sufficiently treated in Chapter XXII.; the degree of importance given to the accessories will, in a great measure, both as regards lines and light and shade, establish the degree of consequence to be given to the head. In giving great prominence to the head, care must be taken that it be not wholly isolated. The accessories are the media which act less as a foil to the head than as aids which assist it to keep its place without impairing its force, as the middle tones find value and clearness only by power of the lights or the strength of the shades.

The accessories should be employed not only to repeat forms, but also to repeat lights. If the head were left a white space in the midst of a large mass of dark, the effect would be that of a *speck* instead of a *mass* of light. The light of the head should be several times echoed throughout the picture in fainter tones. There must be no exact equality in any of the repetitions, neither should there be many, for if the lights are few and unequal, the result will be breadth and repose; if many and scattered, there will be confusion. To keep the chief mass of light clear and pure should be the constant and earnest aim.

The outlines of the figure or of the accessories should not be everywhere visible. When this is the case the effect is thin, wiry, and flat, like carved work without the relief of sculpture. Portions of the objects represented should melt into the background and shadows, which method will be found to produce rich, soft, and mellow effects.

The dress should be of that character best suited for producing harmonious results. It has been the practice of photographers to set their faces against particular colours as unsuitable, such as white or light blue, and always to recommend black silk. It is time this erroneous notion was done away with, and photographers should learn that if they fail to find white—especially silk or muslin—not only a possible, but a quite delightful, colour to photograph, they have not learnt all that it is possible for them to know of their art. What can be more beautiful or picturesque—conducive not only to light and shade, but to texture—than a muslin "Garibaldi" or jacket, worn with a silk skirt of any shade, so that it is darker than white? What can be better for a vignette than the sketchy lightness that is produced by the white dresses and light blue ribbons sometimes worn by children? And yet white and blue are often tabooed!

It is a fault much too common that all subjects are treated alike; gentlemen, ladies, and children are tarred with the same brush, and that often a very black one indeed, when they should be separately studied and treated. Intense lights and darks in conjunction (for instance, a black velvet coat near the face), surrounded by middle tones into which the highest lights and deepest darks are carried, seems to be a system very suitable to the portraiture of men. Ladies and children should always, I think, be treated in a lighter style, with more refinement and delicacy.

And this brings me to a subject which, I think, should

not be forgotten in a work on photographic chiaroscuro—definition and diffusion of focus.

For the last few years some photographs by a lady—many of them failures from every point of view, but some of them very remarkable for their daring chiaroscuro, artistic arrangement, and, in some few instances, delightful expression—have been brought prominently before the public. These pictures, for the qualities I have mentioned, have received the most enthusiastic praise from artists and critics ignorant of the capabilities of the art, and who, because of this want of knowledge of photography, have attributed the excellences which they undoubtedly, as masses of light and shade, possess, to their defects. These defects are, so little definition that it is difficult to make out parts even in the lights; in the shadows it often happens that nothing exists but black paper; so little care whether the sitter moved or not during the enormous exposure which, I have been told, is given to these pictures, that prints are exhibited containing so many images that the most careless operator would have effaced the negative as soon as visible under the developer; and, apparently, so much contempt for what we may almost call the proprieties of photography, that impressions from negatives scratched and stained, and from which, in one or two cases, the film has been partly torn away, are exhibited as triumphs of art. The arguments of the admirers of these productions are, that the excellences exist because of the faults, and that if they were in focus, or more carefully executed, their merit would be less. This is not true, and if it were, I should certainly say, Let the merits go, *it is not the mission of photography to produce smudges*. I think the artist herself is beginning to feel this, for I have seen some later productions much more carefully worked out. If studies in light and shade only are required, let them be done in pigment or charcoal, with a mop, if necessary, but photography is pre-eminently the art of definition, and when an art departs from its *function* it is lost. I must not be understood to mean that I object to that almost invisible diffusion of focus produced by spherical aberration in a lens, or by unscrewing the back lens, as arranged in Dallmeyer's group combinations; this is a power of immense value to a photographer, especially in large pictures; for portraits larger than 10 by 8 the lens should always be unscrewed at least one turn; by this means all parts are brought into focus without visibly injuring the definition in the usual plane of focus.

Having stated sufficient to initiate the photographer into the mysteries of chiaroscuro, and to induce him, I hope, to a further study of art, I will conclude this portion of my subject with an extract from Sir Joshua Reynolds's notes on Fresnoy's "Art of Painting," in which he describes his method of study, and which may be followed with advantage by the student:—

"I shall here set down the result of the observations which I have made on the works of those artists who appear to have best understood the management of light and shade, and who may be considered as examples for imitation in this branch of the art.

"Titian, Paul Veronese, and Tintoret were among the first painters who reduced to a system what was before practised without any fixed principle, and consequently neglected occasionally. From the Venetian painters Rubens extracted his scheme of composition, which was soon understood and adopted by his countrymen, and extended even to the minor painters of familiar life in the Dutch school.

"When I was at Venice, the method I took to avail myself of their principles was this: when I observed an extraordinary effect of light and shade in any picture, I took a leaf of my pocket-book and darkened every part of it in the same gradation of light and shade as the picture, leaving the white paper untouched to represent the light, and this without any attention to the subject or to the drawing of the figures. A few trials of this kind will be sufficient to give the method of their conduct in the management of their lights. After a few experiments I found the paper blotted

nearly alike: their general practice appeared to be to allow not above a quarter of the picture for the light, including in this portion both the principal and secondary lights; another quarter to be as dark as possible; and the remaining half kept in mezzotint or half-shadow.

"Rubens appears to have admitted rather more light than a quarter, and Rembrandt much less, scarce an eighth; by this conduct Rembrandt's light is extremely brilliant, but it costs too much; the rest of the picture is sacrificed to this one object. That light will certainly appear the brightest which is surrounded with the greatest quantity of shade, supposing equal skill in the artist.

"By this means you may likewise remark the various forms and shapes of those lights, as well as the objects on which they are flung; whether a figure, or the sky, a white napkin, animals, or utensils, often introduced for this purpose only. It may be observed, likewise, what portion is strongly relieved, and how much is united with its ground; for it is necessary that some part (though a small one is sufficient) should be sharp and cutting against its ground, whether it be light on a dark, or dark on a light ground, in order to give firmness and distinctness to the work; if, on the other hand, it is relieved on every side, it will appear as if inlaid on its ground. Such a blotted paper, held at a distance from the eye, will strike the spectator as something excellent for the disposition of light and shadow, though it does not distinguish whether it is a history, a portrait, a landscape, dead game, or anything else; for the same principles extend to every branch of the art.

"Whether I have given an exact account, or made a just division, of the quantity of light admitted into the works of those painters, is of no very great consequence; let every person examine and judge for himself; it will be sufficient if I have suggested a mode of examining pictures this way, and one means, at least, of acquiring the principles on which they wrought."

## RECENT EXPERIMENTS WITH COLLODION.

BY DR. VOGEL.\*

COMMUNICATED FROM THE PHOTOGRAPHIC STUDIO OF THE ROYAL INDUSTRIAL COLLEGE AT BERLIN.

IN my earlier experiments with collodion I showed that the quantity of sensitizing salt contained in a collodion influences in general the sensitiveness of the latter: the more sensitive a collodion is, the more salt it contains. I am now about to consider what influence is exerted by the proportion of bromine salt contained in collodion.

A few years back I described the working of bromine salt in collodion, and gave an account of an experiment with two collodions, both containing the same amount of iodine salt, to one of which, however, a bromine salt had been added. The bromine collodion proved to be the more sensitive for dark objects, and the compound containing no bromine was better adapted to light ones, the first giving a soft picture of a plaster cast surrounded by black drapery, the latter a solarized representation of the white cast and an under-exposed image of the black drapery. The bromine salt was, therefore, proved to be the more sensitive to dark rays, and from this fact the conclusion has been deduced that an increase in the quantity of bromine salt secures an increase of sensitiveness in the collodion for dark rays. This belief is very general, and we often hear advice to the effect that in order to soften a hard collodion more bromine salt should be added.

I myself for some time participated in this belief, until, after several observations, scruples arose in my mind as to the correctness of the theory.

On one occasion I added to a collodion which gave too hard results a little bromine salt, when, to my astonishment, the negatives produced therewith became more hard. A similar result was obtained on comparing Meynier's

\* Photographische Mittheilungen.

slightly bromized collodion with mine, containing a large quantity of the salt.

These circumstances induced me to undertake a thorough investigation of the influence exerted by different proportions of bromine salt contained in iodized collodion, and with this view I compounded five different descriptions of collodion. In preparing these samples I employed the multiple proportions of the chemist, so that equivalent mixtures of iodide of cadmium and bromide of cadmium were present in each of the different collodions. The preparation of collodions of this description is very simple. I dissolved 17 parts of bromide of cadmium on the one hand and 18 parts of iodide of cadmium on the other, each quantity in 270 parts of alcohol, and thus obtained two solutions in which the amount of salt in each volume bore the same proportion to one another as the atomic weights of the two compounds. If a collodion containing one equivalent of bromine and one of iodine is required, equal volumes of the two liquids are employed, and in this wise I prepared all my equivalent collodions hereafter mentioned. After mixing the iodizing solutions, three times their volume of normal collodion, containing two per cent. of gun-cotton, was added, and the whole allowed to stand and clarify. The whole of the collodion samples were at first colourless, but after a lapse of several weeks the strongly iodized specimens began to assume a yellowish tint. The collodions I prepared were as follows:—

No. 1.	3 eq. iod. cadmium	+ 1 eq. brom. cadmium			
" 2.	" "	" + 1 "	" "	" "	" "
" 3.	1 " "	" + 1 " "	" "	" "	" "
" 4.	1 " "	" + 2 " "	" "	" "	" "
" 5.	1 " "	" + 3 " "	" "	" "	" "

After preservation for six months the collodions were experimented with. For this purpose a white bust surrounded by black drapery was employed as the object to be photographed, and a Dallmeyer's stereoscopic apparatus as the camera. Of each plate one half was exposed for fifteen and the other for thirty seconds; the plates were sensitized one immediately after the other in the same bath, and all brought together in the studio, where they were exposed.

These comparative experiments were afterwards repeated in reverse order, so as to detect any errors which might possibly arise during the unequal periods of delay occurring between the sensitizing and exposure of the plates. All the negatives were developed in exactly the same manner, the result being as follows:—

(A). Nos. 1 and 2.—Nos. 1 and 2 behaved in the same manner, both yielding a soft, opaque, and at the same time brilliant picture; No. 1 appeared a little more intense than No. 2.

(B). Nos. 2 and 3.—No. 2 gave, as before, a brilliant, opaque, and soft picture; while No. 3 showed less details in the darker parts, and appeared less opaque, and harder.

(C). Nos. 3 and 4.—No. 3 was richer in detail in the shadows than No. 4, but with this exception the results were analogous to No. 3 above.

In all cases the strongly iodized plates were cleaner than those containing more bromine.

(D). Nos. 4 and 5.—No. 4 was the same as in experiment C. No. 5 deviated totally from the others; it was fogged, but at the same time showed much more detail in the darker parts of the picture than No. 4, and was softer, although weaker in the lights.

A repetition of the experiments, sensitizing the plates in the reverse order, gave similar results.

From this it will be seen that the strongly iodized collodions, Nos. 1 and 2, yielded the most brilliant, most opaque, softest, and most harmonious pictures, and that the strongly bromized collodions, 3 and 4, worked less clean, and harder; also that the collodion containing most bromine, No. 5, yielded a very soft picture, which was, however, weaker, and not so intense in the lights as Nos. 1. and 2. An increase in the proportion of bromine has therefore

at first the effect of rendering the collodion harder, and it is only when the bromine is added to the extent of that in No. 5 that softness is again secured, together with fogging and weakness in the lights.

As the tendency of a negative to fog may always be avoided by the use of an acid bath, the last named collodion (No. 5) possesses undeniable advantages for taking certain brilliantly-lighted objects, as, for instance, sun-lit landscapes.

Of peculiar interest is the comparison between the strongly iodized collodion, No. 2, which may be regarded as the most practical of all, and the remarkable bromine collodion, No. 5, which possesses such peculiar sensitiveness. Plates were prepared with both collodions, and exposed under similar conditions: the bromine collodion, No. 5, yielded a fogged picture, while the iodine compound worked perfectly clean. The lights, as also the shadows, appeared quite as elaborate in the strongly bromized as in the strongly iodized collodion, but the latter gave a more intense picture. On employing an older and more acidified bath, the strongly bromized collodion yielded pictures free from fog.

As I am at present prevented from continuing the prosecution of these interesting experiments, I publish the results already obtained. The introduction of new sensitizing salts in the place of cadmium compounds, and a careful study of their action, as likewise the influence exerted by different strong developers, and the employment of other sensitizing agents in lieu of nitrate of silver, and the behaviour of the above iodizers in dry-plate photography, are all open questions of great practical importance, in the solution of which many experiments will have to be undertaken.

A duty of a scientific nature, which promises to be of some importance to photography, calls me into the far south, and compels me to relinquish, for the present, my cherished researches. The reader is on this account requested to excuse the fragmentary form in which the above results have been made known.

#### ON SULPHOCYANIDE OF AMMONIUM.

BY DR. T. L. PHIPSON, F.C.S., ETC.\*

This is a salt which can be obtained in large quantities from the products of the distillation of coal. It accompanies the other compounds of ammonia in the ammoniacal liquor of gas works. In several manufactories it is made to yield its ammonia for the production of sulphate of ammonia; for this purpose it is distilled with lime after the carbonate and sulphide of ammonium have been separated.

For many years I have noticed that the sulphate of ammonia supplied to commerce for agricultural and other purposes often contains a small quantity of sulphocyanide—say from 2 to 4 per cent.—but latterly a much larger quantity, which increases its yield in nitrogen when submitted to analysis, without bestowing upon the product a corresponding value in an agricultural sense. For though the nitrogen of the ammonium in the sulphocyanide can be utilized like that in sulphate of ammonia, that contained in the form of sulphocyanide escapes. In other terms, only one-half of the nitrogen in sulphocyanide of ammonium is available in the manufacture of artificial manures, since the other half is partly volatilized as sulphocyanhydric acid, and partly decomposed by the heat of the reaction, which is sometimes great enough to ignite the bisulphide of carbon resulting from the decomposition.

Within the last twelve months the quantity of sulphocyanide of ammonium present in some kinds of commercial sulphate of ammonia appears to have increased considerably, and several samples which I have examined recently have yielded upwards of 75 per cent. of this salt. In fact they were not sulphate of ammonia at all, but impure sulphocyanide of ammonium.

\* Read in Section B at the British Association.

I found it necessary some time ago to discover a means of estimating rapidly, and with economy, the amount of this product when mixed with sulphate and chloride of ammonium and the various organic matters which usually accompany the commercial product.

Sulphocyanide of ammonium can be separated with tolerable accuracy from the sulphate by means of alcohol, in which it is freely soluble; but this method will not apply when chloride of ammonium is present also, nor does it give the sulphocyanide in a commercial form for weighing.

A method which I have satisfied myself gives very accurate results, and is sufficiently rapid, consists in dissolving a given weight of the product in water, filtering, rendering the solution rather acid, and precipitating the sulphocyanogen as an insoluble salt of copper by the addition of equal equivalents of sulphate of protoxide of iron and sulphate of copper. The whole of the sulphocyanogen is eliminated in this manner. The copper compound is received upon a tared filter, washed, dried at 100° C., and weighed. It is anhydrous, and contains  $\text{Cu}_2, \text{C}_2 \text{N}_2 \text{S}_2$ .

Having prepared a certain quantity of pure sulphocyanide of ammonium, I took the opportunity of studying some of its properties. Of these experiments I will mention only those which appear not to have been made before.

Sulphocyanide of ammonium dissolves copiously in water and in alcohol, and these solutions offer considerable interest. In the first place, in dissolving rapidly in water this salt produces a greater degree of cold than any other compound with which I am acquainted. About half a litre of water being poured upon 500 grammes of the impure salt, I was surprised, in stirring the whole together, to find that hoar frost appeared immediately on the external surface of the vessel. The temperature of the solution was found to be between 2 and 3 degrees below zero, that of the hot water used 96°, showing that the temperature had sunk 98° or 99° Centigrade in the space of a few seconds.

A substance which absorbs so much heat whilst dissolving would be expected to give out again much caloric when it crystallizes; and such is the case. With saturated solutions the crystallization is accompanied, on this account, with some curious phenomena: as one large crystal forms, the adjacent crystals are dissolved again by the heat produced, giving rise to a series of rapid movements in the liquid and along its surface. Some of these vibrations spread along the entire surface with the rapidity of lightning, and continue at short intervals until the whole liquid suddenly solidifies.

From concentrated solutions sulphocyanide of ammonium crystallizes in large transparent plates of a slightly pearly aspect; these plates appear to be formed of long prismatic needles intimately united, and are best obtained in very concentrated solutions; when weaker solutions are caused to crystallize, right rectangular prisms are formed; they are often of great length; I have occasionally obtained them two to three inches long.

The alcoholic solution of sulphocyanide of ammonium presents in the highest degree the peculiar phenomenon of supersaturation. A saturated hot solution, after cooling, will remain liquid for hours, probably for days together; but if the liquid is stirred with a glass rod it is immediately transformed into a mass of small crystalline plates. When, instead of a glass rod, a minute crystal of the salt itself is thrown into the supersaturated solution after it has become quite cold, at the same instant magnificent rectangular plates, having the four faces of the octahedron, begin to form rapidly upon the surface, and the vessel is soon filled with splendid crystals. The supernatant liquid, separated from these, can be made to deposit still a considerable quantity of small crystalline plates, by being stirred rapidly for a minute or two with a glass rod.

A concentrated aqueous solution of sulphocyanide of ammonium has no action upon sulphur, but it dissolves a considerable quantity of iodine, and when the dark-coloured solution is diluted and heated, the yellow compound called "sulphocyanogen" is precipitated, and the liquid becomes

colourless. Bromine acts in a similar manner. Each drop of bromine on falling into the warm solution produces a hissing noise; on boiling the liquid the sulphocyanogen compound is precipitated. These two precipitates are insoluble in alcohol, and soluble in sulphuric acid, like that which is produced by chlorides. The action of chlorine gas upon solutions of sulphocyanide of ammonium is very remarkable. If the solution is dilute, the sulphur is gradually oxidized to sulphuric acid, and no precipitate is formed. If concentrated, a dense precipitate of sulphocyanogen occurs after a little time. It is difficult to obtain the whole of the cyanogen in this form even when the liquid is kept near its boiling point the whole time. When the decomposition is complete, and the liquid separated from the precipitate is evaporated, it yields chloride of ammonium. The action of chlorine on this solution is yet incompletely known. The composition of the so-called "sulphocyanogen" has been much discussed; for some time this precipitate was considered to be the radical of sulphocyanhydric acid, but it was afterwards found to contain hydrogen and oxygen.

The composition assigned to this substance by Laurent and Gerhardt—namely, 3 eq. of cyanogen, 1 of hydrogen, and 6 of sulphur—appear to be inadmissible. The results of my analyses of this compound correspond with those of Voelkel, not with those of Laurent and Gerhardt. It should be stated, however, that Charles Gerhardt, to whom organic chemistry owes so many splendid investigations, whilst criticising Herr Voelkel's labours on sulphocyanogen, based his own opinion in this case upon an incomplete analysis of the substance in question. The product can be completely purified by washing with hot water and with alcohol should it contain any persulphocyanhydric acid, which seldom occurs, or, where it does happen to be present, is generally in too small a quantity to affect the results of the analysis. The dried precipitate is anhydrous. It has yielded me numbers which agree with the formula:  $\text{C}_3 \text{H}_2 \text{N}_4 \text{S}_3 \text{O}$ , as admitted by Herr Voelkel, and not with that of Gerhardt, which requires 24 per cent. of nitrogen (instead of 23.14) and nearly 55 per cent. of sulphur (instead of 52.41); it contains, then, the elements of 4 eq. of sulphocyanogen, 2 of hydrogen, and 1 of oxygen; thus—

The insoluble copper salt above mentioned was suspended in boiling water whilst a current of chlorine gas was passed through the solution, with the expectation of obtaining sulphocyanogen itself, but little or no decomposition ensued. When iodine was substituted for chlorine, the copper compound was partially decomposed, with production of some iodide of copper and an odour of iodide of cyanogen.

In conclusion, I may add, that as the products derived from sulphocyanide of ammonium are very numerous, it is not improbable that some of them may eventually be applied to some useful purpose; if so, it will be satisfactory to know that we possess a supply of this salt as inexhaustible as that of coal itself.

Dr. Frankland (President of the Section), in proposing a vote of thanks to Dr. Plinpson, remarked that the increased degree of impurity of commercial samples of sulphate of ammonia, at the same time that it prejudiced the interests of the agriculturists, offered a promise of the sulphocyanide of ammonium being supplied at a reduced cost for chemical purposes, and, there were no doubt, many uses to which this salt and other sulphocyanides could yet be applied.

Mr. J. Spiller instanced the employment of sulphocyanide of ammonium as a fixing agent in photography as one of the cases where a reduced cost would permit of its extended application. For this purpose the salt would need to be very carefully purified from alkaline sulphides, since these were liable to impart a yellow tinge to the high lights in the photograph. The sulphocyanide of ammonium stood much in the same condition as the hyposulphite of ammonia, which required further development on the part of manufacturers.

## ON A PECULIAR ACTION OF LIGHT UPON THE SALTS OF SILVER.

BY PROFESSOR MORREN.\*

THE molecular movements produced under the action of light present special interest, and in order to show my sympathy with this Association I present the results of some experiments, although they are at present not completed. The facts are these:—If in a tube of white glass from 14 to 15 inches long, and from 1 to 2 inches in diameter, you enclose moist chloride of silver freshly precipitated by means of a solution of chlorine in water, and expose it to the direct action of the solar rays, it will be observed that while the chlorine solution is still yellow the chloride of silver remains perfectly white; but afterwards the chlorine solution becomes colourless and clear, and the chlorine decomposes the water under the action of light. As soon as the chloride of silver blackens at the surface it should be agitated from time to time, and left exposed for a few days to direct light until the whole becomes of a fine black colour.

Now take the tube into a dark place, and you will see the blackness disappear by degrees, chloride of silver becomes reformed, and the contents of the tube become perfectly white, although its structure is evidently different to what it was previous to its exposure to light. Then we may expose it afresh to the sun, and after it has again become black we can make it white again, and this experiment can be repeated indefinitely, and is an evidence that in those successive reactions the chlorine, oxygen, hydrogen, &c., preserve their properties of combination and recombination. These gases manifest the properties which we, in France, call the nascent condition—properties certainly electric, and which only in certain circumstances become evident, but which, without doubt, exist in all bodies when the circumstances are favourable. We have plenty of examples in connection with oxygen, hydrogen, and similar bodies. There is one special and striking example in the experiment which ought to be mentioned. If we place chloride of silver in a thin and fine tube, one millimetric internal diameter, and close it at one end, this little tube being placed in the larger one, its chloride becomes dark under the action of light, but once dark it remains always black, whilst its neighbour, under the alternate action of light and darkness, blackens and bleaches, a manifest evidence of the molecular movements induced by the light upon the chloride of silver when surrounded by a suitable liquid.

It is easy to comprehend the value of the knowledge of this property in photography. We see with what care we ought to get rid of our enemy, hydrochloric acid, from our sensitive papers; to dry them perfectly, and to deprive them of all hygroscopic salts, for without doubt the image, especially the darker portions, will be liable to the decomposition and recombination above described.

Bromide of silver presents the same properties and the same effects; but it is necessary, in order for the bromide salt to become colourless, that a longer exposure should be given. With respect to the iodide of silver, there are special conditions requisite, and I have only been able to cause this salt to blacken in the sun after having sensitized it by means of pyrogallie acid. It does not blacken visibly without a reducing agent. It would be especially interesting to know if the cyanide of silver would behave in a similar manner in the presence of cyanogen; but I have not had time to make this experiment, but I hope to be able to record it at another meeting of the Association.

## ON ACTINOMETRY.

BY L. HING.†

HAVING made a few experiments for the purpose of ascertaining the actinic power of light, which I considered might not be uninteresting to science, I beg to submit the following communication to your notice:—

Permit me, in the first instance, to speak briefly of an instrument of my construction for actinometric purposes, which is already known. It consists of layers of mica, and upon each number of layers of mica is placed a figure corresponding with such number by means of an opaque pigment. This instrument, being charged with sensitive paper and exposed to the action of light, yields a graduated series of tints upon such paper, presenting white figures surrounded by darkened surfaces. The highest visible figure is always surrounded by the palest tint.

This instrument has, however, several defects, the chief of which is, that according to the varying intensities of light its action will vary, as will be explained by the following experiment:—

You might come to the conclusion that, if the intensity of light transmitted through one layer of mica be equal to one, the intensity transmitted through two layers equal one-fourth, through three layers equal one-ninth, &c.; or that the intensities transmitted vary inversely as the squares of the numbers of layers of mica. It does, however, by no means appear that actinism is transmitted through a medium in the same harmonic progression.

From a rather thin negative print a positive, firstly in the direct rays of the sun, exposing at the same time a mica actinometer charged with sensitive standard paper also to the direct rays of the sun. Examine the positive picture from time to time in a so-called photographic dark room, or in any room lighted artificially by a non-actinic light, but remove also, or screen from the light, the actinometer during the time of the examination of the positive. When you consider the positive so far printed as to be fit for photographic toning, remove the papers both from the negative and from the actinometer, and write with a pencil upon the back of the one taken from the latter the word "sun."

Next print a positive from the same negative in diffused light in the open air, exposing at the same time the actinometer, charged anew, to the same light. Pursue the same course as before, and examine your positive from time to time in the dark room, having the first positive at hand for comparison with the second. It is best to fix upon some dark, yet not black, tint in your first picture for comparison with the second; also to hold the first picture by the side of the half of the second picture which you are examining in your printing-frame. Thus make frequent comparisons with the tint you have fixed upon until the two tints appear to be alike in depth of printing. Then remove again the papers from the negative and from the actinometer, and upon the one taken from the latter write the word "shade."

Print now a third positive from the same negative inside a window where daylight is but feebly diffused, exposing again simultaneously the newly-charged actinometer by the side of the negative. Pursue again the same plan as before. After this third positive has been found to be printed equally deep as the two former, place the three papers which have been printed under the actinometer side by side for examination in your dark room.

The paper which has been printed in the direct rays of the sun will present the largest number of figures; next comes that which has been printed by diffused light in the open air; and the least number of figures will appear upon the paper printed inside the window, although the three pictures might be pronounced alike.

The positives would, however, appear not to be quite equal in tone on a more exact examination of the extreme tints in each picture with one another. Their inequality would consist in this:—The positive printed in the feeblest light presents the deepest tint in the darkest shades, and the palest tints in the lightest parts; next comes the positive which has been printed in the more bright diffused light; and the positive printed in the direct rays of the sun exhibits the least contrast between its palest and darkest tints; and its darkest tints, compared with the darkest tints in the other two positives, presents the least depth, just as its palest tint, compared with the palest tints in the other two positives, is decidedly the darkest of the three. Indeed, it does not seem possible to print three positives in three lights of strongly-varying intensities to be exactly alike in all their tints.

If you examine now the tints, instead of the figures, in the three papers printed under the actinometer, they agree with the results presented in the pictures. The first tint of the paper printed in the feeblest light, which paper shows the

\* Read at the British Association, in Section A.

† Read in Section A at the Meeting of the British Association.

smallest number of figures, is the darkest; next in order comes that which was exposed to the next brightest light; and the first tint of the paper that was exposed to the direct rays of the sun, and which exhibits the largest number of figures, is the palest on comparison with the first tints of the other two papers.

I once constructed an actinometer of only seven figures by means of a rather opaque medium. In the direct rays of the sun the printing of a positive from a certain negative required No. 5; in a diffused light in the open air, whilst the sun was shining, a positive from the same negative required only No. 3; and printing one dull winter's day from the same negative, and under the same actinometer, the positive was finished, and not the faintest trace of a figure presented itself upon the paper taken from the actinometer. The margins of the paper, projecting beyond the actinometer, had arrived at the stage of strong bronzing.

This instrument would thus appear to possess but small value, both for the scientific measurement of the actinic power of light, as well as for photographic purposes. It almost seems as if it had no other value but that of verifying, a fact with which most photographers are familiar, namely, that in order to produce good positives from thin negatives they ought to be printed in feebly-diffused light, because the feebler light will readily act through the more transparent parts of the negative, and but very slowly through the semi-opaque parts, thus yielding good contrasts between the tints of the picture; and, in accordance with this fact, the feebler light acts readily through the first few layers of mica, until, after passing through a certain number of layers, it seems to possess but very slow power to affect the sensitive paper.

I hope, however, to show presently some important uses to which this instrument can be applied, and would now beg to describe another instrument of my construction.

This instrument consists of a single tube, open at one end, where light for measurement is admitted, and closed at the other. This tube is constructed of three strips of yellow non-actinic glass, and the fourth side of the tube, where sensitive paper is applied, may either consist of a strip of pure glass, with a scale marked thereon, or of a narrow scale made of metal or any other material, in which case light affects the sensitive paper quite freely.

In this state the instrument can only be used for the measurement of the actinic power of diffused light. By applying, however, a small convex mirror or a small lens at the aperture of the instrument, the direct rays of the sun can also be measured on being received in a divergent direction within the tube. The action of light upon sensitive paper is here seen through the yellow non-actinic glass, and it can be watched without removal of the instrument or of the sensitive paper therefrom. The action of light can also at any moment be stopped, without removal of the instrument, by shutting the aperture with an opaque shutter, and thus excluding actinic light.

The principles upon which this instrument are founded are—

1st. That diffused light, on entering a tube at one end only, varies in intensity within the tube inversely as the square of the distances from the aperture where light enters.

2nd. That any number of tubes, whatever their magnitude, contain the same intensity of light if the ratios of their diameters to their lengths are equal, and if we absorb the light that may be reflected from their sides.

I would now beg to call your attention to the following experiments:—

Construct a series of tubes of cardboard, open at one end, and provided with a cover at the other, of the same diameter (say of two inches) and varying in length by a semi-diameter. Let the first tube be of two inches length, the second = three inches, the third = four inches, up to ten inches, or more, if you like; but these nine tubes will suffice. The inside of the tubes must be blackened, in order to absorb the light that would otherwise be reflected from their sides.

Next construct a number of small mica-actinometers of twenty or thirty figures, and of such dimensions that they can be placed within those tubes. For the sake of convenience, let each actinometer have a letter of the alphabet, whereby to name it, placed upon its first layer of mica instead of figure 1. Charge each instrument with a strip of sensitive standard paper, and insert one at the base within each tube, and secure each base against the entrance of light from without. Let the actinometer named A be situated at the base of the shortest

tube of two inches, B in that of three inches, C in that of four inches, &c., each succeeding letter in the next longer tube.

Expose now all the tubes which are open at the ends opposite their bases simultaneously to the same diffused daylight five, ten, or fifteen minutes, more or less; then take all the tubes at the same time into your dark room. Withdraw the actinometers from the tubes, and the papers from the actinometer.

Please to remember now that each letter of the alphabet will be surrounded by the darkest tint upon the paper removed from the actinometer which such letter represents, because such letter is placed upon the first layer of mica, and let now each paper also be named by such letter.

On comparing the papers with one another, the following results will appear:—

1. Compare with paper A, which was printed within the shortest tube, all the other papers.

The tint around letter B = the tint around No. 3 of paper A.

" " " C = " " " 5 "

" " " D = " " " 7 "

Thus, through the whole series the tint around each succeeding letter printed within the corresponding longer tube being paler by two tints.

2. Take any paper of the series (say paper D), and compare the following papers with it:—

The tint around letter E = the tint around No. 3 of paper D.

" " " F = " " " 5 "

" " " G = " " " 7 "

&c., as before.

3. Compare the papers successively with one another:—

The tint around letter B = the tint around No. 3 of paper A.

" " " C = " " " 3 " B.

" " " D = " " " 8 " C.

each first tint equalling the third tint of the paper printed in the next preceding shorter tube.

4. Compare all the figures which each paper presents with one another. Let, for instance, paper A show twenty-five figures.

	Paper A shows	25 figures,
Then	" B "	23 "
	" C "	21 "
	" D "	19 "

each succeeding paper printed within the next succeeding longer tube exhibiting two figures less than the preceding one.

The defect which has, in a former part of this memoir, been shown to exist in the transmission of the actinic power of light through a medium ought to become apparent in the above experiment. On account of the comparative shortness of exposure given, it can only be traced to a small extent in the fourth comparison of the papers. This does not, however, affect the general character of the experiment.

We may now draw from the above experiment the general conclusion that there is a decrease of two figures and of two tints in each succeeding paper, beginning with that which was printed within the shortest tube; or, if the paper printed within the longest tube be represented by 1, the paper taken from the next shortest tube would equal 3, and, thus continuing, we shall have the numbers 1, 3, 5, 7, &c. On adding these figures from the beginning, we produce the following series:—4, 9, 16, 25, &c., equalling the squares of the lengths of the tubes.

Without further analysis of the above experiment, I think it may be stated now that the power of actinism, as well as the intensity of light, within a tube, varies inversely as the squares of the distances.

Construct, next, two tubes, blackened within, of different diameters, and let the length of each tube be equal to (say) twice its diameter. Let one tube have a diameter (say) of two inches, and the other of six inches; then their respective lengths must be equal to four inches and twelve inches. Place at the base within each tube a mica actinometer charged with sensitive standard paper. Close each base, and expose both tubes simultaneously to the same diffused light for the same period of time. On examining the printed papers no difference whatever is exhibited in their appearance, either with regard to tint or to number of figures. You might make several such experiments, with any number of tubes of various diameters, and with the same results.

Thus the intensity of light as well as the power of actinism is the same in tubes of various magnitudes, if the ratios of their diameters to their lengths are equal.

It will be readily seen that instruments might be constructed by means of tubes of various lengths but of equal diameters, or

by means of tubes varying in diameter and of equal length, in order to produce gradations of light for actinometric purposes.

On account of its greater convenience, I have, however, chosen the single square tube, and of such tube one side, as already stated.

The power of actinism and the intensity of light at any given distance *on this side* of the tube are, however, by no means equal to the power of actinism and the intensity of light at such given distance *within* the tube. But the investigation of the powers of this side-light would be too lengthy for this paper.

I beg, finally, to state that, for scientific purposes, I use a tube one inch in width and four inches in length: for photographic purposes, such as the timing of photographic prints, a tube of half an inch in width by four inches in length.

The instrument is self-registering, and, by means of a continuous strip of paper and a simple clockwork, can be made to register the actinic power of light throughout the day, per minute or per hour, or any other chosen division of time.

By combining several instruments with one clockwork, the powers of actinism during each successive minute, successive hours, and during the whole day, could be registered separately.

### PHOTOPHONOGRAPHY.

BY T. SKAIFE.

A PAPER and some photographs were sent by Mr. Skaife for the inspection of the members of Section A, but were not, for some reason not stated, brought before the section. These were three prints, described as "photophonograms." Nos. 1 and 2 consisted of photographs of a cup of tea, the surface of the liquid being agitated in harmony with the tones yielded by the photophone when emitting the note B flat. The third was described as "a photophonogram representing an octave of the musical gamut, obtained by rubbing the tip of the thumb on a piece of glass chemically prepared to give out any note in the gamut on the surface being rubbed with either finger or thumb, which leaves impressions on the surface corresponding to the notes' vibrations sufficiently dense to print from photographically."

In further explanation, he said these waves were produced by the tip of the thumb coming into frictional contact with the glassy surface of the photophone on which the cup of tea rested, all the nine waves appearing simultaneously and coincidently with the emission of the tone, and remaining, as it were, rigidly fixed, so long as the same tone continued to be emitted. The slightest depression or elevation of tone was instantly betrayed by a corresponding enlargement or contraction of the intervals which separated the waves.

The photophone, on the glassy surface of which the exciting tone was produced, was a wooden box 2 feet long by 1½ foot broad and 9 inches deep, especially constructed to propagate the vibrations of a thin glass plate covering the upper surface when excited by the frictional rubbings of the tips of the fingers moistened with certain chemical solutions, such as protosulphate of iron combined with acetic acid, tincture of horehound, watery collodion, or a saturated solution of bichromate of potash, the sounds emitted by the instrument resembling more or less those produced by the violin or violoncello. The photophone, in common with the violin, possesses the faculty of exciting into sympathetic action any fluid within the current of its vibration, the action of the fluid indicating optically the tone emitted acoustically.

The paper then proceeded to describe the mode employed in producing the negatives by means of the instantaneous combustion of 6 grains of "actinic powder," consisting of a mixture of powdered magnesium, chlorate of potash, and other ingredients.

He concluded with an apology for any imperfection in the illustrations by stating that only one week had elapsed since the cup of tea had betrayed its taste for the photophone's music. Nevertheless, he had thought that, time not allowing for further experiment, it might interest those experienced in the phenomena of light and sound to see results which photographically confirmed the ingenious discoveries previously made in optical acoustics by Helmholtz, Koenig, and Tyndall.

#### "LUX GRAPHICUS" ON THE WING.

THE EXHIBITION OF NATIONAL PORTRAITS--THE TINTYPE OF AMERICA--THE SPIRIT OF PHOTOGRAPHY IN CANADA--THE "WISE WEEK," AND THE TOTAL ECLIPSE OF THE SUN.

DEAR MR. EDITOR,—From various causes I have been absent from your columns as a contributor for some time, but not as a reader. The chief reason for this was the weather, which of late has been so hot and prostrating as to dry up both my ink and my energies. Now that the atmosphere is more cool, moist, and pleasant, my ink and my thoughts may flow together, and the resulting epistle may find a place on some page of the PHOTOGRAPHIC NEWS; if not, I shall not be angry. I know that the world—and photography is my world—is not always mindful of its atoms. The great and immortal Cicero discovered that even he could be absent from Rome, and all Rome not know it. How much easier, then, for your readers not to discover my absence from your pages. But my inability to write and attend to other duties entailed more serious losses to myself. Amongst others I missed seeing the Royal Academy Exhibition, but found a compensating pleasure in going to see the Exhibition of National Portraits at South Kensington. What a school it is for photographers! What a variety of pose, arrangement, management of light and shade, is to be seen in that glorious collection of Vandykes, Hogarths, Gainsboroughs, Reynolds, Opies, Wilkies, Raeburns, Northcotes, Lawrences, Phillips, Shees, Richmonds, Grants, and many others of the present day! I hope many photographers have seen the collection. None ought to have missed the opportunity. All that saw must have profited by the sight. Portraits of great men that have been familiar to me in black and white for years were there before me in the rich mellow colouring of Vandyke, Reynolds, Wilkie, and Lawrence, and the mind seemed carried back into the past while looking at the works of those great artists.

The exhibition will soon close, and all that have not seen it should endeavour to do so at once. There may never again be seen such a gathering together of the great of England, painted by England's greatest portrait painters. The Manchester Art Treasures Exhibition was a great assemblage of the glory of England, but it was not so complete, nor so instructive, nor so comfortable to view as that now open at South Kensington. In addition to the paintings there is a large and valuable collection of rare engravings, both in mezzotints and in line. The latter collection alone would make a visit highly pleasing and, in a sense, remunerative to every photographer. Art is beginning to take root in the minds of those who follow photography, either professionally or for amusement, and those exhibitions are the salt that "savoureth the earth," which in due time will bring forth rich fruits.

The "Tintype" is now being largely practised in America, and is fitted into an envelope or slip, carte-de-visite size. The slip is formed of paper, with an aperture to show the picture, and a flap to fall over it as a protector. I had some of these shown to me a short time ago. The tintype is only another name for the ferrotype or melainotype, which is a collodion positive picture taken on a piece of tin or iron, coated with black japan on the front, and a varnish on the back, to prevent the metal from acting on the bath. The carte-de-visite form of the tintype fitted in the envelope or holder is a very good and ready way of supplying all portraits wanted in a hurry, and its adoption might be found very serviceable to many photographers in England. The American examples that I have seen are very brilliant and beautiful, and, to my mind, next in delicacy of detail and richness of colour to the long discarded but ever beautiful Daguerreotype. I must admit, *en passant*, that the Americans always excelled in producing fine, brilliant Daguerreotypes, and it is much the same with them in the production of glass positives, ferrotypes, or tintypes.

The spirit of photography in America and Canada is admirable. Mr. Notman, of Montreal, has long been doing some excellent cabinet pictures representing out-of-door life, pleasures, and pastimes. Now Mr. Inglis, of Montreal, also produces most beautiful *carte-de-visite* and cabinet pictures of indoor and out-of-door scenes, such as drawing-rooms, libraries, &c., with suitably arranged and occupied figures in the former, and boating, bathing, and fishing parties in the latter. Some of these pictures have recently been shown to me. They are all very fine examples of photography. The tone and quality of some are beautiful. Many of them are admirably arranged, and exhibit considerable knowledge of composition; but some of them, particularly the interiors, are sadly at fault in their chiaroscuro. They possess no dominant light, or, if they do, it's in the wrong place, leading the eye away from the principal object. In most cases the lights are too scattered, giving a spotty and flickering effect to the picture which is painful to look at. With his out-of-door scenes Mr. Inglis is more happy, and probably, from his antecedents, more at home. For example, the "Boating Party" is very happily composed, embracing the double form of angular composition—the triangle and the lozenge—and just a little more skill or care would have made it perfect in its lines. The whole scene is well lighted and got up. The boat, foreground of pebbles, stones, shrubs, and trees are all real; the water is represented by tin-foil, wet black oil-cloth, or something of the kind, which reflects the forms and colours of objects placed upon or above it. The reflections seem too sharp to be those of water. The plan adopted by Mr. Ross, of Edinburgh, is the best. That gentleman has a large shallow trough fitted up in his studio with water in it.

Surely such pictures of groups of friends and families would take in London and the provinces if people only knew where to get them. At present I know there is not a place in London where photographic pictures possessing such a variety and interest can be obtained. Mr. Faulkner, of Kingston Gardens Square, is the only photographer that has yet attempted to produce such rural subjects in London, but I am not aware that he has yet introduced "the boat" into his studio.

This is the "Wise Week," and it is to be hoped that the gathering together of the wisdom of the world at Norwich will in some way be beneficial to photography. You, Mr. Editor, I presume, will attend the meetings, and I shall look forward with considerable interest to your gleanings from the harvest of science that will this year be garnered in the transactions of the British Association.

As I think of the date to affix to my letter, I am reminded that this is the day of the great total eclipse, visible in India, and that several expeditions are engaged in taking observations. The photographic arrangements, I notice, are more than usually complete, and I most sincerely hope that the astronomical photographers are favoured with bright and calm weather, so that they may succeed in obtaining the best photographic representations of the phenomenon. In this I am not influenced by the mere photographic idea of getting a picture, but rather with the hope that photography may be the legitimate and honourable handmaiden to the savants, astronomers, and mathematicians in enabling them to ascertain the constitutional condition, mode of sustenance, and interminable length of life of the great source of all our labours and achievements. Then would the sun write his autobiography, and his amanuensis would be his favoured child, photography.—Yours, very truly,

August 18th, 1868.

LUX GRAPHICUS.

#### DECOMPOSITION IN THE ACETATE BATH.— PARALYSIS AMONG PHOTOGRAPHERS.

DEAR SIR,—A good deal has been written lately about the uncertainty of the acetate bath. A curious affair that has just happened with me may possibly throw light on some of the difficulties. I do not use the ordinary bath, but

generally a mixture of acetic and carbonate of magnesia, not neutral, but alkaline. The bath in question had been in frequent use for many weeks in conjunction with deep red gold, made so neutral by means of heat that an addition of a carbonate gave no perceptible effervescence. This morning I added some of a fresh sample of gold decidedly acid, and was much surprised in a quarter of an hour by finding the bath *black*. It was clean, though slightly yellow when the gold was added, as it is always filtered after use. I thought that by an accident, which seemed impossible, some iron must have got into it, but on testing some more of the filtered solution with gold or silver and *acid* (either nitric or hydrochloric), I found strong evidence of *formic acid*. Before the acid was added it would bear boiling with gold without change. Silver was reduced by the alkalinity and organic matter. Unless I am in error—and I do not think I am—this shows the advisability of neutralizing the gold *before* adding to the bath, and *not in it*. The bath showed signs of being overworked, and roughened the fingers to an unusual degree.

This suggests the much-talked-of question of health. I do not think toning with the hands with an *alkaline* bath injurious to general health, though a carbonate of soda bath may chafe the hands badly. A neutral or acid bath may, perhaps, be dangerous. But it seems to me a much greater evil consists in a careless use of iron solution. The almost impossibility of washing the hands free from smell after iron suggests its power over the skin, and the occasional after sensations, more than skin deep, suggest the chance of still greater evil.

I think it has been mentioned in the NEWS that iron may cause paralysis, but the fact that so many photographers lay the blame anywhere else, no matter how absurd, must be my excuse for drawing attention to it again.—Yours, truly,

ED. SEELEY.

P.S.—Does not iron make a gaseous compound with hydrogen? I think I have met with it, or it and others, for the smell varies.

### Talk in the Studio.

THE QUEKETT MICROSCOPICAL CLUB.—The third Annual Report of the Quekett Club presents a satisfactory record of progress. Amongst many other evidences of the increased interest and success of the Club, the fact that 133 members have joined during the year stands prominent and convincing.

KEEPING PROPERTIES OF GUM PLATES.—Owing to a clerical error in our last, Mr. Gordon is said to have found that gum plates would keep six *months* without deterioration; it should have been six *weeks*, as that period is the limit to which Mr. Gordon has tried them. Mr. Gordon states that he has no doubt whatever that they would keep for that number of months, as the results at the end of six weeks were, if anything, better than those developed on the day of exposure. The limit of his actual experience at the present time proves that no deterioration whatever is found in plates kept four months before exposure, and six weeks after exposure.

ANOTHER SUBSTITUTE FOR NITRATE OF SILVER.—M. Lacan, in *Le Moniteur*, speaks of a new sensitive salt styled *Sel Dubclaroiz*, intended as a substitute for nitrate of silver in printing. The paper for use with this salt, whether plain or albuminized, is prepared without a chloride. The sheets of paper are plunged into a solution of the new salt several at a time. After printing, the proofs are placed in a solution of citric or acetic acid, washed, and then toned, fixed, and washed as usual. The prints are said to be very fine, the paper very sensitive, and the salt one-third cheaper than nitrate of silver. The nature of the salt is, of course, a secret, but from the description of the operation it occurs to us as that possibly it may be a double salt of silver and uranium.

THE GREAT SOLAR ECLIPSE.—Various telegrams give some brief details of the eclipse. At Bombay the eclipse was nearly total, as predicted, but the weather was very unfavourable for observation, and rain fell at the time of greatest obscuration. The eclipse has been successfully observed, however, by two

expeditions at least, though little is known as yet respecting the results which have been arrived at by the observers. Major Tennant states that light fleecy clouds covered the sky, but that the eclipse has been in the main successfully observed. The news is very promising, because his party had undertaken the duty of photographing the eclipse. The Government of India had obtained from England a Newtonian reflector, specially constructed for the occasion, and arrangements had been made by means of which six photographic pictures could be taken during the totality. From the careful manner in which Major Tennant's party had been trained in astronomical photography it is assumed that the photographs they have taken will be eminently valuable and instructive. The communication of M. Janssen states that the eclipse has been successfully observed. The spectrum of the red protuberances which are seen around the black disc of the moon during totality, and which have long since been proved to belong to the sun, has been found to present a very remarkable and unexpected appearance, and a conclusion drawn from the nature of the spectrum is that the protuberances themselves are gaseous.

**OXIDATION OF POTASSIUM AND SODIUM.**—The oxidation of potassium and sodium, when exposed with a clean surface to the air, is accompanied, according to H. Beaunhauer, with evolution of light.—(*Journ. pr. Chem.* cii. 123).

## To Correspondents.

**R. R. (New Brunswick).**—There are various processes for producing blocks to print by means of ordinary type by means of photography; some are secret, others have been made public; all, or most of them, depend, we believe, upon the reaction of light on gelatine, &c., mixed with a salt of chromic acid, and in all cases the image must be a reproduction from a subject in line or stipple. A thick film of gelatine on glass, impregnated with bichromate of potash, is exposed under a negative to the action of light, and afterwards treated with warm water. This washes away the portions which, having been protected from light, remain soluble, and, at the same time, swells up the portions which, by exposure to light, have become insoluble. The lights of the picture will now be represented by bare glass, and the dark portions by the swollen gelatine in relief. From this a cast is taken in plaster of Paris, in which the lights are in relief and the dark portions are in intaglio. From this plaster cast a stereotype or an electro plate may be taken, which will serve as a block to print from, in the same manner as ordinary type. In some cases—as, for instance, in that of which we recently gave an example by Mr. Fawcitt—the processes are multiplied, in order to produce a higher degree of perfection. In some processes the surface is produced by galvanic etching. The metal plates are, of course, as you suppose, mounted on wood like ordinary stereotypes in order to print from. There are several processes of this kind patented, both in this country and in America. Attempts have been made to produce such printing surfaces from negatives taken direct from nature; but, as yet, none have reached sufficient perfection for practical application.

**W. J. A. G.**—We do not, unfortunately, know of any method of arresting the cracking of a negative when it has once commenced. Revarnishing may do something, but we are uncertain; careful application of the method which Mr. Spiller has described more than once in our pages often restores the cracked film. 2. We shall have pleasure in showing you the Solomon prints.

**GEORGE VINCE.**—We have never seen any of Mr. Wilson's stereotypes printed as transparencies on glass, and believe that he has not issued them in that form. 2. We do not know of any views of the Holy Land on glass. Messrs. Negretti and Zambra will most probably have them, if any one. 3. We believe that Mr. Breese has not yet disposed of his stock and plant. So far as we know, he has upwards of a hundred subjects, and a still greater number of negatives, as a great many of his are, as you doubtless know, from two or three negatives.

**LYTLE'S STUDIO.**—We fear from your description that the defect of your collodion is due to the solvent not being sufficiently highly rectified; that is, the alcohol has contained too much water. This is a defect difficult to remedy. Possibly you can work the collodion off by mixing with some made with anhydrous solvents. In working with a collodion containing much water, you may mend matters a little by allowing the film to set very thoroughly before immersion in the nitrate bath. The reticulation and the white opacity in the shadows are both due to the same cause. The white effect and opacity in the shadows may generally be removed by varnishing.

**J. A. CLARKE.**—Your collodion giving a thin image will doubtless improve by age, and give you density enough; but, in the meantime, you perhaps might get rid of immediate trouble by mixing

with another old collodion. The makers you mention will serve if you get it old. The tendency to get lumpy after working a few plates from a bottle will also disappear somewhat with age, the collodion becoming more limpid throughout. You can secure an immediate remedy by the addition of a little ether to the collodion when lumpy. The print enclosed is an excellent illustration of the sensitiveness of the collodion you made after our formula. We shall have pleasure in trying the new sample if you require further advice upon it.

**JUVENIS.**—A well-educated young man, who is a fair draughtsman and has a practical knowledge of chemistry, if he adds to these qualities a good knowledge of photography, ought to be able to obtain a respectable living by the practice of photography. It is right, however, to point out to you that photography has, during the last two or three years, been suffering from depression, chiefly in consequence of over-competition. Really skilful men as artistic photographers, if they possess ordinary business tact, will, however, make a respectable living by the practice of the art. We do not recommend you to give up anything else by which you can make a good living, but at present gain as much practice as you can as amateur, employing your leisure time in different branches. If you ultimately make sufficient progress, you might, if you still wished to become a professional photographer, get an engagement in an establishment where you will obtain further experience.

**BELMONT.**—We have received a letter from "Belmont" enclosing a piece of sensitive paper, referring to some former letter, which, however, we have not received. The paper enclosed exhibits examples of a well-known stain, caused by the silver solution remaining in drops upon the surface, instead of draining and drying off evenly and regularly. The chief cause of this tendency is the use of the paper in an extremely dry state. If it be kept in a damp place for a few hours before sensitizing, the defect will not occur. The use of an extremely strong bath is said to conduce to the same result. When the paper is found to dry thus unevenly, leaving drops standing upon its surface, it is best to blot it off at once, which will prevent the stains occurring without injuring the paper.

**J. H. UNDERWOOD.**—The view is very charming. Thanks.

**J. C. S.**—The collodion has arrived safe. Our absence at the British Association meetings has prevented any trial at present, but we hope to make one shortly.

**B. M. P.**—The sample of pyroxyline is not suitable for a negative collodion. It forms a glutinous collodion, giving a lumpy film with less than 3 grains to the ounce of solvents. It has been made, apparently, with acids at a very low temperature. 2. The proper paper to employ for paper pyroxyline is known as *Papier Joseph*. 3. Excess of ether makes a limpid collodion; excess of alcohol tends to give a somewhat thicker collodion, which flows like oil.

**M. D.**—For small negatives, flatted crown glass may be used with great advantage; we prefer it, indeed, to plate glass. No surface is finer and harder than the natural vitreous surface produced with the manufacture. It is important, however, to notice that the flatted crown has two sides, one of which is excellent, and the other somewhat rough and imperfect, often causing pinholes. You will easily distinguish the rough side by drawing the finger-nail over the surface.

**X.**—It is possible with some varnishes to work on the varnished surface of the negative with a B B pencil; but if the surface be glossy, like that given by a spirit varnish of good body, it will not present a tooth to the pencil. The best plan is to treat the negative, after fixing and washing, with a dilute solution of gum, which will present a tooth to the pencil when dry. A little care is necessary, of course, not to scratch it by careless use of the pencil, and also to produce the right result, as the negative must be varnished over the pencil marks before printing. Of course a little skill in drawing—or, at least, in using a pencil with precision—is necessary. If you have little skill in this way, you must venture little in retouching negatives.

**F. L.**—A metre is a little more than 39 inches; a centimetre is one-hundredth part of a metre; 2½ centimetres are about equal to an inch.

**B. T. R.**—It is difficult to give an answer to your question as to "which is best, black or brown tones?" It is much a matter of taste. Black tones are best for some subjects, and brown for others. We generally prefer warm tones. The question as to how to get rich deep tones is more easily answered. If you have a really good negative, clean in shadows, and dense enough in the lights, you can obtain rich deep tones, of either black or brown, with almost any toning.

**ERRATUM.**—In Mr. Lea's article on Testing for Hyposulphite, on page 321, at the end of the eighth paragraph, the word "sulphidric" has been printed "sulphuric," thus destroying the sense of the sentence.

Articles by Mr. Woodbury, Mr. Robinson, Mr. Werge, and several other writers are compelled, by the demand made on our space by papers read at the British Association, to stand over.

Several Correspondents in our next.

### DOUBLE SALT FOR PRINTING WITHOUT CHLORIDE OF SILVER.

WE have during the last few days been experimenting with a printing process, without chloride of silver, which presents points of interest and promise of advantages sufficient to warrant the further attention of experimentalists. The salt employed is a double-nitrate of uranium and silver, and the process does not differ in principle from some of the uranium printing processes which received attention a few years ago; but it varies essentially in some details of practice.

The first claim of the process to attention is its extreme simplicity; and, second, its great economy. The results which are present, the crude products of early experiment, are not inferior to those usually obtained on plain salted paper. As yet we have not tried a paper coated with albumen of a similar body giving a glazed surface; but we have reason to believe that where fine definition and great gloss are required, a paper so treated would give excellent results by this process.

A very weak solution of double-nitrate of uranium and silver in water forms the printing bath. Plain paper, without any previous salting, is immersed in or floated on the solution for a few minutes, and, when dry, exposed under a negative in the ordinary manner. It is somewhat less sensitive than excited albuminized paper, and requires longer exposure. It yields a very vigorous image of a brown tint, the precise colour varying with the sizing material in the paper employed, some samples yielding in the printing-frame prints of a bistre tint, and others of a purple brown; but all readily toning to a warm or neutral-black under suitable treatment, to which we shall presently refer.

One of the most noteworthy circumstances in our operations was the extremely dilute bath with which we obtained good prints. With a solution containing 5 grains of the double salt—practically less than two grains of nitrate of silver—in an ounce of water, we obtained vigorous images; and, so far as we can judge at present, not more than a 10-grain bath of the double salt would be required under any circumstances. With this solution we tried both floating and immersion; but we prefer the results of immersion. The image was, it is true, more completely in the body of the paper, but it possessed more richness than the surface image obtained by floating only. Plain *Saxe* paper gave a light brown image lacking depth; *Rive* paper, re-sized with a preparation of arrowroot, assumed a light brown tint, but gave a more vigorous image. Paper prepared with a solution of gum lac in borax, for Mr. Woodbury's process, gave a rich warm brown print. Turner's Calotype paper gave rich, warm, purple brown prints of great vigour. A sample of toned paper very slightly sized, such as is frequently used for letter-press printing of illustrated books, the texture being fine, although somewhat soft, gave

prints of a rich purple brown, with a tendency to bronze in the shadows. In all these cases it must be borne in mind that we are describing the tone assumed in the printing frame; and in this process, as in ordinary silver printing, the richer the quality of the image in this stage, the more easy it became to secure a fine, deep-toned print in the subsequent operation of toning and fixing.

The toning operations are important, our first experiments having yielded some curious results. The first prints produced we proceeded to tone in the usual manner, first trying a print with a bath made after Mr. Bovey's formula—that is, chloride of gold, a little chloride of sodium, and hot water—the bath being used the following day. The print, on being immersed in the bath, very rapidly began to disappear, leaving finally a faint purple trace of the deep shadows. Another bath was made of chloride of gold, a little chalk, and hot water, and used in the course of an hour, and this gave precisely the same result, as did also another bath made with half-a-grain of carbonate of soda to a grain of chloride of gold in six ounces of water.

In each case the minute portion of silver which formed the image was attacked by the chlorine which was liberated by the chloride of gold in the process of toning, and converted into chloride of silver. It was clear that the ordinary toning baths were not available, nor any toning bath in which chlorine was liberated. We therefore tried the toning bath of sulphocyanide of gold, and this answered admirably, the prints toning readily and satisfactorily, assuming any desired tint, from a purple brown to a deep black; and this answered alike with all the samples of paper. After toning, the prints were fixed in an ordinary fixing solution, losing little if any depth in the process of toning and fixing. As no insoluble salt of silver is present, theoretically, washing well with pure water ought to remove any traces of the unreduced silver salt; but, for safety, a bath of sulphocyanide or hyposulphite is desirable; but it is probable that, from the exceedingly minute trace of silver present, an exceedingly weak fixing bath would answer every purpose.

When finished, the pictures have much the appearance of good plain paper prints. It is probable that paper re-sized with gelatine, or coated with a dilute solution of albumen without salt, would give vigorous images with fine surface definition, and such degree of glaze as might be desired.

The double nitrate of silver and uranium which we used consisted of a small sample placed in our hands for experiment by Mr. Henry Cooper some years ago, which he had prepared with a view to try in collodion for the *Wothlytype* process, with which the process we have been describing has, as we have said, analogies. To form the double nitrate, concentrated solutions, of nitrate of silver and nitrate of uranium, in the atomic proportions of the two salts, it should

be mixed, and the double salt obtained by crystallization from the mixed solution. The crystals resemble those of nitrate of silver in form, and are of a lemon or citrine tint. To save trouble, those of our readers who wish to make experiments may prepare a solution by mixing the salts in their equivalent proportions in distilled water, and use it without taking the trouble to form the crystals. The atomic weight of nitrate of uranium is 252, that of nitrate of silver 170 grains. If nitrate of silver be dissolved in a quart of water a suitable bath will be obtained.

How far this very simple and economical uranium and silver printing process may be found available for practical purposes we cannot at present say; but it presents, at least, some very interesting points for the amateur and experimentalist.

### MR. BING'S NEW ACTINOMETER.

In our last we published Mr. Bing's paper on Actinometry, read in a meeting of Section A of the British Association at Norwich. We have since been favoured with a call from Mr. Bing for the purpose of showing us the new actinometer which he has recently patented. It appears to work perfectly, and to be free from the sources of error which have been found in the actinometers formed of progressive layers of a translucent medium. Mr. Bing, who has experimented considerably with actinometry, states that in all instruments formed on the latter plan the resistance to light by an increasing number of layers of the translucent substance increases much more rapidly than, according to calculation, the increase in the thickness of the translucent substance would warrant. There may be various reasons for this, into the discussion of which we do not, however, now enter.

The new instrument is based upon another principle. It consists mainly of a rectangular tube of non-actinic glass, with an arrangement to bring a strip of sensitive paper into contact with one side of the interior. This tube is placed in diffused light, with its open aperture towards the sky. Light entering the tube and falling upon the sensitive paper commences at once to blacken it, but its power of so blackening is, of course, only in the ratio of the quantity of light which enters, and which necessarily diminishes as it proceeds further into the tube. To make the matter clear, we may here repeat, in Mr. Bing's words, the principles upon which this instrument is founded:—

"1st. That diffused light, on entering a tube at one end only, varies in intensity within the tube inversely as the square of the distances from the aperture where light enters.

"2nd. That any number of tubes, whatever their magnitude, contain the same intensity of light if the ratios of their diameters to their lengths are equal, and if we absorb the light that may be reflected from their sides."

A carefully-calculated scale is fixed inside the tube at the side where the sensitive paper is fixed, the divisions being marked by a portion of a faint standard tint. When the sensitive paper in the instrument has been exposed for (say) ten minutes, the upper portion is darkened, and the first two or three tinted marks on the scale look white in contrast with the darkened paper: as the darkening further down the tube gradually becomes less, the sensitive paper and standard tint appear of the same colour, and below that the paper is seen to be white by contrast with the standard tint.

The principle seems simple and true, and is capable of easy demonstration, as may be seen on carefully reading Mr. Bing's paper. The mode of application is also very elegant. When the specification is published we shall be at liberty to describe more fully the simple and convenient mechanical arrangements of the instrument.

### VISITS TO NOTEWORTHY STUDIOS.

WORKING THE EBURNEUM PROCESS IN MR. BURGESS'S STUDIO TENNYSON tells us, in his "Enoch Arden," that "things seen are mightier than things heard." Notwithstanding the lucid statements in reference to his operations in the Eburneum

process with which Mr. Burgess has from time to time favoured us, having now seen the actual working of each part of the process, we have a more complete knowledge than before of the minor details, upon attention to which much of success depends. A circumstantial rehearsal of the operations from the beginning to the end of the process will, we doubt not, prove interesting to many of our readers, and enable those who are disposed, to work out satisfactorily a process yielding results of rare beauty, and one by which we are satisfied both credit and profit may be obtained. We will deal with the operations seriatim.

*The Negative* does not require special treatment, nor does it require to be used unvarnished. The more perfect it is, of course, the better; but a good negative such as gives good results on albuminized paper answers here. Indeed, in Mr. Burgess's experience, a large number of sitters, after ordering a dozen ordinary cards, also order some Eburneum prints from the same negative. The price Mr. Burgess charges for Eburneum prints, card size, is half-a-guinea for three, and this, as it will be seen, is generally an absolute addition to the amount of business done, which, whilst it is a boon to the customer to obtain a few such choice pictures for special purposes, yields also a considerable increase of profits at the same time that it cements a connection.

*The Glass Plates.*—Mr. Burgess employs flatted crown as the temporary support for the Eburneum picture, using whole-plates, and producing four impressions on each. The glass is carefully cleaned with rouge and water, the solution being suffered to dry on the plate, and is polished off when dry. Formerly he treated the surface with a solution of wax in ether, in order to facilitate the final removal of the collodion film; but this treatment he has since found unnecessary. If the glass be clean, the collodion suitable, and the operations properly conducted, the film leaves the glass without difficulty.

*The Collodion.*—The selection of the collodion is of some importance, as it must give an image at once delicate and vigorous, and possess the toughness which renders the final transfer easy and certain. The right qualities are most easily learnt by experience. The collodion must be tough, and it must yield a clean, bright, vigorous image, without any trace of fog. Mr. Burgess uses Blanchard's, which he finds answers perfectly.

*The Nitrate Bath* is an ordinary negative bath, 35 grains to the ounce, very slightly acid with nitric acid, and in good condition.

*The Copying Camera.*—Any good copying camera suitable for taking transparencies will serve; but it may be useful to some readers if we reproduce a description of that designed by Mr. Burgess for enlarging as well as copying. It is made of deal, black cloth, and strong elastic, costs about £3, and is so simple that any carpenter can construct one from the accompanying diagrams.

Fig. 1 shows the camera extended to its full length, being 60 inches from the lens to ground glass. A is 24 inches square, slides from one end of the base to the other, and has a projection of half-an-inch at the bottom, which

Fig. 1.

slides in a groove, and serves to keep it square. It is held by two screws at the back, which will be seen in the diagram; these simply screw down into the bottom board

without entering it. B is the ground glass. C the extending body made of black doeskin, and is supported by strips of strong elastic, running from each corner. It will be observed that the bottom of the camera consists of two pieces, one sliding into the centre of the other. D is the box for the negative or transparent positive. It is screwed on to two pieces of wood having grooves to fit the smaller part of the bottom of the camera. The grooves may be seen in fig. 2. E is the slide carrying the negative or transparent

Fig. 2.

positive. B is a hood for the lens; if this is made of black lining (black cotton twill) it will not require any supports. The letters in each figure refer to the same parts.

The negative, generally with an oval mask of black paper in contact, is placed in the slide E, and directed towards the northern sky. A repeating back is employed, so as to produce four images in succession on the plate.

The Exposure depends much, of course, on the negative, the light, and the chemicals. Those we saw exposed varied between ten and twenty seconds. But here is a very noteworthy point to be observed: each successive image is found to require increased exposure. If ten seconds were found to be sufficient for the first, and each succeeding one of the four were also exposed ten seconds, the following three would present indications of under-exposure in increasing degree, the last being hopelessly under-exposed. It is found necessary, therefore, to give each succeeding image about two seconds' additional exposure; the first having had ten seconds, the second receives twelve, the third fourteen, and the last sixteen; and this equalizes the exposure. Some interesting speculations are suggested by this circumstance, but we must here confine ourselves to noting the practical fact. It is well to add that the finest toned pictures are always obtained in a good light.

The Development is effected by means of a 3-grain solution of pyrogallie acid, to which is added 3 grains of citric acid and from 12 to 20 minims of acetic acid. In a recent notice of this developer we omitted to mention the acetic acid; but the image has a tendency to acquire too blue a black tone if the acetic acid be omitted. The extent to which development should be carried in order to secure the desired amount of detail and vigour, and at the same time to avoid burying the image, is most important; but experience is the best guide. The practised eye can distinguish the right stage by looking at it with something dark underneath, better than by looking through it in the mode a negative is examined. If the development be stopped too soon, the image lacks detail, and the blacks are not vigorous; if it be carried on too long, much of the detail becomes buried in the blacks, and is not visible by reflected light. As a rule, the development is more rapidly conducted with the transparent positive than is necessary with a negative. It is imperative that the transparent parts be free from foggy deposit. Mr. Burgess fixes in cyanide.

Toning.—After well washing the fixed image it is toned with a neutral solution of chloride of gold, or rather of the double chloride of gold and sodium, which is the salt Mr. Burgess employs. He uses a solution containing a grain of the gold salt in a drachm of water, without any addition. This is poured on to the plate, and in less than a minute the surplus is poured back into the bottle, the

toning action having generally passed quite through the image in that time. To examine the picture thoroughly a very convenient plan is now adopted. A sheet of white paper is made wet and brought into contact with the wet film. On examining the back of the glass, through which the image is seen against the white paper, it is easy to ascertain if the toning process has been carried far enough, and also whether the print is in all respects sufficiently perfect for finishing.

Varnishing.—After rinsing and drying the picture it is varnished with Solmsee varnish. This part of the process was at one time omitted, but Mr. Burgess has found that the image is more brilliant and perfect if varnished at this stage. The operation involves a little risk, for if an unsuitable varnish be employed, it permeates the film and causes it to adhere to the glass, rendering the final removal difficult. Mr. Burgess has found this occur with some varnishes, but never when the Solmsee varnish is employed.

Retouching.—Defects may now be removed by retouching delicately with a little suitable water colour. Matt silver stains, or other opaque spots or markings, may be scraped away, and so rendered imperceptible in the finished print.

Applying the Eburneum Preparation.—The varnished picture is now ready for the Eburneum coating. Strips of paper an inch wide are coated with a stiff paste (Mr. Burgess uses gum tragacanth). The paper he employs is that which is silvered on one side, and is usually sold by fancy stationers for ornamental uses. It is selected because, whilst it is very pliant, it is also tough, and not readily permeable to moisture. An ordinary paper, pliant enough for easy working, is often so soft and permeable that it bursts away on contact with the hot gelatine solution. It is attached to the back of the plate, leaving about a quarter of an inch to turn up round the edges, and so form a kind of dish of about one-eighth of an inch deep, of which the film forms the bottom. It is then carefully adjusted on a levelling-stand to receive the solution.

Although we have before published the recipe for the preparation, we will, for the purpose of giving completeness to this article, repeat the formula precisely as it is now used:—

French gelatine	...	...	...	5	ounces
Water	...	...	...	20	"
Glycerine	...	...	...	$\frac{1}{2}$	ounce
Oxide of zinc	...	...	...	1	"

The French gelatine is sold in thin, nearly colourless sheets, and is found tougher and better for this purpose than Nelson's, whilst it is about half the price. It is soaked in the water, dissolved by gentle heat, and filtered through flannel. The oxide of zinc is placed in a mortar with the glycerine and a little of the water, and thoroughly incorporated. It is then well mixed with the warm gelatine. It is desirable to keep the preparation warm and liquid for some hours—say six or eight—in order to permit the complete subsidence of the coarser particles of the zinc white. When this is done, and the gelatine has been suffered to cool, the mass may be lifted out of the jar, and the bottom cut off, which will remove all the coarse portion at once. If sufficient time for this subsidence is not allowed, the layer of Eburneum will appear coarse and granulated. If the solution be kept warm too long, too much of the zinc white will be deposited, leaving the Eburneum too transparent; it will lack the solidity and brilliant whiteness which should characterize it.

This preparation is kept in stock, and a portion warmed by placing it in a jar in a pan of water over a fire when required. It is best used at a temperature of about 100° Fah. About two ounces are sufficient to cover a whole-plate to the proper depth. When the solution is fluid, about two ounces and a-half are placed in a cup and set aside for a few minutes. This is an important point. Whenever a gelatinous solution is poured from one vessel

except in patent medicines. Everybody's enlargements are the most perfect ever produced; everybody's collodion is perfect; but one maker, who does *not* appear in the *News*, advertises collodion which is more perfect than the most perfect; but then the maker is an exceedingly clever and honest man, who would not mislead his brother photographers for the world, more especially when he was selling them. The advertising colourists are philanthropists in their polychromic way; they will supply you with "most exquisite finish, ivory-like and brilliant, by first-rate talent," for the small price of sixpence a carte. But I am off the rails again. Let us resume, as poor Artemus Ward used to say.

In turning over the advertisements of the *News*, announcements similar to this will often be found:—

#### TO OPERATORS.

**WANTED**, a Young Man, must be a competent Artist, of gentlemanly manners, a good Poser, and be able to take a faultless negative. Will be expected to make himself generally useful. Send carte of self, &c. None but the most competent need apply, as this is a permanency. Wages, £1 5s. per week. Apply, &c.

For twenty-five shillings a week a competent artist and a gentleman is expected to make himself generally useful! For this miserable sum the man who, if he answered the terms of the advertisement, should have great chemical knowledge added to careful artistic culture, and, perhaps, a college education, is expected to be the drudge of, possibly—even probably—some ignorant fellow who has, let us say, a little bazaar for fancy goods and toys, or a tobacco shop, to which he wishes to add a photographic "gallery," managed, under his superior direction, by five-and-twenty shillings' worth of gentlemanly manners, good posing, and general usefulness. And is this what the noble art of photography is coming to? Is it come so low that perfection in its practice, added to other virtues, are expected to be obtained for a porter's wages? I do not object that five-and-twenty shillings are not enough for a vast quantity of those who have taken up photography; there are, or were, plenty of "doorsmen" of photographic dens who only got ten or twelve shillings a week, which was as much as they were worth; and there are many respectable men who are only worth a small salary; but advertisers of the class I have named have so singular a notion of photography, that when they insert such advertisements in the papers they actually think that they will procure what they advertise for, and are content to suppose that the results produced are the finest in creation, and that the pictures turned out of their establishments represent photography in its highest phase.

I strongly condemn the operation of trade unions; but surely, if anywhere, a standard of ability and a standard of remuneration are required at present in photography!

#### ON TRANSFERRING NEGATIVES.

BY WALTER B. WOODBURY.

It is now a considerable time since, at a meeting of the Manchester Photographic Society, I explained in detail a complete method of taking the negative from the glass on which it had been taken by means of a stout leathery collodion. Since that time I think I may safely say that few have thought it worth while to trouble themselves to try it. I see, however, that M. Marion is again describing the same method as new, and hope that attention will be more fully called to its importance. How many thousand pounds worth of plate glass is now lying idly by! I am told of one large house in France that reckon their stock of negatives—or, rather, the plate glass on which they are taken—at a value of £6,000; and the storage and care of these negatives is not by any means an inexpensive matter. Now, were these negatives transferred to collodion, the space they would require would be nothing, and the photographer would not have his £6,000 lying useless.

Since writing the paper mentioned above on the subject,

I have made some rather important modifications: I found that the coating of india-rubber used to prevent dissolution of the negative by the leathery collodion was not always sufficient to do so, and, besides, that we introduce a changeable, uncertain body into the film, which might afterwards tend to destroy it. Having had varied experiences with the use of india-rubber, I am led to believe that for any permanent work the less we have to do with it the better. What I have found to answer much better for the purpose under consideration is a weak solution of gum, as the smallest proportion seems sufficient to prevent the solvents from acting on the film beneath. When the negative is taken, and after the final washing, the gum-water should be poured on and run over, and then thrown off, and again a second lot applied. It should now be allowed to dry, and then placed on a stand truly levelled, and the transfer collodion poured on. When dry the whole is left to soak in water till the negative detaches itself from the glass. To facilitate this I formerly recommended a coating of wax to be applied before taking the negative, but this I find unnecessary, as, sooner or later, the action of the water will separate the double film from the glass. Some care will be necessary in drying the film when it has left the glass, otherwise it will cockle and assume a shape difficult to flatten again. The best way will be to place it between sheets of blotting-paper under pressure until dry, when it will always after remain flat. Apart from these transferred negatives having the advantage of lightness, the saving of glass, &c., there are others of sufficient importance. With such negatives we can print from back or front with equal sharpness, which, for most engraving and other like processes, is of great value. For decorative work, beautiful designs may be made by photographing a leaf or group of leaves, or of flowers, and printing the image double, one side being reversed: some very useful studies for designers may by this means be produced: kaleidoscopic designs may also be made by extending this principle.

Of the use of transferred dry-plate films for convenience of travel, I shall have something to say on a future occasion.

#### PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN

COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXXII.

THE principles of composition and chiaroscuro having been stated, it will be of use to the student to have pointed out to him how these rules have been observed or neglected in various examples; I, therefore, in this and the following chapters intend to give illustrations from pictures or drawings, as widely diversified in character as possible, with critical remarks on their construction.

My first example is one of those clever book illustrations which have done so much to familiarize the present generation with good art, and which give us enormous advantages over our fathers—who had to give a great price for inferior artistic work—in our opportunities of study. The great advance in the practice of wood engraving has done more than anything else to bring true art home to the people.

The present example is a somewhat hard and formal illustration of angular composition, and shows much clever mechanical arrangement without any subtlety. In this the art is shown almost boastfully, when it should have been the artist's endeavour to suppress too great a parade of knowledge. But it is better to have too much art than none at all, and this example is better for our purpose than one more delicately arranged, because the arrangement is more visible to the student.

We will now proceed to analyze the construction of the lines of this picture.

First, then, observe that the leading lines and points of all the figures run into one another so as to form a series of pyramids or parts of pyramids. The central head—that of the old lady—forms the apex of the first pyramid, which is supported by the two little girls on each side of her; the

diagonal lines of this group, crossing at the top of the grandmother's head, run on the one side to the old man's hat, which crowns the group, and on the other is continued by the figures coming through the door. The pyramid capped by the old man is formed on the right hand side by

the arm of the child he is holding, who reaches down to her brother's head. The dark dress of this boy forms an important mass in supporting the composition; this mass is repeated on the other side by the velvet jacket of the girl looking up. It will be observed that some trouble has been taken to form another diagonal line here with the three children's heads. The arm of the boy in the black velvet dress, cut off as it is by the side of the picture,

appears to me to be a very serious defect in the composition. The upright lines of the door contrast with the flowing lines of the figures, and give stability to the whole. It may be taken as a rule that a few straight lines in a composition, by contrasting with the curves, always add to the general effect.

The smaller illustration, from a drawing by F. W. Topham, belongs to a much higher order of art than the larger

example. This also is constructed on the pyramidal form of grouping, and is so arranged as to admit of very effective chiaroscuro. It will be noticed that the deepest dark is brought into immediate contact with the highest light,

while the other portion of the picture is kept in varying but intermediate tones, thus securing the greatest amount of brilliancy and breadth. It is probable that in the original drawing the sky seen through the open door was

more subdued in tone. There is a sentiment in the composition and chiaroscuro quite apart from, yet very suitable to, the subject.

### PHOTOGRAPHY AND THE IMMURED POMPEIANS.

BY J. WERGE.

EVERY one must be sensible of the many and varied applications of photography. Even photographers themselves, familiar as they are with the capabilities of the art they practise, must necessarily have their wonder excited occasionally at the scope of their art-science, especially when they consider that the process as practised at the present day is not more than seventeen years old. That it should be the historian of the life and manners of the present period more fully and faithfully than any written account is not so much a matter of surprise. Appealing, as it does, to the vanity and affections of the people, it is at once a recorder of the changes of fashion, a registrar of marriages, births, and deaths, and a truthful illustrator of the times in which we live. But that it should be brought to bear upon the past, and make the inhabitants of the world in the nineteenth century familiar with the forms, fashions, manners, life, and death of the people of the first century of the Christian era, is something to be marvelled at, and at first seems an impossibility. Yet such is the fact; and photography has been made the cheap and easy means of informing the present generation of the manner in which the ancients behaved, suffered, and died in the midst of one of the most appalling catastrophes that ever overtook the inhabitants of any part of the world, ancient or modern, as vividly and undeniably as if the calamity had occurred but yesterday.

The foregoing reflections were excited by seeing very recently some photographs from plaster casts of the forms of human beings as they had fallen and died when Pompeii and Herculaneum were destroyed by the first known and terrible eruption of Mount Vesuvius. The photographs alluded to reveal with a fearful fidelity the dreadful agonies of some of those who perished at Pompeii, and, while looking at the pictures, it is very difficult to divest the mind of the idea that they are not the works of some ancient photographer who plied his lens and camera immediately after the eruption had ceased, so forcibly do they carry the mind back to the time and place of the awful immurement of both a town and its people.

That these photographs were not obtained from the lifeless forms of the Pompeians the reader will readily understand, for their bodies have not been preserved entire from that

day to this. The question then naturally arises, "How could plaster casts be obtained from which the photographs were produced?" To answer that question I must briefly explain that Pompeii was not, as is generally understood, destroyed by an overflow of red hot lava, which would have burnt up every particle of human flesh with which it came in contact almost instantly, without leaving a mould or impress of the form which it surrounded. The black mud which flowed from Vesuvius into the doomed town of Pompeii entombed the houses and inhabitants—covered them up and formed a thick crust over them, which gradually hardened, and as the bodies crumbled away to dust a mould or matrix was left, from which plaster casts of great beauty and finish might have been obtained of almost everything that was destroyed. Unfortunately, this was not discovered until very recently, after many of the beautiful moulds had been destroyed by the process of hurried, thoughtless, and unsystematic excavation. It was only a short time ago, since Naples was united to Italy, that careful and intelligent excavation secured to future generations impressions from those matrices made by the most terrible process of natural mould making.

Sig. Fiorelli, who was appointed superintendent of excavations at Pompeii, happily thought of obtaining casts from these natural moulds by pouring in soft plaster of Paris, and thus secure more useful mementoes than by preserving the moulds themselves. Amongst the first casts thus obtained were the forms of four human beings, described as follows in the *Quarterly Review* for 1864:—

"These four persons had perished in the streets. Driven from their homes, they sought to flee when it was too late. These victims of the eruption were not found together, and they do not appear to have belonged to the same family or household. The most interesting of the casts is that of two women, probably mother and daughter, lying feet to feet; they appear from their garb to have been people of poor condition. The elder seems to lie tranquilly on her side, overcome by the noxious gases. She probably fell and died without a struggle. Her limbs are extended, and her left arm drops loosely. On one finger is still seen her coarse iron ring. Her child was a girl of fifteen; she seems, poor thing, to have struggled hard for life. Her legs are drawn up convulsively. Her little hands are clenched in agony. In one she holds her veil or part of her dress, with which she had covered her head, burying her face in her arm, to shield herself from the falling ashes and from the foul sulphurous smoke. The form of her head is perfectly preserved. The texture of her coarse linen garments may be traced, and even the fashion of her dress

with its long sleeves reaching to her wrists. Here and there it is torn, and the smooth young skin appears in the plaster like polished marble. On her tiny feet may still be seen her embroidered sandals. At some distance from this group lay a third woman, apparently about the age of twenty-five, and belonging to a better class. Silver rings were on her fingers. She lay on her side, and had died in great agony. Her garments had been gathered up on one side, leaving exposed a limb of the most beautiful form. She had fled with her little treasure, two silver cups, a few jewels, and some silver coins, and her keys, like a careful matron. The fourth cast is that of a man of the people, perhaps a common soldier. He is almost of colossal size. He lies on his back, his arms extended by his side, and his feet stretched out, as if, finding escape impossible, he had laid himself down to meet death like a brave man. His dress consists of a short coat or jerkin and tight-fitting breeches of some coarse stuff, perhaps leather; heavy sandals, with soles studded with nails, are laced tightly round his ankles. On one finger is seen his iron ring. His features are strongly marked, his mouth open, as in death. Some of his teeth still remain, and even part of the moustache adheres to the plaster."

Such is the description of the plaster casts; and the photographs which I possess of those casts convey to the mind at one glance all that is there written. Wonderful photography! How eloquent in their silence are thy pictures! To what more dignified and sublime uses could any art be put? Only a few can look upon those casts of the dead Pompeians in the Museum at Naples, but the whole world may view the photographs taken from them, and look upon the Pompeians in their forms and habits as they died, and read a page from the unwritten histories of those terrible death-struggles, when the strong man, the tender placid mother, and the young and delicate maiden were all entombed in that fearful sea of mud, amidst darkness and horrors that can never be adequately described.

Such an awful catastrophe will never cease to interest the student of ancient history, and photography will now be the means of deepening his interest, and revealing to his mind with greater force and lucidity many scenes that actually occurred at the very moment of the appalling destruction of Pompeii, on the 24th of August, A.D. 79.

## REMARKS UPON THE RETOUCHING OF NEGATIVES.

BY DR. W. REISSIG.\*

THE retouching of negatives is a subject which is everywhere regarded as of the greatest importance, and already in the *Photographische Correspondenz*, as likewise at the meetings of the Viennese Photographic Society, the various technical methods which have been proposed have been widely discussed. It is my intention here not to go farther into the technical portion of the subject, but to content myself with briefly considering the suitability and permanence of the materials employed in the process of retouching.

In printing from several negatives which have been produced with the same collodion, silver bath, exposure, &c., but which have been developed in the first case with iron and silver, secondly with pyrogallie acid and silver, thirdly with corrosive sublimate,† fourthly with corrosive sublimate and subsequent treatment with ammonia or sulphide of ammonium, and fifthly with Selle's intensifier, it will be found that the plate developed with silver alone will yield the softest pictures. This indisputable fact is, in my opinion, accounted for in the following manner:—The very finely-divided silver particles composing the negative are spread over the plate in several more or less dense layers, and not only does a certain amount of white light make its way between the different particles, but, through the latter themselves, a

small quantity of blue light penetrates. That this is the case may be proved by taking an extraordinarily thin beaten leaf of silver, or a sheet of glass upon which a thin film of silver has been attached, and holding them against the light, when objects may be easily seen through the same, but surrounded by a blue light; sensitive paper may also be blackened by light transmitted through thin layers of silver of this description, though naturally with more or less difficulty. If through the more dense portions of a negative no light is able to penetrate on account of their intensity, it is, nevertheless, not to be doubted that, in the half-tones, not only does light make its way between the particles, but the latter likewise allows blue light to pass, the powerful chemical action of which upon sensitized silver paper is well known.

If corrosive sublimate alone is used for intensifying, a violet subchloride of silver is formed, together with calomel, which—so it appears to me—allows less light to pass between the particles, and, although white, is less transparent than the varnish. The brownish-black sulphide of mercury, the perfectly opaque suboxide of mercury, carmine, &c., all allow either none or but very little light to pass, and this of no— or, in the case of carmine, very little—actinic power.

As before stated, I attribute to the particular behaviour of the silver the fact that the softest and most harmonious pictures are obtainable from negatives which have been developed with silver only. This, therefore, points to the conclusion that, theoretically, very finely divided silver is the most suitable material to be employed for retouching. Precipitated silver is, however, of different kinds, according to whether it has been reduced from nitrate of silver by a solution of iron, or pyrogallie acid, the difference being easily discoverable with the naked eye. That prepared by treatment with a solution of iron is of a whitish colour, the whiter and more metallic it appears the more acid (acetic acid, nitric acid, &c.) having been used in its reduction; the precipitate induced by pyrogallie acid is of a bluish-black tone when viewed in large quantities. The precipitates are not only different in appearance, but likewise different in their chemical constitution, for they are by no means allotropic forms of the pure metal. The first almost always contains sulphate of iron, if only in minute quantities; and the second consists of an organic body in combination with the metallic silver.

Of the presence of this organic body one may easily be convinced. If a dilute solution of nitrate of silver containing actually an appreciable quantity of nitric acid is precipitated by means of a pyrogallie acid solution containing acetic and citric acids, it is very difficult to obtain the warm water which runs off on washing the precipitate of a perfectly colourless description. It may now be thought that the silver is perfectly pure. That this is far from being the case may be proved by digesting some of the silver powder in a warm and very dilute solution of cyanide of potassium, when the fluid assumes a very appreciable wine-colour, and the silver itself becomes of a lighter hue; this operation must, in fact, be repeated several times before the cyanide solution remains perfectly colourless. As silver dissolved in cyanide of potassium yields a colourless solution it is clearly shown that another body of organic origin must be in combination with precipitated silver, reduced by means of pyrogallie acid. A cyanide of potassium solution, even of a very dilute description, is capable of taking up finely-divided silver, and, therefore, determination by means of analysis is impracticable.

The presence of an organic body in the silver film of a negative which has been intensified with pyrogallie acid, is, I may mention, no doubt the principal reason why such negatives become darkened by time, and do not retain their original intensity, as is the case with those treated with an iron developer only. The organic body doubtless suffers modification as the influence of the varnish becomes exerted upon the silver, and those negatives run the most risk that have been developed by means of pyrogallie solution and the liquid from old sensitizing baths, inasmuch as the latter

\* *Photographische Correspondenz*.

† Bichloride of mercury.—Ed. P. N.

contains iodide of silver; thus, beside an organic body, an iodide comes upon plate, which, being precipitated by the pyrogallic solution and decomposed by the action of light, causes a profound change to take place in the silver film. Every one of my readers has, no doubt, observed that in intensifying a negative of which some of the parts have not been properly fixed (the edges and corners of a plate, for instance), and are, therefore, covered with iodide of silver, such portions darken in the light, forming deep black marks upon the negative. In the same manner, but, of course, in a less degree, this decomposition of the iodide takes place upon negatives covered with silver in contact with an organic body, and thus, in time, the black marks we observe upon most plates are produced by the action of light. For this reason I would warn photographers not to employ old negative baths for the purpose of intensifying; it is best first of all to precipitate the iodide of silver by adding a large quantity of water, and then to filter and concentrate the solution again by evaporation. Better still, take pure nitrate of silver solution for the purpose. Unfortunately, all negatives intensified with pyrogallic acid will darken by time, for treatment of the same with a warm solution of cyanide of potassium is impracticable, because, in the first place, the negative is thereby rendered much weaker, and, secondly, because it is difficult to treat the collodion film with a warm liquid without running considerable risk of tearing it.

By submitting the plates to the action of great heat the object would, no doubt, be accomplished, as a high temperature would have the effect of decomposing an organic body; but there would always be formed upon the negative, where the silver adheres to the glass after the destruction of the collodion, a silicate of silver, which would influence the strength of the negative. In practice it would scarcely answer to treat all negatives in this manner, and the encaustic method as at present employed is certainly more advisable, as the original picture cannot then be destroyed.

But to return to the subject of retouching. When the finely-precipitated silver has been mixed with gum and applied to the plate, there need be no fear of any change taking place if the negative remains perfectly dry. At the same time, the variations of temperature to which a negative is exposed during the process of printing in damp and cold weather, being taken from a warm locality into a cold one, or *vice versa*, causes a deposit of moisture upon the surface of the gum and varnish. Once moist, a decomposition of the gum and incorporated silver powder takes place, and if the latter has been obtained by precipitation with a solution of iron, the trace of sulphite of iron becomes basic by giving off sulphuric acid, which soon destroys the cementing materials; besides, the moist gum upon the surface of the negatives may likewise suffer decomposition by coming into contact with the nitrate of silver upon the sensitized paper. These experiences, referred to by M. H. Benqué and others, have caused me to investigate the matter, to obtain, if possible, in the first place, absolutely pure metallic silver in the finest state of division, and, secondly, another cementing material in the place of gum.

With regard to the silver, I first endeavoured to obtain the metal by means of the electrotype process; the method is a good one, but very laborious. It led me to the idea of using the silver powder which is manufactured in bronze factories, and which is of a very fine description, and styled "genuine silver powder." By beating the metal into thin sheets, and afterwards grinding it between large stone rollers (a concentrated solution of gum being added during the process), a powder of extraordinary fineness is obtained, from which the coarser particles have been separated by careful levigation. With this so-called silver-bronze, retouching may be carried on. I possess negatives which were thus retouched with gum four years ago, and which are still quite perfect, although they have, of course, been subjected to but little usage. At the same time, the purchase of this description of bronze is often open to question

if the source whence it comes is doubtful and it is not obtained direct from the manufacturer. Sometimes the powder is prepared by boiling chloride of silver in an alkaline solution of cane sugar, and in this case the silver product contains traces of undecomposed chloride of silver. It is obvious that a silver of this description should not be used. If it is desired to use powdered silver, of the purity of which one is convinced, it is best to precipitate a very dilute solution of nitrate of silver (free from iodide of silver) with the well-known pyrogallic acid solution; the latter should be used in excess, and the mixture well shaken, and, finally, the precipitated powder carefully washed, and afterwards digested in a lukewarm three to five per cent solution of the purest cyanide of potassium. The last operation is continued until the cyanide solution remains perfectly colourless, when the same is poured off, and the powder well washed with water. The process is somewhat laborious and elaborate, but by its means a very pure and reliable product is obtained.

That the employment of gum as a means of retouching is injurious we have already mentioned. Fortunately, the silver powder may be applied with oil of turpentine in the same manner as it is with gum, excepting that with the former its manipulation is somewhat more difficult, and its odour less agreeable; the oil of turpentine, which evaporates and becomes resinous, is unquestionably the best cementing material, but alterations and removals are by its means somewhat difficult of execution. Whether it is owing to these facts or not, I do not know, but in most of the studios photographers prefer to work with carmine, a substance easily obtained, and one which allows of easy removal in the case of bad workmanship, and is safely protected from alteration by moisture by the application of another coating of varnish.

Of special importance is the process of M. A. Angerer, which is mentioned in M. Benqué's work, but which I myself had independently become acquainted with—viz., the process of retouching with graphite. A pencil, Faber No. 1, is rubbed upon a stone, and the powder thus obtained (containing either gum or resin) is applied to the negative by means of purified oil of turpentine. This process I have simplified considerably by employing the very fine powdered graphite, such as is used in the electrotyping process. It is impossible to prepare a finer or more uniform product than the powder I employ, and which, through the influence of a friend, I have been enabled to obtain direct from the manufactory of M. Faber in Nuremberg; I have no doubt that photographers would experience no difficulty in obtaining such supplies of the material as they may require for retouching purposes from the same source.

#### HINTS RESPECTING THE PRODUCTION OF CLEAN NEGATIVES IN HOT WEATHER.

BY L. G. KIEFFEL.\*

DURING hot weather we are accustomed to hear from all sides complaints of irregularities which constantly occur in the production of negatives, and these defects, which generally take the form of streaks, fog, and dark spots in the shadows, are not unfrequently attributed to the inferior quality of the collodion. That this is, however, far from being the case, may be proved by the fact that if the collodion is changed these imperfections still remain, and their production is, therefore, shown to be due merely to the association of certain causes arising from the great heat of the weather.

Fortunately, there are several methods whereby these failures and cares of the photographer may be removed, and I trust that the mode of proceeding here indicated may prove welcome. One of the most important preventions against unclean working is to place the collodion, sensitizing bath, and developer in a metal refrigerator, or metal vessel filled with ice or cold water, and to allow them to re-

\* Photographische Mittheilungen.

main therein for some time previously to their employment. But another, more reliable, and at the same time more convenient method, is that indicated in an earlier edition of my manual, and which is as follows:—

When the coated plate is withdrawn from the sensitizing bath, it is placed in a porcelain dish filled with distilled water, and washed in the same for a period of from thirty to sixty seconds, to remove all trace of the silver solution from its surface. When this is accomplished, the plate is again dipped into the silver bath for the period of one minute, in order to re-sensitize it, and then exposed. On pouring on the developer it will be seen that the liquid flows easily and with great regularity over the whole picture, and also that the negative, if properly exposed, is developed very evenly, and does not become evident by fits and starts, especially in the background or in the sky of the landscape. A more certain result even will be obtained if the plates are not dipped a second time into the same bath, but are treated in a different one.

The same distilled water may be used for several dozen plates without any fear of injury; the film of iodide of silver gains in sensitiveness by the use of the second bath.

## Proceedings of Societies.

### FRENCH PHOTOGRAPHIC SOCIETY.

A MEETING of the Society was held on the 3rd ult., M. BALARD, President, in the chair.

M. DESPAQUIS presented the Society with a sealed packet containing specimens of his new sensitive material denominated *collodion cuir*, which he requested might be kept in the custody of the Society for the period of a year, to ascertain its capacity for being preserved in good order for a lengthened time.

The PRESIDENT thanked M. Despaquis, and stated that the material should be preserved as proposed.

M. ROMAIN-TALBOT submitted to the inspection of members specimens of vertical and horizontal baths, manufactured at Berlin, of moulded glass; they are less weighty than those at present made, and likewise more perfect in shape.

M. LIERISSEL presented the Society with a new description of portable dark frame for dry plates of his own invention.

M. CLOUZARD read a communication respecting certain improved apparatus which he used in conjunction with his portable laboratory, when photographing in the open air. Among other apparatus, he described a bath for sensitizing plates in full daylight, and also a bath and dark frame combined.

M. LE COLONEL AVET exhibited a collection of photo-engravings of views taken from nature, and likewise of maps reduced and enlarged. They were produced by a process recently patented by the Colonel.

M. PLACET stated that on examining two or three negatives which accompanied the collection, it appeared to him that the process consisted of pouring upon the negative itself a layer of bichromated gelatine, which, on exposure to light, furnished the necessary relief required for engraving. If this were so, the process was not new, having been published as far back as 1860 or 1861.

M. ANTHONI communicated to the Society some improvements which he had effected in his portable laboratory, and by means of which he was able to carry on the processes of development and intensifying while regarding the negative as a transparency, and also to wash the same without exposing it to the action of light.

The Society thanked M. Anthoni for his communication.

The proceedings then terminated.

## Correspondence.

### PHOTOGRAPHIC NOTES ON THE CONTINENT.

[FROM A SPECIAL CORRESPONDENT.]

Munich, 20th August, 1868.

AFTER a fortnight's tramp over hill and dale, among glaciers, mountain torrents, rocky gorges, and lofty peaks, sleeping now in some chalet or simple village inn, and now in a roughly-built

*auberge* on some elevated mountain-top, it is not unpleasant to indulge again in the comparative luxuriousness of a well-furnished room and a comfortable hotel, and to partake of fare somewhat more palatable than that furnished in these remote districts. Mountain life in the Tyrol is certainly very delightful, and the people to be met with are, on the whole, intelligent and pleasing, but of course one cannot expect a journey undertaken in a foreign country to be absolutely free from slight troubles and annoyances; everything one encounters does not always appear *couleur de rose*, and one's resting places are rarely so soft and sweet-smelling as to be comparable to a bed of roses, except as regards the fact of both being generally afflicted with specimens of entomology. The bread is one of the most serious discomforts in the Tyrol and its vicinity; rye bread I can eat, even when the same contains a good third of vetch-flour; and the veritable black *pumpernickel* of the Thuriarian peasant I have lived upon for months together; but the nauseous composition sometimes met with in these regions, invariably flavoured either with a large quantity of caraway seeds, aniseed, or fennell, becomes, after a few days, simply an intolerable abomination.

Ever since leaving Heiligenblut the climate has been much warmer, and in some of the valleys the heat is very intense. Maize is grown to an enormous extent in the lowlands, and the roads are often bordered with Spanish chestnuts, while other evidences of a warm sun are apparent. The scenery of the Upper Pusterthal, with its noted Dolomite mountains, is very fine, and of a totally different description to that of the Salzkammergut. Then there is the Tanfers Valley, with the magnificent Tanfers glacier at its head; and beautiful Ennerberger vale, which is but three German miles long, and in which three different languages are spoken, viz., German, Italian, and Romansch. At Franzesfeste, a large fortification at the foot of the Brenner, built by the Austrians to defend the pass, our journey on foot came to an end, and we availed ourselves of the railway, which has been recently opened, to bring us over the Brenner to Innsprich, and afterwards on here.

The Brenner railway passes over a height of more than 4000 feet, and is worked, even at the steepest inclines, which amount to one in forty, with locomotives and carriages of the ordinary construction fitted with suitable breaks. Since the rails have been laid down over the pass the traffic has increased almost beyond credence. Twelve months ago one diligence was sufficient to carry the whole number of passengers to their destination; and now three trains, of eight or twelve carriages, pass daily from one side to the other. The line is worked with great ease and regularity, and is without doubt a very successful undertaking.

After Vienna, Munich is the most important town of South Germany; it is the capital of Bavaria and residence of the king. A very beautiful city it is, with some very fine palaces and churches, and a gallery of paintings which is considered one of the most important in Europe. The late king was a great art student, and made it one of the duties of his life to organise an extensive collection of artistic productions; and it is these museums and galleries that have rendered Munich one of the most popular and remarkable cities on the continent.

Permission has been accorded to copy by photography any of the royal or public paintings. Many photographers have availed themselves of this privilege, and reproductions of the most celebrated pictures in the galleries are to be seen in printsellers' shops. These copies are, however, for the most part very small, the majority being only carte-de-visite size, and the details are, therefore, so small as to render the photographs in some cases perfectly useless. Some large copies, measuring about 12 by 15, which I saw, were everything that could be desired, and were very good substitutes for the originals.

In regard to portraiture, Munich enjoys some considerable reputation. The town includes at least half-a-dozen artists of first-rate order, their productions being, in general, quite equal to those of the best Viennese photographers. Cartes-de-visite are still the favourite formula, but cabinets seem to be coming into fashion gradually and surely. Among other specimens I noted some very beautiful pictures by M. Possenbacher, whose large heads are remarkably fine. Some of the latter appeared to have been taken by the camera direct, while those of extraordinary size were, of course, enlargements. M. Reitmayer's specimens were, for the most part, also very good, consisting chiefly of pictures of smaller size.

The prices asked at the different studios are remarkabl

reasonable, seeing that in most cases the work turned out is of a superior quality. They are lower even than at Vienna, where the charges asked were, as I mentioned in a previous letter, much less than those of Paris or London artists. This can only be accounted for on the score of cheaper labour and materials, for there does not appear to be so much—or, any rate, more—competition existing among photographers as there is in this country. Of course our friends over here know their own business better than strangers, but yet I certainly think that the prices are much lower than they need or ought to be, and that the good work turned out should be made to bear a larger profit than that at present realized, which, in some cases, must be very small indeed.

*Cologne, August 22nd, 1868.*

If anything has done good service to photographers in the capacity of a model it is certainly Cologne Cathedral. The two compulsory things—and the only two—to be done by visitors to Cologne, is to see the *Dom*, and to buy *eau de Cologne*; and as half of the inhabitants of the town appear to be ticket porters and touts, the stranger who wishes to fulfil neither of these duties runs a very fair chance of being hunted down and lynched. Never was there such a nuisance as the Cologne commissionaires. If you do not want an hotel, he volunteers to show you the *Dom*; or, failing that, will at once insist upon leading you off to one of the innumerable shops where the only veritable *eau* is. Under these circumstances it is somewhat monotonous to observe in the shops pictures and photographs of the *Dom* of every size, taken from every point of the compass. The *Dom* from the north, from the west, from the front, back, north front, west front; the *Dom* as it was; the *Dom* as it will be, &c., &c., and so on *ad nauseam*.

I was glad to see a large quantity of Braun's carbon prints on sale, both of large and small size. The prices were in every case as low as, or even lower than, those of silver prints, many of the smaller carbon pictures being obtainable at the small charge of sixpence. Some of M. Braun's views of the Rhine are very good, and are the only series that can at all compete with the pictures of Mr. England.

The portraiture in Cologne cannot compare with the larger towns of South Germany, but is nevertheless of very fair merit. The cabinets are much in favour here, and seem to have beaten cartes quite out of the field. Some pictures by M. Haase were very soft and brilliant, and much above the average of photographic productions; the work of M. Raps was likewise good, and worthy of mention. Other specimens shown were of mediocre quality, although it should be mentioned that the prices asked were in every case very reasonable.

At Coblenz the specimens shown were on a par with those at Cologne, but the number of photographers is not nearly so great. At Neuwied, a small town north of Coblenz, M. Koch does some very good work, especially in cartes; his grouping and posing, particularly of female figures, is remarkably natural and effective, while the photography itself is of first-rate order.

In reference to the question of retouching, a subject at present commanding much attention, I may say that throughout Germany I noticed that in the majority of instances the photographs were freely retouched. In many cases, and by first-rate artists, this retouching appeared to have been done direct upon the negative, a method much more effective and even in its results than that of manipulating the paper positive. Each photographer has his own particular way of modifying the negative, which is worked over to a more or less extent, according to the artist's taste, and he is in general very loath to divulge his mode of manipulation.

#### THE PHOTOGRAPHER'S FUTURE.

SIR,—"Make hay while the sun shines!" was an old adage at one time; but, instead of hay, photographers usually make pictures—at least, so they call them.

Now, did it ever occur to the ingenious minds of your numerous readers that the above adage had an intimate companion: "Look out for a rainy day"? And if it ever did strike their imagination, I fear it was unheeded. What provision have they made for the wet, or rather "old age," when cyanide has secretly undermined the constitution, when disasters occur?

You photographers are like the butterfly race—all life for a season, all show and display. Yet think for a moment: even in the midst of your career misfortune may overtake you, not waiting until the time your frivolous life has had its

natural run, but nip you up in the midst of all your glorious excess, as a frost does your insect similar.

I will own that a woman has but a poor, weakly voice to rouse men from the deep lethargy into which they have fallen concerning a topic so essential to all well-meaning, intelligent classes. To enforce my views, permit me to call attention to the societies which have been formed by different sections of our busy fellow-creatures, and for a moment consider the vast amount of real good and benefit they have done. The fish-mongers, for example, by their pretty almshouses, and amount of pensions received, show how the many may help the few. Let me not be misunderstood. I do not imagine photographers have only to say the word, and it can be done without a struggle, or the work completed without trouble and patience, but they could strive to imitate, and even excel. Everything must have a beginning, and, however small at the commencement, may one day stand proudly forth and speak volumes in praise of its founders; and even should success not attend their labours, it will not be the first time in their lives that photographers have failed, and often in less creditable objects.

Would to goodness men who have striven and worked so nobly for the art, fearing nothing of contradiction and shameful abuse, asserting that which they think of benefit to their fellow-workers—would to goodness, I say, they could be brought to interest themselves in behalf of the widows and children of those belonging to their profession. In this matter I would ask them to leave aside all dissension which is so often indulged in at their scientific meetings, for unity is strength. Who knows but what those who exert themselves now may, in some future time, be glad of the provision made, though they may little imagine such a coming change; but they must not forget that fortune is a fickle jade.

Let me, before closing this appeal, mention that I have searched the columns of your valuable paper in the hope of finding some one who would bring this subject into consideration, but not finding any one, I, a woman, have ventured to plead for my sex in this instance, and have actually the audacity to solicit your favour and support.

In conclusion, allow me to add that although at present I am not in need of aid or support (except your own in inserting this), yet misfortune may overtake the strongest of us, and I cannot help feeling something ought to be done. Trusting you will pardon my trespassing so long on your valuable space, I remain, yours, &c.,

HOPEFUL.

*September 1st, 1868.*

[Our fair correspondent may be sure of our sympathy and aid in such a project. Five years ago we mooted such a question, and on page 589 of our Seventh Volume she will find the first article which appeared on this subject. In the next and subsequent volumes many articles have appeared, urging the same idea. It requires a little band of workers to initiate such a scheme: men who are indifferent to the abuse of malignant persons who will impugn their motives and calumniate them for their best efforts.—ED.]

#### SPONGING WAXED PRINTS.

SIR,—It is perhaps worth while to set many well-meaning, and some ill-meaning, persons right on the action of an encaustic paste in protecting the water colour used in retouching albuminized prints from the action of moisture. I have recently had a curious experience in this matter. Having retouched some prints with that valuable pigment, charcoal grey, mixed with a little gum, I was startled to find that no subsequent application of wax or encaustic paste served to give the retouched spots a glazed surface like the rest. Do what I would, they remained obstinately dead or flat, giving the print a very unpleasant effect. It occurred to me to try to remove them, and on applying a sponge filled with water, notwithstanding that a very thick coat of wax had been applied, the whole of the colour was easily removed. I have repeated this operation since on waxed prints in which spots had been touched out with other pigments and gum, and in all cases I find that sponging will remove the colour. I do not pretend to enter into explanations as to the cause, but any one can test and prove the result. It seems probable that the thin coating of wax is easily disturbed by a little friction, and that the water, being quickly absorbed by the gum or pigment, causes it to be easily removed.—Yours truly,

R.

## Talk in the Studio.

**RECTIFYING ALCOHOL BY MEANS OF GELATINE.**—Whilst witnessing the manipulations of the Eburneum process in the studio of Mr. Burgess, at Norwich, Mr. Burgess mentioned a curious circumstance. When the gelatine and pigment forming the layer of eburneum is quite dry, it is coated with collodion to render it impervious to moisture. This operation he noticed always rendered the eburneum soft and limp, so that it required placing in the drying-box again. The greediness of the gelatine for moisture causes it to absorb the trace of water in the solvents of the collodion, and so become damp. This suggested to us a possible use for rectifying small quantities of alcohol, or removing water from collodion in which the use of imperfectly-rectified solvents has caused a tendency to give crapy films. Place a little pure gelatine in the spirit to be rectified. There is no danger of any portion of it dissolving, but it will absorb the water and gradually swell; it may then be removed, carrying the water with it. This will be found more convenient than the plan sometimes recommended of agitating with carbonate of potash, and after subsidence decanting.

**PORTRAITS OF M. ADAM-SALOMON.**—We have just received proofs of the portraits taken by Messrs. Robinson and Cherrill of M. Adam-Salomon, one 16 by 12, and two 12 by 10 inches in size. We have never had the good fortune to meet with anything in photographic portraiture to surpass the examples before us, very rarely with anything to approach them in photographic perfectness and art excellence. The treatment is similar to that generally adopted by M. Salomon himself, distinguished by singular luminousness and force, and not less marked by delicacy, modelling, and fulness of gradation from pearly-white to rich, deep, velvety, transparent blacks. The portraiture in each is exceedingly good; but one in which the model is nearly in profile, sitting with folded arms, and acute but meditative expression, is a portrait possessing rare embodiment of character as well as technical perfectness, giving a grandeur to the head not often seen in photography. We hope that Messrs. Robinson and Cherrill may be induced to publish this portrait, which, as an example of art photography, as well as for the interest of the subject, many persons would be glad to possess.

**NATURAL ACCESSORIES.**—Our occasional contributor, "A Practical Man," referring to our mention of natural, rustic, and other accessories in the studio of Mr. Burgess, calls attention to his prior suggestion of their use in various articles in the early volumes of the NEWS. No question of priority, however, arises in the matter. Such accessories have been used by some persons as early almost as the introduction of photography as an art.

**CABINET PORTRAITS WITH NATURAL BACKGROUNDS.** We have received from Mr. Durrant, of Torquay, some examples of cabinet portraiture—groups and single figures—with characteristic natural backgrounds of far more than average excellence. The photography is perfect—at once rich, forcible, and delicate—and the art qualities are of a high order. Some of the groups are engaged in fishing, and both foreground objects and the distant landscape are in admirable keeping with the occupation. Other natural accessories and scenery are alike pleasing and characteristic, and manifest a fine feeling for pictorial effect. Mr. Durrant is a young photographer, and, if we are not mistaken, a pupil of Mr. H. P. Robinson, to whose tuition he does much credit. His early efforts give promise of a high position amongst those who endeavour to use photography as a fine art.

## To Correspondents.

A. H.—Your toning bath containing  $7\frac{1}{2}$  grains of chloride of gold ought to tone about from twelve to twenty sheets of paper. It has doubtless become inactive, either from some impurity in the materials used, or from some contamination. Some samples of acetate of soda are impure, carbonate of soda being present, and a toning bath made with such a sample would soon become inert. If, in the process of toning, you touch the solution with fingers which have been in contact with hypo, the bath will quickly lose its toning qualities. As a beginner, you will do wisely not to make so large a quantity of toning bath at once, without ascertaining by experiment that the materials are pure. You can now add protosulphate of iron to the solution, which will throw down the gold as a black powder, and this may be reconverted into chloride of gold by means of aqua-regia. 2. The "want of clearness in the transparent parts" is the result of fog. It may arise from a variety of causes. Try adding a little more acid to your developer.

Test your bath, and if it is not acid, add a drop or two of nitric acid. As a general rule, acid is the great preventive of fog. Read an article on the Causes of Fogging, by Mr. Hughes, which appeared in our pages a few weeks ago. 3. A very simple and efficient toning bath consists of 1 grain of chloride of gold, 1 grain of carbonate of lime, and 6 ounces of water. This should be made twenty-four hours before it is used. 4. There is no especial collodion made for copying prints; but almost any sample which is ripe, that is sufficiently old, will answer.

ARTHUR WINTERTON sends us an interesting print from a negative taken from one of the set pieces in a display of fireworks. The design is brilliantly and perfectly made out, the artificial light having been sufficient to impress the sensitive plate and produce a negative in an exposure of eight seconds. The result is very good and novel.

J. C. S.—We have tried the collodion, which, in our hands, worked well and without any abnormal characteristics, the only peculiarity being some slight symptoms of over-iodizing. We suspect that you had tried it in a somewhat weak bath, in which case, the collodion being very fully iodized, a superficial layer of iodide of silver would be formed, which easily breaks up and is washed away.

YOUNG.—If Marion and Co. are not prepared yet to supply their transparent pellicle, we do not know of any one else who is. Mr. Woodbury has not anything of the kind ready for the market. You can easily make such a pellicle for your own purpose. Coat a plate of glass with a thick collodion containing 10 per cent. of castor oil; when dry, coat it with dilute albumen, then coat with sensitive collodion, and proceed to produce your positives in the usual way, and finish as may be required. Then remove the whole from the glass. If a suitable tough collodion have been used for the basis, this will be easily done.

YOUNGSTER.—Zinc would not be suitable for a waste trough or sink in the dark room, as it would readily corrode; varnished wood will answer better.

T. M. (Manchester).—There is no work published on photo-lithography. The fullest details which have been published will be found in Lieut. Waterhouse's recent articles on the subject in our pages. An excellent article was contributed by Mr. Butter to our YEAR-BOOK for 1867.

A. X., who recently inquired of us where microscopic photographs can be obtained in this country, is informed that Mr. J. Beard, of Old Bond Street, Bath, can supply him.

20, KENT ROAD.—Various materials have been recommended for retouching negatives; but it is difficult to find anything but water colour suitable, if you wish to remove it at will. Old negative films ground up with turpentine and strained through muslin have been recommended; blacklead ground up with turpentine in the same way has been recommended by some, and we have heard very good accounts of the material recommended by Mr. Bell. See an article by Dr. Reissig in the present number.

C. E. F.—In order to add gelatine to a developer you must add it first to the water, and dissolve by heat. In the small proportion necessary after it has once been dissolved by heat, it will remain in solution. One grain in a pint of a developer will often prove sufficient. Gelatine is never dissolved by cold water if it be of good quality. If you wish to add some to a developer in existence, make a solution in hot water, and then add a little to your developer.

W. J. A. G.—We have not had sufficient experience with the plates in question to form an opinion. We have occasionally used them, and have not found them blister. Try moistening with a mixture of alcohol and water.

E. JENNINGS.—Mr. H. C. Jennings first sent a letter to the First Volume of the PHOTOGRAPHIC NEWS, and has continued to send us occasional letters at intervals since. The first was, we believe, in the number for January 7th, 1859. The volume is out of print, but copies can occasionally be obtained.

MR. MAYCOCK.—We can scarcely undertake to say which is the most portable tent in the market. Blanchard's, sold by C. E. Elliott, is very portable; so is Meagher's; so is Roueh's. Thomas's is exceedingly complete, but it is not intended to be carried by one person. Murray and Heath's is similar. We do not remember their respective prices. A bromide does not produce crappiness in collodion. Crappiness is generally due to excess of water in the solvents.

J. W.—You will find a good process of printing on muslin and similar fabrics on p. 98 of our last YEAR-BOOK.

F. W.—We have not seen the work issued by Virtue and Co.; but such of Caldesi's photographs of the pictures in the National Gallery as we have seen are very excellent. The mode of copying them employed was, we believe, first to secure a good facsimile in charcoal by a clever artist, and from this monochrome copy a negative was obtained. 2. The reduction of the image in the hypo bath is due to various causes. Sometimes it is due to the original preparation of the paper, excess of chloride being used. It is more frequently due to the action of the toning bath, which, if used new and containing much free chlorine, converts part of the image into chloride of silver, and this is dissolved by the hyposulphite solution.

Several Articles in type are again compelled to stand over until our next. Several Correspondents in our next.

### ENCAUSTIC PASTES.—M. ADAM-SALOMON'S FORMULA.

THE value of an encaustic paste in improving the effect of photographic prints is becoming very generally recognized amongst photographers. A good encaustic confers three special benefits on the print; it gives depth, richness, and transparency to the deep shadows; it renders apparent delicate detail in the lights which would otherwise remain imperceptible; and it aids in protecting the surface, and so tends to permanency.

The first and last of these three advantages are generally appreciated, but it is not so well known—or, at least, we believe that it has not been so specially noted—that the application of a wax or of an encaustic preparation practically brings out minute detail not before apparent. But on careful observation it will be found that this is so. A familiar and palpable illustration of the kind of effect produced is furnished by the process of varnishing or French polishing a piece of fine-grained wood. When its surface is rough the character of its grain is scarcely perceptible, but is rendered partially visible by planing, scraping, or rubbing smooth. However perfectly smooth it may be made, however, much of the most delicate part of the grain remains invisible until it is polished or varnished, giving it a slightly diaphanous surface. So it is with the photographic print. Photographers know that when it is rolled, and so made smooth, the definition and detail look finer than they did before. But the effect of an encaustic paste is to make detail bear out which was not seen before. The delicate pearly gradations which surround the high lights, which were buried in the texture of the paper, are, when the surface is made diaphanous, perfectly visible, and the bringing out of such gradation has the effect of giving a singularly delicate quality of modelling, and a rare brilliancy in the lighter portions of the picture. We have heard it remarked of some photographs finished in this way, that the faces have the appearance of being modelled in white marble. This is scarcely true or good criticism, by the way, for flesh should not look like marble. But the idea has been suggested by the diaphanous surface rendering visible a great deal of very delicate detail which gave an effect of roundness and modelling without the aid of deep shadows, an effect very similar to that of a white marble statue, in which the diaphanous surface shows every dimple, and undulation, and gradation, which would be lost in a coarser or more perfectly opaque substance.

Various formulæ for the preparation of encaustic pastes have been published, and many of them very excellent. The qualities required are, easiness of application and the capacity of giving richness and depth without too much gloss, and of yielding a hard, firm, permanent surface. The exceedingly fine surface and the great richness in the

shadows of the pictures of M. Adam-Salomon naturally renders it a matter of interest to learn the especial formula of the preparation he employs in finishing his prints. On his recent visit to London, in answer to inquiry, he gave us, from memory, the recipe, stating a doubt as to its exactness, and promising to send us the precise details of an improved formula on his return. Experimenting with the formula he left us, we produced, by a very slight modification, an encaustic paste of exceeding excellence, which gave us admirably satisfactory results. It stands as follows:—

Pure white wax ... ..	5 drachms
Gum elemi ... ..	1 drachm
Turpentine ... ..	2 drachms
Essential oil of lavender... ..	1 drachm
Essential oil of spike ... ..	1 drachm.

The wax is cut into shreds, and melted in a capsule over a water bath. Placing it in a jar, and the latter in a pan of hot water, will serve. Powder the elemi, and dissolve it in the turpentine and essential oils, using gentle heat. Some samples of elemi are soft and tough, and will not admit of powdering, in which case it may be roughly divided into small portions and placed in a bottle with the solvents. Elemi is generally a tough gum, of a mottled-looking, mixed character, containing a good deal of impurity. It will invariably need straining through muslin to remove impurities and insoluble matter. The clear solution is then added to the melted wax, and well stirred. It is then poured into a wide-mouthed bottle and suffered to cool. It forms a firm paste, very easy to apply, and yielding a fine, hard, rich surface.

To Messrs. Robinson and Cherrill, M. Salomon stated the materials without proportions. They have favoured us with an example of a formula worked out by experiment, and with some prints treated with it. Mr. Robinson writes to the effect that the trouble they had experienced in getting good results with encaustic pastes on large pictures had induced them to give up its use; but that all difficulties seem to be removed by the preparation the formula of which we subjoin:—

Pure white wax ... ..	2½ ounces
Gum elemi ... ..	1 ounce
Turpentine, about ... ..	5 ounces
Oil of spike ... ..	1 ounce.

Mix as above, and then add 1 drachm of essence of lavender. This paste is much thinner than that made by the formula preceding it, and Messrs. Robinson and Cherrill prefer it on that account. It has the disadvantage, however, in some cases, where the surface of the paper is soft and absorbent, that it permeates the whites, and leaves a slight discolouration like grease, which is very slow to disappear, notwithstanding that the solvents are volatile.

Within the last few days we have received the improved

FORMULA OF M. ADAM-SALOMON.

It stands as follows:—

Pure virgin wax	...	...	500 grammes
Gum elemi	...	...	10 "
Benzole	...	...	200 "
Essence of lavender	...	...	300 "
Oil of spike	...	...	15 "

Those who wish to try a small sample can substitute grains for grammes. Melt the whole on a water bath, mix thoroughly, and strain through muslin. A simpler plan will be to dissolve the elemi in the solvents, as described above, and, after filtering, mix with the melted wax, as the filtration, which is chiefly intended for the gum elemi, is more easily managed before the wax is present. This, when finished, forms a stiff paste, not differing much in quality from that produced by the formula we have first given; but better, we think, in the fact that it dispenses with turpentine, which we regard as an advantage. In each case it will be seen that, as in all such preparations, wax is of course the principal ingredient; but the gum elemi serves to give firmness, toughness, and hardness to the surface obtained by its application.

The encaustic paste is put on the print in patches in three or four parts, and then rubbed with a light, quick motion, with a piece of clean flannel, until a firm, fine surface is obtained. If a rich thick coating of the encaustic be desired, a very light pressure in rubbing is necessary, so that a polish may be acquired without rubbing off the paste in the operation. If a print be retouched, more especial care is required to use a light hand in applying the encaustic paste.

We add to these formulæ for preparations for finishing positives one which M. Biennert gives in the *Archiv*, which, despite the curious mixture it seems, is said to give good results:—

White wax	...	...	11 grammes
Ether	...	...	32 "
Plain collodion	...	...	24 "
White shellac varnish	...	...	16 "
Alcohol	...	...	8 "

This is to be applied with a pledget of cotton wool, rubbing rapidly until a polish is acquired.

### URANIUM AND NICKEL PRINTING PROCESS.

SINCE the publication of our last, we have heard of another economical printing process possessing much promise. A few weeks ago we received from Dr. Liesegang, amongst some other novelties, a very fine albuminized print, at once soft and brilliant, with the simple inscription at the back running thus,—"Albumen, nitrate uranium, nitrate nickel." On inquiry as to the mode of using the materials mentioned, and whether they are the only agents used in producing the process, we learn that the print is produced by a process suggested by Dr. Liesegang three years ago, and which, it seems, Herr Wothly has recently been working out with some success.

So far as we can learn at present from the details kindly furnished by Dr. Liesegang in a private letter, as in the process upon which we have recently experimented, described in our last, silver is the colourific agent of which the print is formed, but uranium and nickel play an important part in the process. The solution contains nitrate of uranium, nitrate of nickel, and a very small portion of nitrate of silver. Albuminized paper, without any chloride, is floated on this bath, which is sufficiently charged with ether and alcohol to prevent solution of the albumen, notwithstanding the small quantity of the silver salt present. The especial part played by nitrate of nickel in this pro-

cess appears to be that of an accelerator, and, like most accelerators, it also tends to produce softness, excess producing weakness. The greatest advantage of the process is obtained when the paper is exposed wet from the solution. This can only be done, of course, in solar camera printing, but for this purpose it is found very valuable. Dr. Liesegang has tried keeping the paper moist by means of steam during the progress of printing, and has found that the exposure was reduced one-half by such treatment.

The precise formulæ and details of this process have not yet reached us, but are promised shortly, when we shall lay them before our readers. Any printing process which minimises the use of silver possesses a two-fold advantage—first, economy; and, second, greater probability of permanency. The last claim may require explanation, which will, however, be readily understood. It is this: the smaller the proportion of a silver salt in the paper, the less the proportion of any fixing agent necessary to remove the unchanged salt; and the less fixing a print requires, the less risk there is of forming unstable compounds in the fixing bath, and the less trouble there is in removing from the print traces of the fixing agent, which, if left in, endangers its permanency.

### ECHOES OF THE MONTH.\*

BY AN OLD PHOTOGRAPHER.

DISCOVERIES, PRINTING PROCESSES, AND PATENTS—DRY PROCESSES—BRITISH ASSOCIATION MEETING—SALE OF POISSON'S BILL—AMERICAN BROMIDE PATENT—SCHONBEIN—MR. FRUWIRTH'S PROCESS.

RECLINING lazily under the cool shelter of a rock, listening to the wondrous philosophy murmured out by the sad sea waves, I have been led to speculate on the curious fact that invention or discovery in connection with photography seems to flow in tidal waves, one pressing rapidly upon another for a time, to be followed by a period of "slack-water." At one time the tide of invention sets in with printing processes, and a flood of new and valuable methods of producing fine prints from the negative overwhelms photographers, who, perhaps, embarrassed by the wealth of choice, neglect to work out any of the new methods proposed for their advantage. In 1864 we had Swan's carbon process, the Wothlytype process, and your own collodio-chloride process. The carbon process, being undoubtedly the most important of these, has been steadily making its way, and must, in the end, be the prevalent, if not the only, mode of printing photographs. The Wothlytype process, as I have always believed, deserved more attention than it received, but it was unfortunate, both in the time and in the manner of its introduction, and there were uncertainties and vagaries in the action of the materials employed which were never well understood or explained. The collodio-chloride also suffered by forming one of a crowd of printing processes, having to divide the attention of the photographic public with the new uranium and carbon processes. But it suffered most from being a free gift to the public, and having become everybody's property, it became nobody's business. If it had passed into the hands of some individual or firm whose interest it would have been to work out its applications, to prepare and supply suitable materials, and feel a special interest in its commercial success, I am satisfied that its adoption would have been more general, and the interests of photographers and of proprietors more perfectly served. Monopoly of some kind seems to be necessary to repay inventors, or they have little stimulus to exertion. The Leptographic Company, who have appropriated your collodio-chloride process, endeavour to protect themselves by affecting secrecy as to the exact mode of application. But surely the Patent system is better than secrecy? By the latter, knowledge is buried; by the former it is published,

\* The "Old Photographer's" copy did not arrive in time for insertion in our last.—ED.

but its originator has secured the profits of such knowledge for a few years. Without the certainty of the possession of these profits it would often be impossible to work out inventions.

This is an aspect of the Patent question too often overlooked. Take two especial examples: the carbon process and the photo-relief process. Unless Mr. Swan had possessed an absolute property for a time in his labours he could never have worked out the carbon process to the degree of perfection it at present possesses; and without the constant experiment and persevering labours of a capable person, who must be in a position to spend much time, much money, and much brain-power on the work, it would never have attained the practical and perfect character it now holds. So with the photo-relief process. The discovery made by two gentlemen, independently, of the original principle of printing in semi-transparent ink from intaglios, in which shadow was represented by variation of depth in the recesses, was valuable enough; but the working-out of that principle has involved an amount of labour and cost which would have been literally impossible to a person without an absolute property in the results. Every piece of apparatus, every material employed, has involved some novelty, and has required its conditions of success to be determined by costly and protracted experiment. And if these labours had not presented a prospect of eventual commercial success, it is more than probable that the process would have been relegated to the limbo of ingenious possibilities.

My speculations by the sea-side, however, referred to dry plates; but having referred to printing processes as an illustration of the tidal character of invention, these reflections on one phase of Patent law, which have often passed through my mind, found a chance of expression which I had not the energy to resist. Last year we had a high tide of dry processes: England's collodio-albumen process, the morphine process, the coffee process, the gum process, and some others. This summer there has not been a single new process proposed, and only one or two slight modifications of existing methods, a circumstance which, having in view the number of excellent processes already in existence, I regard as a matter for congratulation, as it affords time, without the distraction of new suggestions, to appropriate, work out, and master properly the novelties of last year. I have had but little time or energy as yet for this work, but I have done a little. The morphine process, with its delightful simplicity, I find I can only rely on within a few days after the plates are prepared. I have found them good at the end of three weeks, but I cannot rely upon a repetition of the experiment, having found them both insensitive and inclined to fog at the end of a week. England's process I find capital. The plates keep two or three weeks, and the negatives are very satisfactory. Nothing, however, exceeds in my experience the coffee process; it is simple and certain, less sensitive than morphine plates, but not slow. The plates keep well, and the negatives are excellent. Gum I have not yet tried; but from the negatives I have seen, and the accounts I have seen, it certainly seems to be the *ne plus ultra* of dry processes.

The British Association meetings at Norwich scarcely seem to have been very successful, judging from what has appeared in the reports, and from the private account of a friend. With the exception of some portion of Dr. Phipson's paper, and Mr. Bing's paper on "Actinometry," no matter of special photographic interest seems to have been brought before the sections. Professor Morren's description of a new action of light on chloride of silver seems to contain nothing which Mr. Spiller's papers on the same subject, published years ago, did not contain. I understand that the innkeepers of the ancient town distinguished themselves by fleecing members to a serious extent; and it was reported that at the entertainment or fete given by Mr. Harvey to the members of the Association, eighty pounds' worth of silver plate was stolen. As, however the company included—

surreptitiously, I am told—many hundreds of persons not in any way connected with the Association, and of a class clearly not accustomed to "sit at good men's feasts," the philosophers can scarcely be held accountable for the loss.

The new Pharmacy Act, doubtless well intended, will be the source of some annoyance to dealers in photographic materials, or such of them as are not at the same time pharmaceutical chemists. The more stringent the conditions under which the sale of poisons is permitted, the more restricted, of course, will become the chances of accidental poisoning. Suicide will not be much affected by a difficulty of procuring poison—seeing that the avenues from life are so numerous—except in so far as ready facilities sometimes create temptation. King John exclaims,—

"How oft the sight of means to do ill deeds  
Make ill deeds done!"

But if the precautions now made binding upon the pharmaceutical chemist had been made binding upon all who had occasion to vend poisons in the regular transaction of their business, surely the end would have been gained. If I send up to the dealer in London who supplies me with all my photographic requisites, for a case of goods, surely it is hard that he cannot send me a bottle of chloroform varnish, or a little cyanide or bichloride of mercury, articles necessary in my studio for occasional use, although abandoned in my general practice. It is an ill wind, however, that blows nobody good. I suspect that the dealers who are also chemists will frequently gain by this arrangement; for if it be absolutely necessary to send to them for a few things, it will often be found convenient to order other things at the same time. Your advice to lay in stocks of the prohibited articles is good in two ways: it will, if carried out, clear out the stock in the dealers' hands, and rid them of a difficulty, and will save, possibly, some little trouble to the consumer in getting a further supply.

All photographers of cosmopolitan spirit must congratulate their brethren of the United States on their emancipation from the iniquitous bromide patent, which was not only a tax upon their pockets, but a perpetual outrage upon their common sense. Intelligent American photographers who had for a score of years past used bromine in photographic processes, and who would so naturally employ a bromide in the collodion process in their earliest experiments with it, just as we did in this country, must have felt themselves terribly outraged in having to pay a constant tax for permission to use bromine because some one contrived to secure a patent for its use in 1854, three or four years after its use in collodion was known in this country, and fourteen years after its use in equivalent processes was common throughout the world.

I notice the death of Schonbein is just announced, in his 69th year. He little thought when he discovered gun-cotton that it would form the basis of such a revolution of the photographic art as it has proved! Photographers owe him a tribute of grateful remembrance for rendering so much possible in their art—so much already accomplished—so much to be accomplished by the collodion process.

I am glad to recognize in the examples of Mr. Fruwirth's process I have seen, indications of unusual excellence in a phototype process. One of the difficulties which such processes have to encounter is the necessity of having to reproduce subjects in mechanical gradation. To do this they must reproduce engravings which have been already published, or original drawings expressly produced for the purpose. The temptation to do something original often makes the inventor choose the latter, and it so rarely happens that capable draughtsmen are obtained to prepare the original drawings. Hard, scratchy, ill-drawn things in conception, and execution of the feeblest kind, are too often produced; and the conclusion which follows is, however unreasonably attained, that the process is unsatisfactory. It is to be hoped that Mr. Fruwirth will avoid splitting upon this rock.

The societies have only met in the fields, and then less for photography than for social enjoyment. In another month many of them will commence the winter session, and then discuss, it is to be hoped, the materials won during a summer's campaign.

### Foreign Miscellanea.

In the *Bulletin de la Société Française* is an account of the method of photo-engraving recently patented by M. Henri Avet, a colonel on the staff of the Italian army. The process consists in pouring upon the collodionized side of a negative a sensitive mixture—as, for instance, gelatine and bichromate—and exposing the layer, when dry, to the light under the negative. The gelatine is then washed in the dark, and a relief is thus formed, adhering to the negative, from which a metallic fac-simile may be obtained by the electrotype process, or, if preferred, an impression from the relief may first be obtained in wax, and this afterwards electrotyped. A very deep relief may be produced by repeating the process of coating the negative with gelatine, and exposing it. A mould of this kind is proposed by the inventor for stamping porcelains and other transparent materials, while the less deep metallic intaglios are for printing reproductions of engravings, drawings, maps, &c. If an artificial grain is necessary for printing a picture, the inventor produces the same by exposing his negative first of all in front of a black cloth screen covered with white net lace, and afterwards at the object to reproduce, or *vice versa*, the fine markings not prejudicing the image upon the plate in any way. The same effect may be produced by placing two negatives together—one having an object depicted on its surface, while the other has the fine lines—and producing a gelatine relief from both at the same time.

Dr. Krippendorf, of Aarau, describes in the *Photographisches Archiv* his method of operating out of doors. As a tent he uses his tripod camera-stand, the legs of which are but twelve decimetres in length. By enveloping the stand in a large black cloth cover made for the purpose, and using as a resting-place a small foot-stool, he is enabled to conduct his operations with ease and comfort, the space afforded being amply sufficient for his wants. A vessel of water placed a slight elevation above the tent, and fitted with a flexible tube, supplies the means of washing, and a small aperture cut into the side of the black cover and fitted with yellow calico provides for light and ventilation. Care must be taken that one of the three legs is facing the direction in which the camera is pointed, so that the whole affair may be as rigid as possible.

A photographer in Freiberg is making seals upon which photographic portraits are engraved. He exposes a film of bichromated gelatine under a glass positive, and then places the same in water. The film swells out in parts, and a picture in relief is thus obtained, from which an impression is taken in plaster of Paris, a metal cast of the latter being afterwards produced by the electrotype process. The seals thus obtained are sold at the rate of six shillings each.

M. Sigwart, of Elberfeld, in making a few remarks upon the carbon process, recommends the employment of a solution of gutta-percha in chloroform instead of the india-rubber solution generally employed. He states that the gutta-percha may be applied with the same facility, and possesses the advantage of drying within a few minutes after its application, forming a film of the most adherent character, which clings with especial tenacity to india-rubber paper. M. Sigwart states that he has experimented with several kinds of carbon material, and affirms that he obtains the same result on a sheet of American paper in five minutes as that produced upon Swan's material in fifteen minutes; at the same time, for the development of pictures on the American paper, a lengthened manipulation was necessary in water of 70° to 80° C., while the English paper developed

much more easily, and required treatment with luke-warm water only.

General Count Nostitz, of St. Petersburg, communicates to the *Archiv* the satisfaction he has found in using dry plates prepared by Mr. Gordon's gum process. So sensitive has he found them that he has been able to secure instantaneous negatives by their aid, the exposure required being about one-third longer than that necessary for wet plates. They remained in good order for months, and might be kept for some time after having been exposed, without being found to suffer. As a modification to the process, the Count approves the employment of an iron developer instead of the alkaline treatment formerly used by Mr. Gordon. The exposed plate is first moistened with distilled water, and then the developer, to which a trace of silver solution is added, is poured on; a few more drops of silver solution may afterwards be supplemented. If by this means sufficient density is not obtained, the plate is carefully washed, and intensified with 1 gramme of pyrogallie acid, 1 gramme of citric acid, and 240 grammes of water to which a few drops of silver solution are added immediately before employment.

### METHOD OF OBTAINING INTENSE NEGATIVES.

A CORRESPONDENT sends us the following in the form of a printed slip, which has apparently been supplied by some "process vendor." We may remark that it is very similar to the method which Col. Stuart Wortley used to employ in intensifying the very thin images he obtained in his instantaneous process. If this method be employed upon a negative already possessing some degree of vigour there is a risk of over-intensifying. For reproductions, or any subject requiring great density, this process answers well:—

"The novelty of this process consists in applying the pyro and silver last, instead of the usual way, which is before the fixing. Greater intensity is obtained without injury to the half-tones if the process is conducted with care and taste. With views the chemicals should be poured upon the skies, and worked principally upon that part to avoid chalking the lights and half-tones.

"The negative, after being developed with iron, fixed with cyanide, and washed, is, while wet, flooded with bichloride of mercury, 10 grains to the ounce of water; well washed, and again flooded with iodide of potassium, 3 grains to an ounce of water; again washed; then with pyrogallie 2 or 3 grains, acetic acid 5 drops, water 1 ounce, commence the intensifying by first pouring on the pyro alone to equalize the flow, then with the addition of 3 or 4 drops of nitrate of silver 5 or 10 grains, water 1 ounce, pour on and off four or five times, watching the picture carefully as it increases in depth; wash well the instant sufficient intensity is obtained. If the picture does not come up to the mark after a few applications of the pyro, do not continue its use, but wash it well and commence again with the bichloride and iodide, or iodide alone, taking care to wash well as at first; this will probably complete the picture; if it does not, pyro and silver must be applied again, increasing the proportion of silver. Should a brown stain occur in the deep shadows, it can be removed when the intensifying is finished by pouring the bichloride on and off until it changes to an opalescent hue, which will be no impediment to the printing. The operations are to be carried on in open daylight."

### PRACTICAL HINTS IN OPERATING.

BY FRITZ HAUGK.\*

#### I.—SALTPETRE IN NITRATE OF SILVER.

Some time since, while engaged in operating, I found that one of my negatives had been so vigorously acted upon by the fixing solution that no vestige of a photographic image remained upon its surface, and nothing was visible but a

\* *Photographisches Archiv.*

transparent film. According to Hardwich, a result of this description is caused by a collodion compounded of pyroxyline which has been prepared with acids of insufficient strength, the product formed being incapable of furnishing a film of the required hardness; moreover, in such a collodion the iodide of silver is stated to be formed more upon the surface of the film than actually inside the same. In the present case I was convinced of the faultless composition of the collodion, and it was necessary, therefore, to seek the cause of failure elsewhere.

My suspicion at once fell upon the nitrate of silver which had been used for compounding the sensitizing bath. It had been freshly made up on the day of its employment, and experiment which I hereupon instituted with the nitrate of silver in question at once proved the same to contain an appreciable quantity of saltpetre. The bath was on this account, therefore, comparatively weak, a circumstance which rendered the cause of failure evident, for after the solution had been evaporated to two-thirds its original bulk, the fixing agent ceased to exert any deteriorating effect upon the negative.

According to my knowledge, I believe no one has yet pointed out this particular source of failure, and as in my early days of photography a similar instance came under my notice, I think it but right to make known the same for the benefit of my less experienced colleagues.

Generally speaking, it is by no means so rare a circumstance to receive nitrate of silver adulterated with saltpetre as one is apt to suppose, and every photographer who does not draw his supply direct from firms of well-known reputation should make it his business to ascertain the purity of the article delivered to him, if only for the purpose of estimating its value. To do this a small quantity of the nitrate is dissolved in a little distilled water, and so much chemically-pure hydrochloric acid added, drop by drop, until no more chloride of silver is formed. The clear liquid is then filtered off into a dial glass and evaporated by a gentle heat. Does the nitrate of silver contain saltpetre, there remains, after the liquid has completely evaporated, a network of crystals upon the surface of the dial-glass; if no saltpetre is present, no deposit of any kind will be perceptible.

That failures from the cause in question are of seldom occurrence is accounted for by the fact that sensitizing baths are generally prepared in the proportion of one to ten, and possess, therefore, a concentration which conceals the presence of saltpetre; if, however, a bath in the proportion of one to sixteen is prepared, it will be found that, out of an average of twelve samples of so-called chemically-pure nitrate of silver, at least two will betray the presence of saltpetre, and yield results similar to the one I have described.

## II.—THE INTENSIFYING OF NEGATIVES.

Many of my colleagues, when making professional tours, practise the custom of simply developing their plates at the moment of their production, and postpone the operations of intensifying and fixing until they have more leisure to devote to the purpose. I myself have also practised this method of operating, but have always remarked that the film of precipitated silver formed upon negatives produced in this manner is of a much coarser description than in those which are perfectly white in a moist condition. From such coarse-grained plates as these it is, of course, impossible to obtain delicate prints, and I would therefore recommend that, whenever practicable, the process of intensifying should immediately succeed that of developing. When this is impossible the negatives should not be allowed to become dry, but should be kept moist by constant pouring over of water.

## III.—TEARING OF THE COLLODION FILM IN VARNISHING.

Now and then the question arises as to the cause of injury sometimes inflicted by the varnish upon the film, and as the subject has again been discussed very recently, I here make known my own experience in the matter. It is usual to

ascribe the evil to the too-concentrated condition of the alcohol used in the manufacture of the varnish, and this is, no doubt, in most cases, the case; but even with the employment of a dilute alcohol the unpleasant result may be brought about; when, namely, the plate is rendered too hot previously to its being varnished. Everything depends, however, upon the description of collodion used, for with some kinds I have purposely overheated the plate to a considerable extent, and the latter has sustained no injury, while with negatives prepared with other materials a slight excess of temperature was sufficient to bring about their destruction.

## IV.—STAINS AND STREAKS.

Inexperienced photographers are greatly troubled with these evils, the majority of which are due to the manner of pouring on the developer. Even with skilful treatment of the developing solution, however, strains are sometimes unavoidable; for instance, when the different photographic compounds have not been carefully prepared. The silver bath may have been made too strong in comparison with the iodizing of the collodion, or *vice versa*, and in such a case stains must inevitably be produced, even if the developer is poured upon and spread over the plate in the most accomplished manner.

Another disagreeable phenomenon which causes some of our colleagues much uneasiness is, the dark streak which commences at the upper end of the plate and continues down to the middle of the same, or even lower. This is the result of a freshly-prepared bath and too much alcohol in the developer. In almost every photographic manual it is stated that the addition of alcohol to the developer is only necessary when the bath has become somewhat alcoholic by the sensitizing of several plates. This warning is, however, generally disregarded, and an alcoholic developer is frequently used with a fresh bath; the result is, that as soon as the developer is allowed to run off the plate, in order that the picture may be examined by transparency, these streaks are at once formed. Many obviate the same by carefully washing the plate and removing the developer prior to an inspection of the negative, but by this means it is impossible to watch properly the gradual appearance of the picture, a very necessary part of the operation of developing. For this reason, therefore, no alcohol should be used in the developer when a new bath is employed, a little being added only when the bath has been some time in use, and the quantity afterwards increased when the bath has become appreciably alcoholic. If this precaution is properly attended to, the developer may be poured on and off, and the picture inspected from time to time, without any risk of staining.

## PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN

COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXXIII.

THE landscape photographer could not improve himself in the esthetics of his art more thoroughly and easily than by an exhaustive study of Turner's *Liber Studiorum*, more especially if he had opportunity of comparing the original drawings with the engravings and the various states of the plates showing the many corrections and alterations of the artist in his endeavour to reach perfection. Fortunately, this study is possible to those within reach of the South Kensington Museum, where a large proportion of the drawings, as well as the engravings—either in the originals or by photographic copies—are exhibited. Many of the engravings were etched by Turner himself, who seemed so fond of some of the plates that he found it impossible to let them go, but kept retouching and finishing until they eventually were almost transformed into different subjects to the first sketch. These alterations are of extreme value

to the student, showing, as they do, the progress of artistic thought. Ruskin has said that one of the original etchings is a drawing-master in itself.

This famous work, which consisted of seventy-one drawings in sepia, fifty-one of which are at South Kensington, and in fine condition, originated in rivalry with Claude's *Liber Veritas*, a book in which this famous painter registered a sketch of every picture he painted, in order to authenticate his works. In the *Liber Studiorum* Turner intended to show his command of the whole compass of landscape art. The comprehensiveness of the scheme will be understood by a glance at the list of six heads into which the engravings are divided; viz., historical, pastoral, elegant pastoral, mountain, marine, and architectural. Turner never did anything in a fragmentary manner. He used the only method of attaining success, he did what he had to do with all his might. While on the subject of this great work of our greatest master, I may incidentally allude to the enormous

increase in value of works of art of late years: the subscription price for the "Liber" series was £17 18s., but a good copy now sells for 200 guineas. Mr. Stokes formed a complete collection, consisting of etchings, proofs, and duplicates of each plate in its various states. This collection was offered to the authorities of South Kensington Museum for £2,500, and refused; it afterwards sold in detail for more than £3,000. But expensive proofs are not necessary for the student. Photography has unlocked this treasure-house of art, that all who care may enter. Three or four years ago the late Mr. Thurston Thompson made two magnificent sets of photographs from the original drawings, which were very widely circulated, and are as valuable for study as the originals. The Autotype Company also are, I believe, about reproducing these pictures in carbon, which will be a great boon to the lovers of art.

Lessons may be learnt from every drawing in the series, but I have selected "The Stackyard" for illustration,

because of its simplicity, and because it shows how interest may be imparted to the poorest materials, when in the hands of a true artist, by judicious selection of the point of view, so that the objects may compose picturesquely and artistically, and by skilful distribution of light and shade. I of course do not suggest that the photographer has equal power with the painter in arrangement, and light and shade, but he possesses these qualifications, as I have repeatedly stated, in a much greater degree than is generally supposed. The enormous power, for instance, possessed by the photographer in the possibility of partial or local development for regulating light and shade is seldom thought of, much less used. In the "Stackyard" the general form is wedge-shaped, repeated by smaller forms of the same kind within the general form. The thin ends of the wedges are always supported or accented. See the general outline supported by the man with the barrow and the willow trees; also notice how the pool in the foreground assists in forming the wedge. The point of the wedge

formed by the rick, the two men, the ladder, &c., is supported by the white horse, while the group is balanced by the horse lying down in the foreground. It will be noticed in this picture, as in the sketch by Topham in the last chapter, that the principal dark, the interior of the barn, is in close contrast with the chief light, the white horse. This is an arrangement which, if it can be secured in a composition, always gives brilliancy and vigour.

The illustration is from a block engraved by Mr. Fruwirth's process from an admirable wood engraving by W. J. Linton, in the *Illustrated London News*. It rarely occurs that the touch of the master is so faithfully reproduced in an engraving as we see it here; this fidelity of reproduction may be especially noticed in the trees behind the barn, and in the sharp touches of shadow throughout the picture. This example affords a good illustration of the capacity of Mr. Fruwirth's process for yielding with success reduced copies of any subject produced in mechanical gradation.

## ON THE EMPLOYMENT OF BLUE GLASS IN PHOTOGRAPHIC STUDIOS.

BY M. ALOIS NIGG.\*

THE employment of blue glass for the first time in this country by M. Ludwig Angerer, who has glazed the entire front of his new studio with that material, has led to many discussions as to its practical value, and the various opinions expressed by competent authorities in its favour and against sufficiently prove how unprepared we are at present to form a definite judgment of its merits. On this account I do not feel myself called upon to defend my own ideas on the subject, the more so from the fact that Professor Pisko, in his last lecture upon "Light in Relation to Photography," explained in a most convincing manner the action of blue glass from a scientific point of view, the opinions expressed by the Professor agreeing perfectly with those entertained by myself.

To the remarks of the above-mentioned interesting lecture, I would supplement the opinion of another gentleman, whose experience has been gained by practical tests. Dr. Pohl, a Professor of the Imperial Polytechnic Institute of this town, instituted experiments with blue glass as far back as fifteen years ago, and arrived at the conclusion that the chemical action of the light was by its means accelerated, and that the glazing contrast of several colours was thereby softened and rendered more harmonious.

Without admitting in any way the theory based upon his observations, it is, nevertheless, certain, that not only do the active blue rays penetrate light blue and other glass of a similar description, but many of the other light rays likewise make their way through; and on this account he believes it probable that the latter have the effect of placing the blue rays in such a condition as to facilitate their transmission.

The opinion expressed by Professor Pohl, of great importance to photographers, goes so far as to presume that the same effects as those produced by the employment of blue windows, curtains, walls, &c., may be obtained in the most simple and perfect manner by using a small disc of light-blue glass ground with parallel planes, and placed either in the central diaphragm of the lens, or in front of the inner portion of the same. It is certainly desirable that the correctness of this statement should be substantiated as early as possible, and no greater incentive ought to be necessary for the prosecution of experiments of this description on all sides. For if it should be found that the action of the blue glass possesses a decided advantage, it will then be a further question whether it is necessary to employ large quantities of the material in glazing a studio—a very costly, and, at the same time, on account of the difficulty in obtaining the requisite colour, very laborious undertaking—or whether a two to four inch disc of blue glass, costing a mere trifle, would be sufficient to bring about identically the same effect; the latter contrivance possessing, besides, the feasibility of employment outside the studio, and more particularly in the taking of landscape views. Should the disc of blue glass be found to answer all requirements, then the same cannot be regarded in any other light than that of a simple and useful improvement in photographic apparatus.

I have instituted a series of practical experiments with a view to obtaining the requisite results, but have abstained from regarding the conclusions at which I have arrived as convincing arguments, or inviolable proofs, until I have had more experience in the matter. Nevertheless, a detailed description of the manner in which I am conducting these experiments may not be out of place. The following are the questions required to be solved:—

1. Is it really possible to obtain a softer blending together of antagonistic colours by the employment of blue glass?
2. Is it possible to produce the same effects by means of a disc of blue glass fitted to the lens, as that obtained by illumination through blue windows?

3. Is the photographic process accelerated by the use of blue glass?

If we refer to the circumstance of people with weak eyes, who are unable to bear the glare of a strong light, and therefore have recourse to blue spectacles, by means of which all objects are seen in precisely the same way as if they were illuminated through blue windows, we should feel disposed to answer the first two questions at once in the affirmative. As, however, we have no means of proving that photochemical agents are endowed with exactly the same kind of sensitiveness as the retina of the eye, we must leave the questions at present undecided.

In my experiments conducted in this direction I have made use of a porcelain statuette about twelve inches in height, which I photographed first of all in the ordinary manner, and afterwards through a sheet of blue glass placed before it; finally, I removed the blue glass screen, and took a third picture of the statuette with a small disc of light-blue glass fitted into the central diaphragm of the lens. This mode of operating I repeated with a portrait, employing first the blue disc placed in the central diaphragm of the lens, and afterwards in front of the inner part of the same.

The last-named operation I likewise observed by means of an orthoscope.

In another more careful and reliable experiment I employed an ordinary stereoscopic apparatus, furnished with two perfectly-identical lenses, and used the disc of blue glass in the manner before alluded to alternately with the right and the left lens. By this means it was possible to obtain upon one plate two pictures produced in the same light, by the same exposure, and under the same conditions, and calculated, therefore, to yield the most convincing results.

The pieces of blue glass, ground with parallel planes, which I employ, were purchased from M. Stettinger, an optician of this town, at the very reasonable cost of one florin each, and fulfil their object satisfactorily. A piece of blackened cardboard, made into the shape of a large pill-box lid, has an opening cut into the centre, against which the blue glass is gummed, and the whole may then be fitted on to the tube of the lens. I should also mention, that the term ground with parallel planes must not be taken in its strictly mathematical sense, as such glasses would be of a very expensive kind, and are, moreover, not needed, those employed by me answering the purpose perfectly, and not causing any malformation of the image to be reproduced; this, however, would by no means be the case with ordinary coloured glass obtained in the regular way from tradesmen.

After this explanation of the subject it is hoped that no objection will be made upon the part of photographers to undertake a few experiments in this direction, which may be carried on without inconvenience, and with very little trouble; and I would ask those gentlemen present to give the matter an early consideration, and to communicate any results they may obtain, in order that a correct and unanimous decision upon the merits of blue glass may be arrived at.

It can in no way be denied, that by using blue glass as a means of illumination, not only are obnoxious sun-rays considerably toned down, and disagreeable reflections from neighbouring buildings avoided, but the objects in the studio are lighted up in a softer and pleasanter manner; to obtain this same description of illumination, M. Ludwig Angerer coated his glass studio with starch-paste as long ago as 1861. Whether there is any other beneficial action besides to be derived in photography by the employment of blue glass remains yet a disputed point.

## SEL CLEMENT.

Those of our readers who may be disposed to give further trial to the *Sel Clement* for printing will do well to follow the recent directions issued in regard to it, some of which may, by the way, be useful in relation to the ordinary silver

\* Read before the Vienna Photographic Society.

printing process. A commission appointed by the Mar-seilles Photographic Society to make trial of this substitute for the ordinary nitrate report favourably, and express a conviction that it is more economical than pure nitrate of silver.

#### DIRECTIONS FOR USE OF SEL CLEMENT.

1. Dissolve the Sel Clement (60 grains per ounce water) in distilled water. Filter the solution (which will turn the litmus paper light red). If the colour is too deep, add some drops of ammonia, taking care not to exceed the above mentioned light red colour.

2. Float the albuminized paper two minutes only.

3. Dry; print a little deeper than wanted; tone, fix, and wash as usual.

4. If a quicker printing is required, use a bath of 30 grains Sel Clement per ounce distilled water with ammoniacal fumigations.

The following is a good toning formula, used for the present specimen.

(A) Half ounce acetate soda in 1 quart of water.

(B) Ten grains chloride of calcium in 1 pint of water; after filtering this solution (B), mix it with (A).

(C) Add 15 fluid ounces of a solution made with 15 grains chlorid of gold in 30 fluid ounces of water.

(D) Add to the whole: 30 fluid ounces of the toning bath used the day before (for beginning, water will do). If bluish black tones are wanted, a mixture of 10 grains chloride gold and 5 grains chloride platinum should be used.

4. The silver bath (marking 48 degrees English when containing 15 per cent. Sel Clement) must be strengthened with a fresh quantity of the salt when it descends below 40 degrees; the silver bath should be kept supplied according to the quantity used.

5. When the silver bath becomes too deeply coloured, filter twice consecutively through a filter-paper containing one-third of its weight of powdered charcoal.

6. Keep the sensitized paper (which will remain white for many days) protected from light, damp, and alkaline vapours, enveloped in common paper, without any other precaution.

#### PHOSPHORESCENT PHOTOGRAPHS.

THE *Scientific American* has some remarks on a new kind of photograph, made on the so-called phosphorescent surface, of which absolutely nothing can be seen in the daylight, but which is distinctly visible in the dark. "Many years ago," it remarks, "compounds were invented which had the property of shining in the dark many hours, and even days or weeks, after an exposure to sunlight for only a few seconds. These phosphoric compounds, called after their inventors Canton's, Baldwin's, Bolognian phosphorus, &c., were formerly of no use whatever, but it was hoped that they might eventually reveal something concerning the nature of light; and such has indeed been the case, as the phenomena connected with these experiments are a strong argument in favour of the undulatory theory, and the correlation of forces.

"An English photographer\* lately conceived the idea of covering a sheet of paper or glass with a layer of such a phosphorescent substance, and then treating it in a similar manner to paper or glass sensitized in the ordinary way for taking a photograph. Pictures taken in this way seem by daylight to have no existence, but the places where the light has acted upon become phosphorescent or luminous in the dark, the shadows remaining invisible, the semi-tints slightly luminous; and the result is such a change in the surface that the picture is only perceptible in a dark room by an unearthly glow of a greenish, blue, red, or purplish tint, according to the preparation used.

"We notice this invention only by reason of its oddity, and not for its utility. The only practical use we see for it would be to terrify the uninitiated by the exhibition of luminous images of skulls, skeletons, demons, and similarly cheerful subjects suddenly appearing on the walls, window panes, curtains, or other unexpected localities at the moment the lights are extinguished. It is very easy to make such pictures. A sheet of albumen paper is moistened to make it sticky, and then equally covered with a thin layer of the

finely-powdered phosphorescent substance, or a pane of glass is covered with a thin coating of paraffine, to which also, when warmed, the powder will stick; then the prepared surface is treated as in taking an ordinary photograph, either by placing it in the camera, or exposing it for a few seconds under a positive to the rays of the sun or the magnesium or electric light.

"The only thing remaining to state is the preparation of these phosphorescent substances. One of the cheapest is Canton's phosphorus, and it is made by burning oyster shells for half an hour, powdering and mixing with an equal weight of sulphur, and heating again for one hour in a covered crucible. The produced substance must, of course, be preserved in the dark, and protected from moisture in a well-closed bottle. Wachs found that the luminosity is much increased by moistening the mixture of shells and sulphur, before the second heating, with a solution of sulphide of arsenic in liquid ammonia. The powder thus obtained emits so strong a light of blue colour that it does not require perfect darkness to perceive its glow.

"Baldwin's phosphorus, mentioned above, is prepared by dissolving chalk in nitric acid, then heating and grinding it to powder. The Bolognian phosphorus is made by simply heating a mixture of powdered heavy spar with the white of eggs, gum-water, or a solution of tragacanth. Fluor spar is naturally such a phosphorescent substance, some specimens, however, more than others, and diamond appears to be the best; but the expense of the powder would hardly admit of its employment for the above-mentioned purpose. Experiments have proved this property, in some degree, to exist in a great number of substances not suspected to possess such a singular quality; for instance, many natural compounds of lime, baryta, strontia, and magnesia, besides corals, fossil bones, and teeth, the shells of eggs, oriental pearls, dry bleached linen, white paper, and even the stones extracted from the human bladder.

"Grotz has found that the same luminous rays—the blue and violet—which produce the photographic pictures, also produce this effect, and that the rays which have no photographic powers—red and orange—not only do not produce it, but extinguish the existing luminosity. However, this is not because it is easily extinguished, as handling, and even immersion in water, will have no effect upon it, neither plunging the body in different gases. Groszer found that the luminosity was not even in the least impaired in a perfect vacuum.

"Some philosophers have already, and with apparent good grounds, mentioned their suspicion that in nature the same phosphorescence may take place on a larger scale that we see in different minerals, fossils, and preparations on a small scale; and if so, planets and comets are luminous partly by light reflected from the sun, and partly by phosphorescence of their own. That comets possess such a light of their own has been proved by Arago's conclusive observations by means of polarized light; and perhaps the peculiar appearance of the moon during its eclipse is due, besides the refraction and absorption of light in our atmosphere, to such a phosphorescence; even ice shows luminosity in the dark for several hours, when suddenly withdrawn from sunlight exposure to a dark room. The periodical obscuration taking place during the moon's phases is so slow that no phosphorescence can show itself, but on the occasion of an eclipse the obscuration is so rapid that any phosphorescence on its surface persisting for an hour or half an hour must become visible."

In a subsequent number it remarks:—

"The foreign journals report that an American has taken out a patent in France for a style of printing which may be read in absolute darkness. We have not seen an account of the details of this invention, but have no doubt that the process is similar to that of certain photographs which we recently described. Nothing is easier than to print with an ink made of powdered phosphorescent substance mixed with some gum or varnish. Such a print may be either visible or entirely invisible by daylight, according as the colour of

\* Mr. J. T. Taylor, we believe

the ink differs from or resembles the colour of the paper upon which the print is made; but in order to render it visible in the dark, all that is required is simply to expose it for a few seconds to the sun, strong daylight, or to electric, calcium, or magnesium light; and when, after some time, it becomes invisible, a renewed exposure to light will make it again visible. In this respect it has a great advantage over the luminous photographs, which cannot be exposed to daylight except under the glass positive, as the whole surface of the paper is covered with the phosphorescent substance, and must therefore be preserved in the dark. The printing here described, however, improves and becomes more luminous the more it is exposed to light, as only the letters consist of the strongly phosphorescent substance, and the rest of the paper is in its natural condition; that is, it requires a very strong light to make it feebly phosphorescent.

## COMMUNICATIONS ON PHOTOGRAPHY.

BY M. CAREY LEA.

I HAVE received communications from various parts of the country that furnish points of interest that seem to deserve publication.

Mr. Joseph Voyle writes me from Tuscaloosa, Alabama, that he has obtained considerably increased sensitiveness from the use of carboic acid in collodion, but still better in the negative bath. This latter assumed a violet colour, and gave plates that worked faster and better than another bath, exactly similar, without the addition.

The use of carboic acid is not new, having been suggested by Dr. Kaiser in the *Bulletin Belge*. That photographer, however, looked rather to preserving the bath from change, and does not speak of the sensitiveness being increased. This last observation, if confirmed, will be due to Mr. Voyle. Carboic acid is a reducing agent, and reduces silver at the boiling point of water. The violet colour assumed by the bath is doubtless due to the reduction of small quantities of silver.

Mr. Charles Kneeland writes me from Pittsburg, that he has tried the application of pyrogallie acid to a plate before placing it in the camera, and found a fully-exposed plate in the slide. This mode of operating was proposed in Paris some time back, with the idea, that by a proper arrangement the development might be watched through yellow glass, and the exposure stopped at the right moment. It will be observed that this method differs essentially from the self-developing plates that I lately published in this, that here all the usual manipulations are necessary, the difference being that the developing agent is applied before instead of after exposure; whereas, in mine, the plate is simply coated with a peculiar mixture, and the sensitizing and application of developing fluid are entirely suppressed. It seems doubtful, however, if the matter will be more than one of curiosity.

Mr. Kneeland thinks that plates that have received a treatment with pyrogallie acid before exposure are peculiarly sensible to weak radiations, and thinks that this principle ought to be made the foundation of a method for instantaneous exposures. He got the best results by using as a developer, water, 1 ounce; acetic acid, 1 drachm; pyro and citric acid, 1 grain each. If the citric acid was less, the exposure was increased; if more was used, the exposure was shortened, but the image almost disappeared in fixing.

Paper sensitized and treated with this last solution, and exposed under a negative for a minute or two to the light of a lamp, gave a bold and vigorous picture. Mr. Kneeland tried this for enlargements, and succeeded very well, except that after five or six minutes the paper began to stain on the back, and went on till the back turned quite black.

## ON THE PREPARATION OF IODIC ACID AND IODATE OF POTASSIUM.

BY PROFESSOR J. S. STAS.\*

*Iodic Acid.*—I prepare this acid by the action of pure iodine on normal nitric acid. To effect this I operate on four litres at a time of pure nitric acid, to which I add a tenth of its weight of iodine. The yield of iodic acid given by this method has been much exaggerated; the quantity produced only represents one quarter of the weight of the iodine employed. In order to remove with certainty the nitric acid which the iodic acid always contains, I dissolve in water the solid yellowish residue obtained on evaporating to dryness the liquid resulting from the reaction of iodine on fuming nitric acid. The solution of this crude acid, when introduced into a vessel made of glass unattacked by acids, is evaporated to dryness; the whole residue is heated to 200°, and kept at this temperature to bring it to the state of iodic anhydride, and to remove with the water the last trace of nitric acid which it contains.

As the action of nitric acid on iodine took place in a large retort of ordinary glass, the iodic acid obtained contains traces of iodates of sodium and calcium, which I have not been able to remove.

I hoped to have been able to employ iodic acid in the determination of the atomic weight of iodine; with this object I prepared more than 2 kilogrammes of crystallized iodic acid by the action of boiling dilute sulphuric acid on iodate of barium; but, in spite of all precautions, I found it impossible to prepare in this manner either iodic acid or iodic anhydride free from barium, the greater part of which existed in the state of sulphate. After the efforts I made to remove the barium, I believe I may affirm that it is impossible to prepare pure iodic acid in this manner.

*Iodate of Potassium.*—Requiring large quantities of this salt, I tried many methods of preparing it. Only two furnished me with a product which was unalterable in the air. One consisted in transforming an aqueous solution of hydrate of potash into iodide and iodate, by acting on it with purified iodine; the other was based upon the formation of iodate by the action of heat on a mixture of equal molecular weights of iodide and chlorate of potassium. This is how I prepared the iodate by the latter method. I mixed intimately the iodide and chlorate of potassium previously purified from foreign metals by means of a solution of sulphide of potassium. The well-dried mixture was introduced into retorts till they were about two-thirds full, and they were then placed in sand-baths. In the same bath I inserted rather deeply a small retort containing pure chlorate of potash. Each retort had connected with it a curved tube dipping into water. I elevated the temperature of the bath until the chlorate of potash in the small retort fused, and oxygen commenced to be evolved. When I had succeeded in well graduating the temperature so as not to overstep the temperature of decomposition of iodate of potash by heat (a temperature which is sensibly higher for iodate than for chlorate), I had completely transformed the iodide into iodate, and the chlorate into chloride, without any disengagement of oxygen.

To separate the iodate from the chloride I added to the mass, after cooling, cold water in sufficient quantity to disintegrate the mixture. The saline mass was then ground up, and, after being introduced into a displacement apparatus, was lixiviated with cold water until almost all the chloride was removed. The iodate was then submitted to three successive crystallizations. After each crystallization, which was effected rapidly, the salt was submitted to a methodical washing. After the first crystallization I was unable to discover a trace of chloride or iodide.

The iodate thus prepared remains indefinitely without becoming yellow in the presence of air. This cannot be said of the salt which is obtained by attacking chlorate of

potassium by means of iodine. Even when the terechloride of iodine which is always formed along with the iodate of potassium is decomposed by carbonate of potash, the salt so produced becomes very appreciably yellow in the air, even after it has undergone five successive crystallizations, each time followed by methodical washing. I have not been able to ascertain what is the substance which communicates to this iodate of potassium the property of becoming yellow, but the fact has always been so.

### CON-ELLIPTICAL VIGNETTE.

BY PROF. JOHN TOWLER, M.D.\*

A VERY interesting vignette for the cabinet picture is the con-elliptical, which consists of a white elliptical space between two elliptical surfaces, which are printed whilst the space is protected.

Many of our readers may not be acquainted with the practical mode of making an ellipse, and, on this account, those who have the knowledge must not criticise us for being unnecessarily minute. The cut will help to illustrate what I mean.

In the first place, in order to make the vignette, you require an elliptical opening in a piece of tinfoil which is of the same size as the negative. This opening must be so placed as to comprehend the head and bust of the picture (the head being about one inch and a half in length from the crown to the chin). Take the tinfoil and flatten out all the creases and irregularities, and then draw a line with a blacklead pencil through the middle of each end, and find the centre of this line. Measure off one inch from this centre on either side, and drive a pin through either point through the foil into the table beneath. Now take a piece of strong thread, six inches long, double it, and make a knot, so that the length from the middle up to the knot is exactly two inches and one-half. Open this so as to comprehend the two pins within the knotted thread. Take a sharp-pointed blacklead pencil, and, placing the point on the inner side of the thread, and keeping the thread taut all the time, proceed round the thread, and make a mark on the tinfoil; this mark will be an ellipse, sufficiently large for the vignette in question. The size of the ellipse can be varied at pleasure, taking care always to make the double thread longer than the distance between the two pins, which may be placed at any distance apart desired. The next operation is to cut out (and throw away) the part of tinfoil

situated within the elliptical curve; this can be done quite easily with a sharp-pointed penknife. Now place the tinfoil with the opening in the middle over the negative, in the proper position as to the figure, so as to obtain a uniform vignette; over this lay the sensitive paper, and expose to the action of light until the picture is sufficiently printed. The next operation requires a piece of tinfoil or cardboard one-eighth of an inch larger than that cut out from the first tinfoil. Drive the pins as before, on a straight line, and two inches apart, through a piece of cardboard, for instance, and with a thread knotted as before, but whose length, when doubled, from the middle to the knot, is two inches and five-eighths, draw an elliptical curve. The space comprehended within this curve must be carefully cut and preserved.

Lay this piece of cardboard upon the print in such a manner as to overlap the print equally all round, and again expose to light until the colour of the parts exposed is the same as that under the elliptical shield. Now tone and fix in the ordinary way. You will find the majority of your customers will like this novel vignette, which costs but little extra trouble.

### ON PURE WHITE GUTTA-PERCHA.

A PAPER on this subject, read by Mr. F. Baden Benger, at the recent meeting of the Pharmaceutical Conference, contains some remarks of interest to photographers. "I have examined," he remarked, "specimens of the so called 'pure white gutta-percha' now commonly sold, and find that for the most part they may have been designated almost as correctly 'pure white oxide of zinc,' being made up with this substance in very large proportions, and, I believe, thereby rendered less tough, durable, and fit for the purpose. This opinion has been strengthened by the fact that persons to whom the pure and afterwards the commercial article have been supplied have frequently complained of the inefficiency of the latter. I am further induced to describe the process I use, by the very high price required by makers of the really pure substance.

"A good sample of crude gutta-percha will yield at least 75 per cent of the pure resin. Some care should be taken to obtain a specimen with as little impurity as possible. The bottle marked No. 1 [exhibited to members] contains some of the kind I find best; it is imported in roundish blocks, which are exceedingly hard and difficult to cut, but any of the large gutta-percha manufacturers will supply the same torn into fragments similar to the accompanying specimen. Four ounces of this digested with five pounds of methylated chloroform for a few days will form a solution sufficiently fluid to filter through ordinary bibulous paper. This should be conducted in such a manner as to allow little or no loss of chloroform by evaporation, the apparatus for filtering volatile liquids described in Mohr and Redwood's 'Pharmacy' answering the purpose; the addition of another pound of chloroform rendering the filtration more expeditious. To the filtered solution, which should be bright and nearly colourless, add an equal bulk, or a sufficient quantity, of spirit of wine to precipitate the gutta-percha, which will separate from its solvent as a white bulky mass; this should be rinsed with spirit, pressed in a cloth, and dried by exposure to the air; its condition is then that of the accompanying specimen, marked 'No. 2,' perfectly white, but too porous for dental use. It should then be boiled for half-an-hour in a porcelain capsule, and rolled in sticks whilst hot, as specimen 'No. 3.' The chloroform can now be separated from the spirit by the addition of water; and, lastly, the spirit from the water by distillation, at the leisure of the operator.

"There is, therefore, no reason why the chemist should not prepare this substance himself, and if he is careful to prevent the loss of chloroform and spirit in the process, its reduced cost and greater purity will compensate him for the trouble.

## Talk in the Studio.

**OUT-DOOR MEETING.**—On Saturday last the South London Society held an out-door meeting at Hampton Court. Some members brought cameras, but the majority contented themselves by examining the fine palace which Cardinal Wolsey built, and the pictures, &c., it contains, and by rambling and enjoying the picturesque country. All met together to "high tea" at *The Mitre* at 5 o'clock, to chat over photography—its processes and prospects.

**MR. BLAIR'S CARBON EXPERIMENTS.**—Mr. Blair, of Perth, has favoured us with two interesting examples of carbon printing, by processes with which he has been experimenting lately—one with good half tone, without transfer, which is excellent, and derives additional value from being a portrait at all, and another of himself, with one transfer only. More particulars shortly.

**TONING BATH OF SULPHOCYANIDE AND HYPOSULPHITE OF GOLD.**—Our friend Dr. Liesegang writes to the effect that since we published his formula for a toning bath containing sulphocyanide of gold and hypo, he understands that some English photographers have not succeeded in obtaining good results with it, and encloses us some fine toned prints to illustrate its capabilities. We may add that we have ourselves tried it, with—so far as the tones are concerned—the most perfect success. Dr. Liesegang adds:—"At present I do not say anything about the permanence of the prints; but since I have worked this method I have not had one which has changed. About three thousand have been treated in this way in my studio. I shall keep them until they are one year old, and if then they are good I shall present them to the readers of my journal."

**PHOTOGRAPHIC EXHIBITION IN HAMBURG.**—A photographic exhibition will be held in Hamburg in November, to which English photographers are invited to contribute. Dr. Liesegang kindly offers, if our best men will send examples of their work to him, unmounted, by hook post, to get them mounted suitably, and exhibit them collectively. We hope that photographers who can worthily represent English photography will avail themselves of this courteous offer.

**LIQUID GLUE, BY M. KNAFFL.**—This useful article, which is employed for a variety of purposes—as mending porcelain, glass, mother-of-pearl, &c.—is not nearly so good when prepared with vinegar and nitric acid as that obtained by the following process:—Three parts of glue broken into small pieces should be covered with 8 parts of water, and left to stand for some hours; one-half of chlorhydric acid and three-fourths of sulphide of zinc must then be added, and the whole exposed to a temperature of from 81° to 89° C. during ten or twelve hours. The compound thus obtained does not gelatinize; it only needs to be allowed to settle, and will be found a most useful agent for joining purposes.—(*Wochenschrift des Niederösterreichischen Gewerbevereins*).—[It is scarcely necessary to say that this glue must not be used for mounting photographs.—Ed. P. N.]

**THE GERMAN OBSERVATIONS OF THE ECLIPSE.**—A correspondent of the *Times* gives a short account of the operations in photographing the eclipse at Aden. He says:—"On the evening of the 17th almost all the rank and fashion of Aden made an exodus to Marshag-hill, the eastern promontory of Aden, where the German party were established with all their instruments. The night was very cloudy, and much anxiety was felt by all interested in the success of the observations. At grey dawn, however, and just before first contact, the banks of clouds separated into broad bands, occasionally shutting out a view of the eclipse. Totality commenced at 6h. 29m. 28s. A.M., and lasted 2m. 55s., during which interval a most magnificent view of the phenomena was obtained, and four most successful photographs were taken. The only planets and stars observed during the totality were Venus, Jupiter, and Sirius, which at once shows that the darkness was not great. At the time of totality the height of the tide was 7½ feet, or for Aden a good average spring tide. The preceding spring tides (about a fortnight before) were very bad, the rise and fall not being more than 4 feet. On first separation a most beautifully soft light stole out from behind the moon, lighting up the sea and rocks of Aden in an indescribably beautiful manner. The sun was, unfortunately, behind a cloud at the final separation, which could not be,

therefore, determined within a second of time. The times were, of

						H. M. S.
Totality ...	...	...	...	...	...	6 29 28
First separation ...	...	...	...	...	...	6 32 23
Totality...						0 2 55

The German party were delighted with all their experiments, and consider themselves amply repaid for their trouble. They had most superb instruments, and were particularly civil and obliging in explaining their use, mechanism, &c. Among the most interesting was a photographing telescope, which is made self-acting by means of a most ingenious clock-work mechanism, which, with the help of a simple pendulum and endless wheels, is so delicately adjusted as to counteract the motion of the earth, and to keep the telescope rigidly fixed on the star or planet during the ten or fifteen seconds required to receive the impression.

**THE INVENTOR OF GUN-COTTON.**—*Galignani* announces the death of Schonhoin, the inventor of gun-cotton, and, as it is believed, of collodion also, for it is asserted that he was aware of the solubility of gun-cotton in ether. His name is also associated with the discovery of ozone. He was 69 years of age.

**ACCIDENT IN BOILING DOWN A BATH.**—A correspondent sends the following account of a singular accident in boiling down a bath:—"I have just met with rather a curious accident whilst boiling down an old silver bath. It was in an evaporating dish over a gas boiler; I had just raised the gas slightly, the more readily to fuse the nitrate of silver, as the water had quite evaporated; the dish split, the silver poured down through the wire gauge of the boiler, which it consumed like so much paper, and a most furious combustion took place upon the bench, which lasted about twenty seconds. At the end of that time there was a deep hole burnt in the bench, and all that remained of the silver was a very little light-coloured ashes, which, as far as I have been enabled to examine it, is perfectly valueless."

## To Correspondents.

P. F. P., referring to the Eburneum process, asks whether the pictures are reversed, adding: "I think it is the wrong side of the picture which is seen, and consequently, with all its beauty, I do not think the process worth the trouble." Now a very little reflection might have satisfied our correspondent that in a process of camera printing he could either produce the image in its proper position as in a paper print, or in its inverted position as in a direct collodion positive. It depends upon whether the negative is placed in its groove in the copying camera with the film facing the light or facing the lens. He should also remember, however, that he requires to produce a reversed image on the glass, because when the picture is finished it is the back of the collodion film which meets the eye, and the image which appeared inverted when on the glass is non-inverted when on its Eburneum support.

W. G.—Your microscope will furnish the chief necessities. We cannot describe the operations at length here; but you will find satisfactory instructions by Mr. Cherrill on page 56 of our *YEAR-BOOK* for 1866. 2. You have probably used the acids too strong, or the temperature too low. Agitation with a little carbonate of soda or potash may now help you. The presence of methylated spirit often tends to prevent the liberation of free iodine. 3. We shall have pleasure in examining the results to which you refer.

SILEX.—Gelatin does not form an insoluble compound with silver, like albumen; on the contrary, gelatin may be dissolved in a solution of nitrate of silver. 2. The accident you met with is very singular. We print the statement in another column.

A DILEMMA.—The milky appearance assumed by your solution of pyrogallie acid in distilled water when a few drops of silver are added may arise from a variety of causes. Sometimes the acetic acid contains a trace of hydrochloric acid, and this would cause a slight turbidity from the formation of chloride of silver. Possibly the silver solution is taken from the nitrate bath, in which case turbidity would be caused by the precipitation of iodide of silver. Do you find any special inconvenience follow this turbid appearance?

A. LADY.—Unless our fair correspondent is familiar with the various modes of intensifying, or is prepared to experiment a little, so as to master their peculiarities—in which case almost any of them

would give good results—we can recommend nothing simpler and safer for intensifying a fixed negative than pyro and silver. Try 3 grains of pyro and 3 grains of citric acid in an ounce of water. Flood the plate with this until it flows easily, then pour it back into the developing cup and add a few drops of a 20-grain solution of nitrate of silver, and apply it again to the plate. This, as a rule, will intensify satisfactorily. Washing the film first with the solution of iodine, rinsing, and then applying the pyro and silver, sometimes makes the operation still more satisfactory. Let us know if you succeed with this.

W. G. G.—We have not had time for fully and carefully testing your collodion, but have made one or two trials. It is somewhat thin and limpid, and when applied to the plate so as to secure a thicker film gives a much more creamy coating in the nitrate bath. This suggests that probably a little more cotton would be an improvement, although, as a rule, 6 grains should be enough. We have used samples of which 10 grains were necessary to give a satisfactory body. Having a large proportion of a bromide, a strong bath or long immersion will generally be necessary to sensitize the plate properly. Probably, moreover, another grain of iodide of cadmium per ounce might be an improvement. It is very probable that the collodion in its present state would work well in a dry process.

W. J. A. G.—Mr. England in his last year's campaign did not use distilled water at all, but he had generally access to pure rain water. As a rule, we recommend distilled water for the first wash after leaving the nitrate bath; after that it is of less importance. The chief object of using distilled water is to avoid contact between silver solution and any of the salts in common water, such as chlorides, carbonates, &c., by which traces of insoluble silver salts might be formed on the film. Very thorough washing after applying the albumen is not necessary. We should regard "a few drops" as meaning six or eight. In no case is the silver solution to be added to the albumen, but in all cases applied separately, as directed. For winter use, first white of egg, and after that a 30-grain silver solution; for summer use, dilute albumen, followed, in like manner, by dilute silver solution.

G. K. W. (Massachusetts).—We believe that arrangements are in progress for a sale of Mr. Woodbury's American Patent to Mr. Pollock, with whom then all arrangements for licenses, &c., would rest; and he will, doubtless, make the matter known to American photographers. Thanks for the photographs, which are very excellent, both portraits and landscapes. The group is very successful. What a pity none of them has any name written underneath! Avoid using a tint of a decided sulphur yellow on your mounting boards. A true India-tint is much more neutral, and much more satisfactory in its effects on the picture.

W. H. W. (Ross).—Thanks for your friendly letter. We will bear in mind the suggestions in further experiment.

J. M. (Bath).—We cannot state with absolute accuracy the relative distances between the component lenses forming the triple combination; but the distance of the back lens from the back surface of the central negative lens is about twice the distance between the front surface of the central lens and the front lens of the combination. 2. We should not use as much bromide or iodide as you propose; from 4 to 5 grains of an iodide, and about 1 grain of a bromide, is a good proportion for collodion for the wet process. The proportion of salts does not usually affect the collodion as to crappiness, except so far as it sometimes happens that water is used in assisting to dissolve them, and water will produce crappiness. 3. Mr. Breese does not get instantaneous pictures by moonlight, nor asserts that he does. The moon, and sometimes light clouds immediately in contact, are, of course, genuine moonlight pictures, but the landscapes into which they are printed are, of course, taken by sunlight. We believe that Mr. Breese once produced a photograph of a white statue by moonlight, with a very long exposure. 4. We are glad that you find the albumen and alc process so satisfactory. Mr. Davies, of Edinburgh, was, we believe, the inventor. 5. The composition of *Sel Clement* is a secret. It is said to consist of nitrate of silver and nitrate of magnesia.

J. H. (Birmingham).—It is probable that you have added too much water, and possibly too much salt. If too much water be employed, the chloride of silver precipitates very slowly; and if too much salt be added, the chloride of silver becomes partially dissolved again. Add a little nitric acid, and agitate the water; this will assist the chloride in falling. 2. Your statement and question as to your prints are rather too indefinite to enable us to help you. "Some days," you say, "my prints are very dull, as if on badly albuminized paper; other days they are brilliant and full of gloss: will you tell me the reason and remedy?" It may be that the albuminized paper does vary in quality; it may be that the negatives are not always good; it may be that the silver bath gets too weak, or that the paper is floated too short a time; it may be that the prints are at times washed excessively before toning; it may be that the toning bath is not in good order, being possibly newly made and bleaching considerably; it may be that at times the printing is

done in the sun instead of in diffused light; or it may be that other reasons exist. You must be a little more precise in the statement of your operations and conditions before we can give you efficient advice. 3. To obtain highly glazed prints use highly albuminized thick *Rive* paper, a 60-grain bath, and a good negative. To obtain black tones, use the lime bath, made a couple of days before use.

B. A. G. (Fulham).—As a rule, the smaller the amount of light, the more difficult it is to obtain intensity in a negative, and, therefore, when producing an enlarged image with a lens considerably stopped down, it is more difficult to get a vigorous negative than when working with a large aperture upon a well-lighted subject; the ordinary gelatino-iron developer will, however, generally suffice, when sufficient exposure is given to produce a dense image. We have not tried the nitro-gelatino-iron developer, but as nitric acid does not generally tend to density, we should scarcely use it in such a case. If the collodion and bath are in good order, a full exposure and gelatino-iron developer ought to give sufficient intensity. Should it fail to do so, it will not be difficult to get any amount of intensity after fixing, by first applying mercury and iodide, and then following with pyro and silver. 2. The developed print is somewhat a sad affair, but scarcely surprisingly so. When you try again, do not attach the paper to glass by wetting it, which is a tolerably sure means of staining the back of the paper. Next, remember that to attempt to get a print on paper by exposure in the camera with diffused light is a comparatively hopeless operation. Instead of an exposure of 10 seconds to a minute, it is probable that half an hour would not be more than sufficient. Further, until you are very familiar with printing by development, do not use hot gallic acid solution. Both in exposure and development take care to keep the back of the print dry.

JOHN MACK.—Your lighting appears satisfactory, and the work generally is very excellent indeed. We hope that you will find the new premises answer in every way.

J. H. UNDERWOOD.—Mr. Thompson, 48, Pall Mall, is the person, we believe, about whom you inquired in reference to the issue of coloured photographic landscapes.

W. DURANT.—We shall be glad to see examples of your continued progress.

CLIFTON.—We have received a portion of a letter dated "Clifton," without the conclusion or signature. When we receive the name of the writer we will answer by post.

L. B.—We have seen the theory as to the part played by organic matter to which you refer, and we agree considerably with the writer. 2. We have no objection to theoretical contributions; but, as a rule, we reject speculative articles. They may be at times interesting, and even occasionally useful; but much depends on the quality of the mind which speculates. The speculations of the writer in question are generally interesting, and often useful. 2. We have had occasion more than once to refer to the presence of a visible image on a wet plate before development, and to point to its bearing on the chemical theory of the latent image. The subject is not of sufficient importance to re-discuss at present. You will find an allusion to the fact that a visible image is sometimes visible on the wet plate, and the reasons why it is not generally the case, on p. 423 of our Ninth Volume. Thanks for your kind remarks and good wishes.

H. S.—Received too late for attention this week.

Several correspondents in our next.

### INDIA-RUBBER AS A PROTECTION FOR NEGATIVES.

It is somewhat singular that in almost every photographic purpose to which india-rubber has been applied, it has turned out a disappointment and a failure. About a twelve-month ago considerable attention was called to its use as an adhesive medium for mounting photographic prints, and sanguine persons saw in the waterproof layer it interposed between the picture and the mounting board not only immunity from the dangerous decomposition which such materials as gum, paste, and glue are supposed to undergo, but a protection from hyposulphites or other injurious materials in the cards themselves. After a few months' trial, the issue has been in a large number of cases, as we feared it would, that the prints have curled up and left the mounts, the adhesive quality of the elastic gum having been insufficient to preserve the attachment between the print and the mount. We have heard of many such cases, and, as time progresses and the india-rubber undergoes its inevitable change into a pliable resin, we fear that many more disappointments will be experienced.

We have recently had our attention called by a correspondent of very extensive experience to another very serious failure in india-rubber to subserve the purpose for which it was proposed. A few years ago its use was suggested by a gentleman of high repute and large practical skill as a means of preserving negative films from cracking. The negative was to be treated with a coating of india-rubber previous to varnishing with the ordinary spirit varnish. It was not unnatural to suppose that two valuable ends would be gained by this treatment: first, it would give a waterproof coating to the film, which would effectually protect it from moisture; and second, by interposing an elastic layer between the film and varnish, it would protect both from the effect of unequal contraction and expansion. This seemed probable in theory, and was said to be borne out by practice. Our present correspondent calls our attention, however, to a disastrous and unexpected result. A large number of negatives have been so treated, and in almost every one the film has cracked; whilst others, produced and kept under the same conditions, but treated with less care, inasmuch as the india-rubber was omitted, in every instance remained without injury.

Another difficulty was also experienced, in some cases, with the india-rubber coated negatives. The soft nature of the india-rubber layer, even after it was coated with the spirit varnish, was found to militate materially against the protection of the negative. Instead of the hard, glassy sur-

face which a good varnish should yield, permitting the negative to be submitted to any reasonable kind of treatment in printing, it was found that the triple film remained soft, and very easily scratched and abraded, so that almost as much care was necessary to prevent injury as if the negative were unprotected altogether.

These are important facts to be noted, and we shall be glad to learn the experience of others in the same direction. Mr. Woodbury has recently found that the perishable or changeable nature of india-rubber renders it a very undesirable adjunct in forming a layer to act as a support instead of glass for transferred negatives, and finds gum-arabic a more suitable material. Has any one found any disadvantage from the use of gum as a preliminary coating? We have no doubt that cases may be cited in which india-rubber has not disappointed its votaries. Single failures may be exceptional, and still a few such destroy certainty, and it is only by a careful and extended collation of cases, with precise conditions stated, that we can hope to arrive at certain and satisfactory conclusions.

### PARAFFINE IN ENCAUSTIC PASTES.

A CORRESPONDENT who has had some difficulty in procuring pure white wax—the sample he has obtained being considerably contaminated, apparently, with fatty matter—reminds us of our former suggestion that paraffine may be substituted for the wax, and asks if it can be employed in the formulæ given in our last.

We may say at once that paraffine, we fear, cannot be substituted for wax in these formulæ, or in the preparation of encaustic pastes generally, and that its value for application to photographs will be much more limited than we at one time—after some early experiments—hoped. Since we last called attention to it we have experimented pretty considerably with its various preparations, treating photographic prints with decreasing satisfaction, and a growing conviction that the end desired in applying it to photographs could only be obtained by the use of pure wax.

It is, in the first place, a difficult thing to make and keep an encaustic paste of paraffine, from its singular tendency to crystallize out of its solvents, whether the proportion added have been sufficient to form a paste or a solution. If a solution containing fifty grains (say) of paraffine in an ounce of benzole be prepared at a temperature of 70° Fah., it is probable that if the temperature fall to 60°, much of the paraffine will be found to have crystallized out of the solution. If a thick paste be prepared by shredding the paraffine fine, melting it, and then adding sufficient benzole to make the consistency required, it is probable that in a few days the solvent will be found to have partially separated, and the paraffine will show a tendency to crystallize. When this

paste is applied to the albuminized print—especially if the weather be cold—instead of assuming that soft, unctuous quality which characterizes wax, and which finally yields, on continued rubbing, a hard, polished surface, it behaves quite differently. When the solvent has evaporated, the paraffine begins to assume the form of dry scales, which rub off the print instead of adhering to its surface, so that it is difficult to obtain more than a very slight coating of the material on the surface of the print, and therefore impossible to secure the same depth and richness which can be obtained with a paste of which wax is the chief constituent.

Pure white wax can generally be obtained of retail chemists. It is supplied in round cakes at a few pence per ounce, and is in this form, as a rule, tolerably pure. Unfortunately, when contaminated with other fatty bodies, it is very difficult to separate the two, as most of the solvents of the one are also solvents of the other, and it is not less difficult, except to persons accustomed to chemical manipulations, to test the wax for fatty adulteration. Where difficulty in obtaining a pure sample exists, it may not be equally difficult to obtain honeycomb from which the honey has been removed. This, after well cleansing with boiling water, may be safely employed in preparing encaustic paste for photographs.

We may add here, for the information of those who have difficulty in procuring pure materials, that Mr. Newman, of Soho Square, is preparing encaustic paste made after M. Adam-Salomon's recipe, for commercial supply, and a sample of it forwarded to us answers admirably.

#### UNCERTAINTIES OF DRY PROCESSES.

ONE of the greatest boons which a trustworthy experimentalist can confer on the photographic community, or at least of the amateur portion of it, will be the accurate determination of the causes of uncertainty and discrepancy of results in the dry processes generally. It is of less importance to produce a rapid dry process than it is to produce a certain one. There are at least a dozen dry processes in existence with which those *au fait* at their practice produce charming pictures, but there is scarcely one in regard to which most contradictory experience is not described, and with which, instead of successes, a large number of experimentalists make woeful failures.

The discrepancy of result described does not occur simply in the hands of novices or bunglers, but often in the practice of men of approved ability. It is no uncommon thing to us, it is true, to receive communications from readers, who, having read the account, carefully stated by a practical man, write, saying: "I have tried the process most carefully, following the instructions precisely as they are given, and after exposure and development, do not find the ghost of an image." Sometimes we can trace such failures to some gross error, as when a correspondent trying a very rapid plate on a bright open subject, which should have required fifteen seconds, explains that he gave it eight minutes, and was surprised to find the film blacken all over immediately the developer was applied. At other times we can gain no clue to the source of failure, and having carefully gone through the operations ourselves and succeeded, we can only recommend the novice to overhaul his materials carefully, begin *de novo*, and try again and again until he succeeds.

But it is not to the uncertainties experienced by novices that we refer, but to those of practical and thoroughly trustworthy men. Take an illustration: some weeks ago we published an extract from a letter from Mr. Russell Manners Gordon, in which he stated that he found gum plates keep four months before, and six weeks after exposure, without the slightest deterioration, the plates developed six weeks after exposure being, if anything, finer than those developed on the same day. Almost contemporaneously we find M. Constant-Delessert, of Lausanne, writing to the effect, that having been, during the hot weather,

testing the relative keeping powers of coffee and gum plates, he finds the coffee plates keep well, but not the gum plates, the latter reddening all over in six or eight days. We have scarcely read these remarks before we meet with the experiences of Dr. Towler with coffee plates, which he prefers to any other, where the plates have to be used within a day or two; but adds that he would not have confidence enough in these or other dry plates of a month old in a case where success was of importance.

This is by no means an exceptional illustration of the discrepancy in experience to which we have referred in the hands of capable men. Mr. Gordon is, perhaps, the most extensive and skilful experimentalist of any we know. He has tried almost every dry process in existence, not in a merely desultory or casual manner, but comparatively with other processes, and under varying conditions, and has tabulated carefully all the results with the qualifying conditions. He is, moreover, a man of most fastidiously faultless taste, and to satisfy him a negative must possess all the technical perfectness upon which the capacity of pictorial excellence so much depends. In his judgment, which possesses the highest value, the gum process is the most perfect he knows for keeping, as well as for the excellence of its results. M. Constant is a gentleman well known to photographers as an ardent experimentalist, especially in dry processes, writing with evident knowledge and judgment, and, from the examples of his work which we have seen, we believe him to be a highly skilful as well as an enthusiastic amateur. He finds that gum plates give him more charming results than any other, but, instead of keeping months, they are spoiled in a week, whilst coffee plates keep. Dr. Towler, whose name has been known for years to photographers as that of a constant experimentalist and able writer on photography, and whose dry plate work we have often seen, likes coffee plates best, when kept only a day or two, but loses faith in them afterwards.

No such uncertainty as this prevails in the wet collodion process. Varying degrees of excellence are found in results, generally clearly traceable to varying degrees of care and ability, or differences in material facilities. Dr. Towler says, in terminating some remarks which we quote on another page: "Finally, I think I can get a good negative with almost any of the dry plates in vogue, and I start for Niagara Falls, in a few days, to work with the wet process!"

In what, then, consists the elements of uncertainty in dry processes? We cannot tell. There is but one dry process in which we ever heard of any approximation to general certainty—indeed, in relation to which we do not remember to have heard of any case of absolute failure—and that is the collodio-albumen process. It does not, indeed, possess nearly the rapidity, except pushed with hot developers, of some other processes; nor is it so rapid or simple in manipulation; nor, without the final wash of gallic acid, will the plates keep indefinitely. But it does seem tolerably certain. Few, if any, fail with it. Mr. Mudd has more confidence in a collodio-albumen plate than a wet plate. Mr. England, with his process, which is but a simplified collodio-albumen process, produced last summer three hundred negatives, never once unpacking his wet plate appliances, which he carried with him as a *dernier ressort*. An achievement like this is a tolerably close approximation to certainty; but we wait to see it repeated in other hands.

We conclude by repeating our first remark, that one of the greatest boons which can be conferred upon photographic amateurs will be a knowledge of the causes of uncertainty in dry processes. To determine this absolutely a more perfect understanding of their theory than has yet been attained will be necessary. This part of the subject we do not propose to treat here, but shall probably have something to say on it shortly. We have, however, one or two hints to offer on the question of practice. As in the dry processes the operations are more numerous, whilst the conditions of success appear to be comprised within narrower limits, cleanliness and neatness in manipulation, and pre-

cision in carrying out prescribed formulae, become more absolutely imperative than in the wet process, which permits some licence, both in manipulation and formula, without risk of failure. Next as to keeping properties. In our observation the keeping properties of plates are quite as much affected by the mode of keeping as the mode of preparing them. The boxes should be quite dry, and absolutely air-tight. The latter condition may be secured by placing gold-beaters' skin over the joint formed by the lid of the box. Damp and foul air will prove fatal to the keeping of the best plates, prepared by any process.

### IS PHOTOGRAPHIC APPARATUS "PERSONAL LUGGAGE"?

A QUESTION of some importance to photographers, both professional and amateur, is at the present moment *sub judice*. Is photographic apparatus "personal luggage"? That is, can a photographer pack up his apparatus in a box for transit during a tour, short or long, and require that it shall be conveyed by the trains by which he may travel under the same conditions as the portmanteau containing his wardrobe? At the first glance it would appear so perfectly a matter of course that he should do so, providing that it did not exceed the proper weight, or require an especial treatment during carriage, that one would not dream of asking the question. The question has been raised, however, by a company declaring that photographic apparatus conveyed under such circumstances was not "personal luggage," and not, therefore, subject to the conditions obtaining in regard to personal luggage. The following are the facts as stated by a correspondent:—

"Mr. Owen Angel, the well-known photographer, of Exeter, lately brought an action against the South Devon Railway Company for the recovery of £2 14s. 9d., the claim arising under the following circumstances. He was engaged to go to Bovey, to do some work for a gentleman residing at that place. He left Exeter by the morning train, and took with him a box containing his photographic apparatus, which was duly placed in the luggage van. On arriving at Newton, where a change of carriages takes place, it was discovered that the box was missing, having been taken out by the Company's servants at Teignmouth in mistake for Bovey. In consequence of this the photographer had to return to Exeter. On the following day he posted to Bovey, and he now claimed the sum named for travelling expenses and loss of time. The Company disputed their liability, on the ground that 'photographic apparatus' was not 'personal luggage.' His Honour the Judge said he would take time to consider, and give his judgment at the next meeting of the Court."

The question must of course be decided by law, and should the decision of the Judge in the County Court be in favour of the dictum of the Company, we hope a case will arise in which the decision of a higher Court may be obtained. We are assuming for a moment, however, as a possibility, a decision which is scarcely probable. Presuming that no definition of personal luggage is found in any of the railway statutes in existence, or in the Standing Orders, or By-laws, the decision must be left to precedent and common sense. The latter certainly suggests that, provided a box does not exceed the proper weight allowed to the passenger, nor require facilities for conveyance other than are common to luggage, it cannot possibly concern the Company what that box contains. It cannot possibly concern the railway authorities whether it contain a black calico tent in which the photographer chooses to enshroud himself, or a black domino as his costume for a masquerade. It cannot be a matter of interest to them whether the box contains a camera or dressing case, if both are within the proper weight. We believe that precedents already exist in which a similar estimate of the case is taken. We are assuming, of course, that no qualifying circumstances beyond those stated exist

in this instance. If so, little doubt can be entertained as to the issue; nevertheless, photographers will look with some interest for the decision.

### Critical Notices.

"RETURNING HOME." A PICTORIAL COMPOSITION, Photographed from Nature by H. P. ROBINSON.

As Thomson is the poet of the seasons, so may Mr. Robinson be regarded as their photographer. He is evidently a lover of nature: a keen observer of her varied phases, and a lover of English rural life and its varied episodes. We have had from his camera "Early Spring," and "Autumn," and "May Gatherers," and "Gleaners," and many other pictorial photographs of similar subjects. Whilst others have discussed the art powers of photography, he has demonstrated that power by producing pictures, the true art and beauty of which have won the recognition and praise of the most cultivated artists and art critics.

In his last attempt to demonstrate the capacity of photography as a fit vehicle for art expression—a composition twenty-four inches by seventeen inches in size, produced from five negatives—we have another autumnal aspect of nature. "Returning Home" represents a scene and incident common enough during autumnal months, and very beautiful in effect, but almost as difficult to render by photography as they are beautiful: A broad stretch of champagne country, not absolutely flat, but with sufficient undulations to give a picturesque character without interrupting the range of vision over many miles, until the plain meets the sky. The foreground is rich with clumps of underwood: the bramble teeming with wealth of rich blackberries; the twisted wild briar red with hips instead of roses; furze, and bracken, and grasses, all give a most inviting charm to the near landscape. The middle distance is in part the same, and part more perfectly wooded; the tender far distance appears to be of the same character, but there is no effect of tameness or monotony.

The time is manifestly towards evening, and there seems to be a dewy, moist feeling in the atmosphere and on the landscape, as when—

"The western sun withdraws the shortened day,  
And humid evening, gliding o'er the sky  
In her chill progress, to the ground condensed  
The vapour throws."

But the sun is not yet withdrawn; two-thirds of the picture are bright with sunlight which glints on rock, and stone, and leaf, each sparkling as they catch the direct ray; light, bright, feathery wreaths of cloud spreading the light in this portion of the picture, and producing a rare sunniness. The other portion of the picture, sky and landscape, are wrapt in gloom. A sudden squall has arisen, obscuring the heaven and overshadowing the earth:

"a burst of rain,  
Swept from the black horizon, broad descends  
In one continuous flood."

The flood of rain descends like a broad grey wall, a strange contrast with the sunny sky it is rapidly sweeping over, shutting out its brightness and dimming the horizon. Hastening from the rain, though scarcely likely to escape it entirely, is the one figure in the landscape, a rustic lass with a sheaf of "gleanings" under her arm, her head and eyes half turned round towards the dark shower which seems rushing on as if resolved to overtake her. This figure gives the name to the picture; she is "Returning Home" from the wheat field.

The scene, as we have said, is one somewhat difficult to render. It is closely studied from nature, or rather it is nature absolutely produced from the actual phases represented. But it is no easy task to render by photography, in one picture a sunlit landscape with only delicate, light cloud

shadows flitting over one portion, and the grey gloom of a rain-squall overshadowing another. Few photographers would have dared to attempt such a scene, still fewer would have so far succeeded. In many respects this is one of Mr. Robinson's most successful pictures; it is wonderfully full of tone and harmony; wonderfully full of light and atmosphere; and it possesses a singular technical perfectness as a photograph. The figure is admirably placed, and is full of "go," and the landscape is charming, both in detail and as a composition.

The open Kent scenery is essentially different from the heavily-wooded character of the Warwickshire, which has furnished the scenes from which Mr. Robinson's pictures have hitherto been elaborated. With fresh scenes often comes fresh zest, and we hope for many more similar photographic triumphs in the field of pictorial art from Mr. Robinson's hands.

#### CARBOLIC ACID IN THE SILVER BATH.

THE use of carbohc acid in the silver bath, suggested some time ago by Dr. Kaiser, has not received the attention which it will probably be found to deserve. Mr. Voyle, a correspondent of our Philadelphia contemporary, describes the beneficial results of some experiments of a purely empirical character, but no one seems to have examined the subject with a special regard to the known peculiar reactions of carbohc acid. One of the common sources of trouble to the photographer is the tendency in old baths to fog, caused by the decomposition, or of the alcohol and other organic substances which accumulate in his bath giving rise to aldehyde or bodies of similar constitution, from the presence of which fog must inevitably follow. Carbohc acid has the especial peculiarity of arresting decomposition and fermentation, and it is reasonable to believe that in the nitrate bath it would prevent the fermentation change which alcohol undergoes in the bath, and so check the troubles which follow.

In preventing the decomposition of albumen, this substance should be invaluable to preparers of paper, and to dry-plate men its use in preventing fermentation in preservative preparations should not be overlooked. We have already pointed out its value in preventing putrefaction or fermentation in adhesive materials, such as gum, paste, glue, &c.

Mr. Voyle says that by adding a trace to his negative bath he gains the following advantages:—

"Increased sensitiveness.

"Less liability to change or go out of order, allowing the bath to be kept nearer neutral, mine being but slightly acid.

"A developer can be used with less acid; often with none.

"I have repeatedly developed pictures with no acid in the developer (simple iron and water). They come up just as with the acid developer. There was no tendency to crawl. But sometimes this result was not obtained; why, I have not yet discovered. One thing, however, I have noticed: the bath solution must flow evenly over the plate before it is removed and exposed.

"The colour of the bath is pink, deepening into red. I do not attribute the colour to silver in a reduced state, for it will not settle or filter out. I am inclined to the belief that it is of the nature of the aniline colours. I can, as yet, neither precipitate, change, or destroy it. Sometimes it becomes slightly turbid. It is cleared by shaking with kaolin, and subsequent filtering.

"My reason for first trying it was its action when combined with iodine for medical purposes. Supposing it might have some action on iodides I tried it first in collodion; the bath became so much discoloured that I abandoned it, notwithstanding its evident advantages. Each plate added more acid to the bath. A constant quantity in the bath proving itself to be of the same benefit, I used it thus, and am still using it."

#### VISITS TO NOTEWORTHY STUDIOS.

##### M. REUTLINGER'S STUDIO IN PARIS.

DURING the last three or four years English photographers have become familiar with certain card portraits—of actresses, chiefly—published in Paris and sold in this country, possessing specific qualities which have won general admiration. For the most part they consisted of a large head and bust vignettcd. The arrangement of a head and bust for vignetting is not supposed generally to give much scope for skilful and artistic posing; but in these pictures the turn of the head and the point of view selected were always graceful and striking. The lighting of the pictures was always admirable, and they possessed a degree of relief and modelling seldom attained. Notably a three-quarter face, or rather, five-eighths, of Adelina Patti, possessed these qualities in rare perfection, and excited universal admiration. English photographers became familiar through these pictures with the name of M. Reutlinger as that of an art photographer of unusual skill and capacity.

M. Reutlinger's studio is situated in one of the most frequented thoroughfares of Paris, the Boulevard Montmartre. Ascending many flights of steps to reach the top of a very lofty building, we find the reception-room and studio, both on one floor, and both somewhat smaller in size than is quite convenient for the transaction of a large amount of business in portraiture. At the time of our visit we find the *salon* crowded, and the prominent feature of interest in the shape of specimens are cabinet portraits, which are displayed in profusion. Here, as in his cards, we find fine taste in posing, admirable lighting, and great delicacy, richness, and vigour. The photography was, in short, excellent, and in most respects the artistic qualities were very fine; there was but one drawback in our estimation, and that consisted in the use, in some cases, of scenic backgrounds in which painted columns, painted vases, and painted curtains were found in odd and incongruous juxtaposition. It is true that the objects were not sharply pronounced, the whole of the background being kept tolerably quiet and unobtrusive. When we first examined these backgrounds we consoled ourselves with the notion that want of skill and taste in the production of such things was not confined to England. In the course of conversation with M. Reutlinger subsequently we were disillusionized in this respect, as we learnt that the backgrounds in question had been received from London! In the later examples of his work which we have seen they have been abandoned. Recently in cabinets, as formerly in card portraits, M. Reutlinger has devoted himself considerably to the production of vignette heads, a style in which he is very successful in securing singularly fine modelling and relief, and great brilliancy and vigour without sacrifice of delicacy.

On introducing ourselves to M. Reutlinger, we meet with a very kindly and cordial reception. After a few minutes' conversation, the demands upon him by sitters compel him to leave us, with a request that we will occupy ourselves for a few minutes with the specimens, and he will then show us his studio.

M. Reutlinger is a German by birth, and has not been many years, we believe, in Paris; but he has rapidly made his mark there. Of a bright, active, genial temperament, he is quick, impulsive, and courteous in manner, rapidly going through all his work. He poses and arranges every sitter himself, and seems, moreover, to keep an eye upon all other departments. Now he is for a moment in the reception-room answering a question; then in the dark-room examining a negative—filling up the brief intervals between one sitter leaving the atelier and another being ready to sit; but never neglecting the principal occupation of attending to the sitter. A clever photographer and skilled artist, M. Reutlinger is also, we conceive, a prompt, active man of business, a circumstance of no light importance where large transactions in publishing portraits are carried on.

We now enter the studio, which is of the pent-house or

lean-to fawn, lighted from the north side only. The room is about thirty feet long, and less than twelve feet wide. The roof, like that of Adam-Salomon's studio, is of ground glass, the side light, which is eight feet high, descending to within two feet of the floor. Three feet and a half of the lower portion of the side light are of ground or stippled glass, and four feet and a half of the upper portion clear glass. This is the only clear glass in the studio, and when we were present only a space of ten feet laterally of this was uncovered by curtains. The lower portion of the side-light being partially obscured was a matter of necessity rather than choice, the intense reflection of sunlight from windows at the opposite side of the street entering the studio and proving troublesome until a portion of the side-light was obscured. Although the studio is lighted from one side only, no reflecting screens are used, the expanse of soft top-light through ground glass sufficiently relieving the shaded side of the face from blackness.

Whilst we are looking on, M. Reutlinger proceeds to pose and arrange a group of two persons, for which, by the way, his studio is not so well suited as for single figures. The group consists of a tall English gentleman and a lady, and the task is not an easy one. The gentleman is a little angular and stiff, as well as tall, and he has bright-red hair and whiskers. He manifests evident distaste to the application of powder to his whiskers, which M. Reutlinger feels it necessary to make. The lady being petite and the gentleman tall, of course the latter desires to stand and allow the lady to sit, and he is with difficulty persuaded to seat himself and allow the lady to lean upon his shoulder. M. Reutlinger perseveres, however, with good-humoured tact, and succeeds in getting a tolerably easy pose. His perceptions are quick, and all his actions rapid and lively, and pervaded by a pleasant, cheery manner. He manifestly feels the necessity of getting through his work, as there are several sitters waiting; but this induces no slovenliness or lack of fastidious care. Two card negatives of the group having been obtained, one of which is pronounced satisfactory, a gentleman next sits for a cabinet, and two good negatives are rapidly secured. M. Reutlinger, who has maintained a lively conversation at intervals between each exposure, now requests us to sit for a card vignette. The arrangement is rapidly made, and four exposures in succession are made on one plate. The negative does not quite satisfy M. Reutlinger, but we decline to trespass longer upon his time on that occasion. His chemicals are not working quite satisfactorily, a tendency to pinholes and hardness being present, which occasions some anxious communications between M. Reutlinger and the assistant operator in a very small dark-room opening out of the studio. We note that the exposures seem long—we sat thirty-five minutes. M. Reutlinger remarks that the chemicals are not in the best order; that with the very excellent lens he was then working—the No. 2 B of an English maker—his exposures were generally rapid; but that he, as well as photographers generally in Paris, usually gave fuller exposures than English portraitists seemed to think necessary.

M. Reutlinger believes it to be the duty of the portraitist to make the best of his work, and he generally works upon the negative, sometimes slightly, sometimes to a great extent. All the negatives we saw were more or less retouched, a lead-pencil having been used, deep shadows being softened, wrinkles modified, &c. The negative was treated with a solution of gum whilst wet, and the surface so obtained affords an excellent "tooth" to the pencil when dry, and renders effective retouching readily possible. After retouching the negative is varnished.

The work chiefly in hand whilst we were present consisted chiefly of cabinet portraits; but amongst the specimens in the reception-room were many exceedingly fine large portraits, some of which were apparently from negatives elaborately stippled, the delicacy, modelling, and rich chiaroscuro of which were very effective indeed. White draperies were common amongst the specimens, and always

managed with great skill; no chalkiness, no masses of white without detail and texture, ever being present.

In the cabinets a variety of scenic backgrounds were used, half-a-dozen different kinds being at hand in his studio, and readily changed for use. The examples of English scenic background were, as we have said, the least satisfactory things in his establishment, and have since, we believe, been discarded.

M. Reutlinger, besides a large practice in private portraiture, publishes largely, and was one of the first to see the advantages of the cabinet picture, which he has done much to popularize. He is, we believe, very successful, and well deserves his success.

### PHOTOGRAPHIC OBSERVATION OF THE ECLIPSE.

Our readers are aware that amongst other expeditions for observing the late total eclipse, and obtaining photographs from favourable positions, one was sent out by the Prussian Government—or rather that of the North German States—to Aden, of which the photographic arrangements were under the charge of our friend Dr. Vogel. His letter describing the operations will be read with much interest.

*On Board the Steamer "Carnatic," in the Red Sea, 20 deg. N. lat.  
23rd August, 1868.*

MY DEAR SIR,—I am now enabled to give you an account of the results of our expedition. Our voyage proceeded without any danger, and the weather being extraordinarily favourable, we had a calm sea; but nevertheless, we were not spared the sufferings generally imposed on the traveller who passes through the Red Sea at that hot time of the year. This sea, enclosed on both sides by deserts, and connected with the Indian Ocean only by a very narrow channel, forms an isolated bay, where, in consequence of the customary calms and want of currents in the water, the temperature increases in the same degree as you advance towards the south. The perspiration flows down your body just as if you were in a steam bath; the whole of the skin is heated and irritated, and happy is he who finds a spot on deck where a slight breeze cools him for a moment. We were glad to reach the more airy ocean, and anchor near Aden on the 2nd of August.

The aspect of this town is not in the least an agreeable one. You see a quite bare, savage mass of rocks, interrupted by some works of fortification, warehouses, shops, and coal sheds. This was the exterior of the town, where we were obliged to stay for about a fortnight. There was not a bit of green colour in the whole nature. Amongst the screaming and roaring Arabian crowd, our baggage and we ourselves were put on shore. Here we learnt that the English Government had received our friends who had arrived before us in a most obliging manner. We were shown to their station on the east side of the peninsula, where they occupied two Indian huts, called "pungaloes," which are general in that climate. There we found them, together with the members of the Austrian expedition (Messrs. Oppalzer, Riha, and Dr. Weiss), established with as much comfort as may be expected on that bare shore. The English Government proved a very generous host. A whole attendance, cook, &c., waited upon us; ears, camels, and asses were placed at our service. We were quite at ease. The temperature (26° F.) was low in comparison to that of the Red Sea. A fresh breeze was to be felt at the summit of Marshag-hill, where our pungalo was situated.

In the above-named members of the Austrian Expedition I found three gentlemen of the most amiable character, and of great scientific knowledge. One of them, Dr. Weiss, is the first who called the attention of scientific Europe to the great importance of this eclipse of the sun, and has therefore induced the governments to despatch expeditions.

The heat was supportable as long as we were not at work; but as soon as we began the slightest exertions, the discomfort was very great.

We had still ten days for our preparations for taking the eclipse. They were spent by fixing our photographic telescopes, placing them, and taking exact informations. Our observatory was a pungalo, the roof of which had been partly removed in order to give way to the telescope. The remainder of the cottage served for studio, store, and cleansing-room.

This bird-cage of reed (for nothing else it was) afforded sufficient protection from the wind, but not from the dust. Water was carried up to us in leather bags. Two tents, which we had carried along from Europe, were employed as dark rooms. Some apparatus for landscape and portraits served for taking some landscape and anthropological views, and offered at the same time an apt means for trying our chemicals. Some slight faults of the latter were soon mended, but it was difficult to protect them from the influence of dust and evaporation. The least exertion drew forth perspiration in currents; it was flowing down from the fingers and faces, and it often happened that a newly-polished and prepared plate was spoiled by a drop falling down upon it. Experience, however, taught us how to avoid even this.

We tried successfully to take some views of the sun, and could expect the day of the eclipse without fear. Only one thing was not quite sure—the weather. All accounts about Aden had induced us to expect a serene sky; we had been told that rain very seldom fell, and that clouds scarcely ever appeared. We were therefore utterly disappointed when, on our arrival, the summits of the volcanic rocks were covered with clouds, and a shower of rain fell down the next morning. Our disappointment increased when, day after day, the sunrise was concealed by clouds, and the weather became worse and worse instead of better. Our prospects were bad enough, and soon all hope vanished.

At the day of the eclipse we rose at four o'clock in the morning. Nine-tenths of the sky were clouded, and resignedly we began our work. It was the task of the North German expedition to take a photographic view of the eclipse during its totality. For this purpose we had a long telescope with a lens of six inches, without difference of focus, and with a focal distance of six feet. This lens, constructed by Steinheil, afforded a solar image of three-quarters of an inch in diameter, which was taken upon a photographic plate by means of an ordinary sliding chest for two images. As sun and moon appear to be in motion, such an instrument would naturally afford images of no sufficient sharpness if it were motionless. Therefore the telescope was moved by a rackwork exactly in the same measure as the stars. In order to avoid shaking the telescope, the trap-door of the objective was not in immediate connection with the telescope, but supported by a separate foot, and communicated with the telescope through an elastic coupling hose.

The totality of the eclipse at Aden was about three minutes long (in India five minutes); nevertheless, we had chosen Aden for our station because there were already photographic observers in India, and because the totality appeared at Aden about an hour earlier than in India. Therefore a comparison of the different results would enable us to decide the question, if the protuberances appearing at a total eclipse of the sun were changing in the course of time or not.

Our task was now to get within these three minutes as many views of the phenomenon as possible. For this purpose we had exercised ourselves in the employment of the photographic telescope, like artillerymen with their guns.

Dr. Fritsche prepared the plates in the first tent, Dr. Zenker put the sliding chests into the telescope, Dr. Thiel exposed, and I myself developed in the second tent.

We stated that it was possible in this way to get six images (three plates of two images) during three minutes.

When the decisive moment was fast advancing, the sky, hitherto covered with clouds, showed some openings, through which the sun, already covered partially by the moon, was to be seen. The landscape around was illuminated by the strangest light, a medium between moon and sunlight.

The chemical strength of light was exceedingly weak. A proof plate gave a wholly exposed image of the cloud after fifteen seconds. The sun crescent became smaller and smaller, and the opening in the clouds seemed to increase.

The last minutes before the totality (which began at twenty minutes past six o'clock) went rapidly away. Dr. Fritsche and myself crept into the tents, where we remained, consequently we have seen nothing of the totality. Our work began; we exposed the first plate five and ten seconds, in order to know what was the just time.

Muhammed, our black servant, brought the first attempt into my tent. I poured the iron developer over the plate, eager to know what was to come. At this moment my light was extinguished. I called for light, but nobody heard me, as all were about their task. I stretched my right hand out of the tent, holding the chest in the left, and happily caught a small

oil lamp, which I had previously prepared at all events. And now I saw the image of the sun appearing on the plate. The dark margin of the sun was surrounded by a series of peculiar elevations, the other side showed a strange hook; the phenomenon being exactly the same in both views. My joy was great, but there was no time for enjoyment. I soon received the second, and, after another minute, the third plate. "The sun is coming forth!" exclaimed Dr. Zenker. The totality was over. All this seemed to have been done in a moment.

When I developed the second plate I perceived only very weak traces of an image. The clouds had veiled the sun at the very moment of the exposure. The third plate gave two brilliant views, with protuberances at the lower margin. Glad to have reached so much, we washed, fixed, and varnished the plates, and immediately took some copies on glass, which were to be despatched to Europe separately.

I here give you a design of the plate; a more exact drawing will be published afterwards. Over the margin of the sun we see the protuberances (*a b*); on the opposite side we perceive

the strange hook already mentioned. Its height was about one-fourteenth of the sun's diameter, and it would therefore in reality be 12,000 miles high. On the third plate we got the protuberances (*d e*) at the lower margin. After some time a more special description of the views, a comparison with those of the French and English expedition, and the results drawn from them, will be published.

How much we were favoured by fortune in our work is to be seen in the circumstance that at another point, situated at a distance of half a hour from our station, there was nothing to be seen of the total eclipse, the clouds hiding the sun during the eclipse.

Having thus performed our chief task, we had no cause for longer staying at Aden. Therefore we packed the telescope, watch, and other innumerable instruments and chemicals, loaded them on camels, and got them transported to the port. On the 21st of August we bade farewell to the bare shore, and set off for Suez.

I close my account with some photographic experiences which I made at Aden, in regard to the rapid evaporation of the ether, and the difficulty of managing etherial collodions in a high temperature, in further regard to their easily decomposing. In connection with iodides, I had prepared a collodion containing only cadmium salts, by dissolving—

Maun's gun-cotton	...	...	...	2 parts
Alcohol	...	...	...	80 "
Ether	...	...	...	20 "

After three weeks' settling, the bulk was decanted, and immediately combined with the iodides, consisting of—

(a) Iodide of cadmium	...	...	...	18 parts
Alcohol	...	...	...	270 "
(b) Bromide of cadmium	...	...	...	17 "
Alcohol	...	...	...	270 "

Two measured parts of the first solution were mixed with 1 part of the second solution and 9 parts of plain collodion. A plate prepared with this collodion immediately after settling showed streaks and a weak veil. A collodion prepared at the same time, and containing more ether—according to my ordinary formula—gave plates without any fault. Therefore I added 2 ounces of ether to the collodion. It was so rapidly absorbed, that in consequence of the absorption of the very vapours of the ether there was a vacuum after shaking the bottle. The additional ether gave very fine results, since after twenty-four hours we got plates without any streak or veil.

The bottles containing the collodion were luted by a mixture of sulphur and brick powder; a cement which prevents etherial fluid from evaporation in high temperature. There was, how-

ever, the drawback that some portion got into the bottles when they were opened, and that, in consequence of this, new decanting was necessary.

The English collodion brought to Aden by Dr. Fritsch was closed by india-rubber, which proved to be much better. They contained excessively more ether, and soon became yellow, and gave streaks very readily, and, what was worse still, dry spots.

The above-mentioned collodion proved to be free from any of these drawbacks. I developed some plates a whole quarter of an hour after exposure, and, in spite of the high temperature, I received faultless images free from dry spots. Even after weeks, the collodion was colourless. The opinion that collodions with cadmium salts give dry spots seems therefore, to be erroneous. The chief cause of that phenomenon is perhaps to be found in the amount of ether and in the quality of the gu-cotton. The above-mentioned collodion was not only employed for our astronomical views, but also for landscapes and portraits, and always proved equally good. In order to prevent the collodion from being spoiled by the dust, the collodion flowing from the plates was received into sundry bottles.

The silver bath employed was an 8 per cent. solution, containing some nitric acid.

The developer consisted of—

Sulphate of iron and ammonia...	...	7 parts
Acetic acid	...	5 "
Plain water	...	100 "

The intensifying bath contained—

Nitrate of silver	...	2 parts
Citric acid	...	3 "
Water	...	50 "

which, when used, were mixed with some parts of the above developer.

In the torrid zone we are obliged to employ an acid silver bath, an acid developer, and an acid intensifying bath, if we want to get good results.

I will shortly send you the account of some other experiences.—Yours,  
HERMANN VOGEL.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XXXIV.

The arrangement of a family group is certainly one of the most difficult things to succeed well in accomplishing perfectly in photography, more difficult even than the composition of a picture that would take a much higher rank in art, but of which the materials were more under the command of the artist as regards selection and disposition. In a portrait group every face must be prominent, no figure must be sacrificed for the sake of pictorial effect, and, therefore, there can be little or no subordination, one of the chief elements of success in art. This difficulty is felt by painters who can devote time and particular attention to each figure, and who, moreover, can place his figures on different planes; but the photographer has still less opportunity of taking artistic liberties with this kind of subject, and it is only by double-printing that he can hope, in some

measure, to succeed; even then he has difficulties to contend with that will often cause him to despair of success.

West's groups of portraits of his own family, which affords this week's illustration, is a capital example of a family group. This was a favourite picture with Leslie, who says of it: "We undervalue that which costs us least effort, and

West, while engaged on a small picture of his own family, little thought how much it would surpass in interest many of his more ambitious works. Its subject is the first visit of his father and elder brother to his young wife, after the birth of her second child. They are Quakers, and the venerable old man and his eldest son wear their hats, according to the

custom of their sect. Nothing can be more beautifully conceived than the mother bending over the babe sleeping in her lap. She is wrapped in a white dressing gown, and her other son, a boy six years old, is leaning on the arm of her chair. West stands behind his father, with his palette and brushes in his hand, and the silence that reigns over the whole is that of religious meditation, which will probably end, according to the Quaker custom, in a prayer from the patriarch of the family. The picture is a very small one, the engraving from it being of the same size. It has no excellence of colour, but the masses of light and shadow are impressive and simple, and I know not a more original illustration of the often-painted subject, the ages of man. Infancy, childhood, youth, middle life, and extreme age are beautifully brought together in the quiet chamber of the painter's wife. Had he been employed to paint these five ages he would have given himself a great deal of trouble to produce a work that would have been classical, but, compared with this, common-place; while he has succeeded in making a picture which, being intended only for himself, is for that reason a picture for the whole world; and if painters could always thus put their hearts into their work, how much would the general interest of the art be increased!"

The student will by this time be able to analyse for himself the composition of this picture; I only introduce it to show what beautiful results arise from extreme simplicity of treatment. The object of the visit is the new-born child. Notice how everything is made to lead the eye to the "little stranger," especially the chiaroscuro. Observe, also, the very simple yet effective background, and the manner in which it is used to relieve the groups, the dark portion supporting the light mass formed by the mother and child, and the light, even-tinted wall throwing out the darker forms of the men. The black shoes of the grandfather and uncle play no inconsiderable part in the composition, and help to join the two groups and emphasise the whole.

Good as this picture is as an example of grouping, I would not advise the photographer to try to imitate it exactly in any group he may have to photograph, but he may allow it to guide him in the composition of a similar group. I have repeatedly insisted, and I again recommend, that the student should not attempt to imitate the works of others until he has thoroughly grounded himself in the principles of art, and knows the causes of the beauties of line and tone in good works, and these I would not have him imitate servilely. To one who has mastered the grammar of his art, and is able to originate fine thoughts, suggestions from the works of others are often useful. A notable instance of this I had the pleasure of seeing lately. When M. Adam-Salomon visited England a few weeks ago he brought with him one of the most delightful things I have seen by him: a noble boy, partly reclining on a chair, with his head supported on his hand, and with the face turned upwards. This charming portrait, of which words cannot give an idea, the artist informed me was suggested by a print after Sir Thomas Lawrence's "Master Lambton;" but although the idea was suggested by the engraving, the working out was very different, and the beauty of the photograph was the result of M. Salomon's knowledge of art and his skill in adaptation, and did not consist in the fact that he had taken this picture for imitation. In the hands of one who had no acquaintance with the rules of composition and chiaroscuro the attempt must have ended in failure as great as the abortive results of those photographers who collect a set of poses prepared for them by persons as ignorant as themselves, and fit their sitters to their haphazard.

#### DR. TOWLER ON THE COFFEE PROCESS.

SOME months ago Dr. Towler published the results of some interesting experiments with dry plates developed with the nitro-gelatine developer. As the results were less favourable with the coffee plates tried than Col. Baratti, the inventor of

the process, believed would have been produced by the process as first proposed, he protested against the experiments as examples of the results of his process. Mr. Jex Bardwell, an American photographer, also offered a similar protest, and as extracts from the remarks of both gentlemen were published in our pages, we now give the response of Dr. Towler, and the record of some further valuable experiments, which he publishes in our *Philadelphia* contemporary. Dr. Towler says:—

"The experiments that I made last winter in Albany, on dry plates, were executed with care, in order, as I said, to ascertain the comparative merits of three well-known dry plates, when treated with an iron developer. Now, the authors of the three processes had recommended an iron developer, and I, therefore, took no liberty with either process, excepting to substitute my favorite nitro-gelatine iron developer for any other that might have been recommended. Mr. Bardwell looks upon pyrogallie acid as the proper developer for a dry plate. This point I will not contest here, because it is irrelevant to the question; but I do not see how he can complain of me for making the experiments, and stating explicitly why I made them. The results were certainly those which I recorded. I wish Mr. Bardwell and others would make similar and more extensive comparative experiments on different dry plates, with the developer peculiar to the process, as well as with the same developer, for each process, both in winter and summer, but especially in winter, when the temperature is too cold to admit any operations with the wet process."

After some further remarks Dr. Towler proceeds:—

"I feel inclined to prefer the coffee process, when the plates are to be used within a day or two, to any other dry process; and this preference is founded on the simplicity of the process; but Col. Baratti says 'his process is much more complex.' The Colonel objects to my formula, because it is not the same as his. After all, the difference is very slight. It is my habit to transcribe all foreign formulæ into American weights and measures, because our practical photographers have no acquaintance with grammes, litres, &c.

"My transcribed formula is as follows:

Water	...	...	...	8 ounces, or 64 drachms
Coffee, roasted and ground	...	...	...	6 "
Leaf sugar	...	...	...	3 "

Now multiply each of these numbers by five, which will not change the ratio, and we have—

Water	...	...	...	320 drachms
Coffee, &c.	...	...	...	30 "
Sugar, &c....	...	...	...	15 "

But Colonel Baratti's formula is—

Water	...	...	...	300 grammes
Ground coffee	...	...	...	30 "
Refined sugar	...	...	...	15 "

Thus the difference is very slight; that is, I use one fifteenth part more water than he does. But the Colonel wants to know why I boil the mixture.

"I boil the mixture in order to get a better decoction of coffee; and, by boiling, the extra twenty parts of water are evaporated, and then the two formulæ coincide. But the two solutions, I admit, are different: my decoction is more consistent than the Colonel's infusion, and it remains to be proved whether it is better or worse than his for practical purposes. We take it for granted, there can be no objection to the use of loaf sugar, for this is refined sugar.

"The Colonel totally misunderstands my meaning when he supposes that, by moisture retained in the film, I mean dampness condensed on the plate. The plates I used were smooth and highly polished; they were thoroughly dried according to the common acceptance of the term, and there was no visible dampness on the film.

"The developer, it is admitted, is quite different.

"There was no alternative but to test the matter, in order to see whether I had so egregiously erred by making the above changes.

"I mixed the coffee solution and developers according to the two formulæ, and went to work and prepared plates *secundum artem*. When exposed, I cut each plate in two, and developed one-half with the nitro-gelatine developer, and the other with

the Colonel's developer. There is quite a difference of colour between the two sets of negatives; with the nitro-gelatine the colour is grey-black, with the other it resembles that of a tannin plate developed with aceto-pyrogallie acid. The former develops more intensely than the latter, but, upon the whole, I should prefer the Colonel's developer; its action is exceedingly smooth and uniform, whilst that of the former is slightly granular, a condition not occurring on wet plates with the same developer. The negatives prepared with the decoction of coffee are in all cases more vigorous than those prepared with the infusion, so that I have no hesitation in recommending the coffee to be boiled.

"I next compared results with aceto-pyrogallie acid and the Colonel's developer. These are so similar in every respect that it becomes impossible to desery any difference; therefore, since the results are the same, I certainly give preference to the iron developer.

"Finally, I compared result with a sulpho-gelatine iron developer and the nitro-gelatine, and found the granulation absent in the former. The negatives are grey-black in colour with the sulpho-gelatine, and the film is smooth and uniform in the development.

"All the plates used in these experiments were previously coated with a thin film of albumen; I tried some without a substratum, and invariably had trouble in retaining the film on the glass during development and fixing, and they were all dried spontaneously at a temperature of about ninety degrees Fahrenheit. It is possible that artificial drying may be beneficial, and, as the Colonel states, a *sine quâ non*. I will test this point, and give my experience.

"Finally, I think I can get a good negative with almost any of the dry plates in vogue, and I start for Niagara Falls in a few days, to work with the wet process.

"Since writing the above, I thought I would try a few plates that were prepared thirteen months ago—collodio-albumen plates. I exposed the first plate two minutes, and developed with the sulpho-gelatine developer (iron). After much coaxing and patience, I obtained an intense negative. This is a proof that the collodio-albumen plates retain sensitiveness for at least thirteen months; probably, in winter, I might have had to expose the same plate half an hour or more, to produce the same result. I exposed two more similar plates, each three minutes, and got no pictures, for the film fogged all over, and gave but a faint outline of the view in the general fog. It may be that I exposed too long, or got too much nitrate of silver in the developer, omitted something, or did something too much. Uncertainty is fatal to the dry process; the practical photographer cannot afford the slightest probability or chance of uncertainty; he must see the picture before he leaves the ground, or, at least, the neighbourhood.

## SOLAR PRINTING BY DEVELOPMENT.

THE Editor of the *Philadelphia Photographer* describes a recent visit to the establishment of Mr. A. Marshall, of Boston, to witness his operations in producing solar prints by development, which was done at the rate of about six per hour. Mr. Marshall, he states, contrives, on a clear day, to print his solar prints in the morning, having a lad to assist him, before his studio becomes thronged with visitors. The following is the formula:—

Take of condensed milk 12 ounces, and about 40 ounces of water; put them into an evaporating dish, and heat over the fire until brought to the boiling point; drop in glacial acetic acid until the milk is thoroughly curdled; strain off the liquid through a coarse cloth or fine wire strainer; mix up the white of one egg well with the filtrate, put over the fire, and boil once more. By the use of the egg the whole becomes perfectly clear, and can be readily put through filtering paper.

After filtering dissolve 10 grains of iodide and 5 grains of bromide of potassium in the liquid.

### Silver Solution.

Of silver, 30 grains in summer, and 40 grains in winter, made quite acid with glacial acetic acid.

### Developing Solution.

Pyrogallie acid	...	...	...	15 grains
Acetic acid...	...	...	...	1½ ounces
Water	...	...	...	10 "

### Mode of Working.

The serum of milk is applied in the same manner as silver to plain paper; then let it dry (yet not too dry); after which tack to the solar printing-board, and silver the same as it is iodized (carefully excluding all white light). Now print until the shades of the picture are plainly seen, then brush the developing solution smartly over it. When it is as dark as desired, immerse it quickly in hyposulphite of soda, and let it remain long enough to stay the action of the developer; then take it out, rinse well in water, and immerse it in a second solution hypo, sufficiently strong to fix the picture thoroughly (say) from five to ten minutes. Sufficient carbonate of ammonia should be added to give a strong alkaline reaction. Care should be given that the pictures are taken out just as soon as fixed, and then thoroughly washed.

## REACTIONS OF HYPOSULPHITES AND SULPHO-CYANIDES UPON ALBUMEN PRINTS.

MY M. CAREY LEA.\*

ALTHOUGH very much has been written upon this subject, yet, nevertheless, its extreme importance may excuse a few words more upon it. There is no greater reproach to photography than the insecurity always felt as to the permanency of its productions; and this doubtful permanence we all know to be due to some action of the fixing bath. Without undertaking to find decisive solutions to any unsolved problems, it is, perhaps, worth while to put on record the result of the following experiments.

And, first, I may remind my readers that it is a well-ascertained fact that albumen is capable of entering into distinct chemical combinations with certain metallic oxides, and, amongst these, with oxide of silver. When, therefore, a sheet of paper coated with albumen mixed with an alkaline chloride is floated upon a bath containing an abundant quantity of nitrate of silver, there is formed both chloride and albuminate of silver.

Suppose, then, the fixing to have been performed in the usual manner, and most thoroughly, and also that the print has been thoroughly washed, the question arises, Is any silver left in the whites? and, if so, why? and how much?

The first of these questions has already been decisively settled. There does certainly remain silver in the whites. To obtain an answer to the other questions, the following experiments were made.

Some albuminized paper was sensitized in a 50-grain bath of plain nitrate, and was washed and fixed without exposure. Different pieces were left in the hyposulphite bath, which was a perfectly fresh one, consisting of 1 part of hypo to 4 parts of water, for different periods of time, varying from a few minutes to half an hour.

These pieces were then tested with hydrosulphate of ammonia, applied with a clean quill, and in sufficient quantity to fully produce whatever effect it was capable of. The result found was this: that although, even from the pieces left the shortest time in the fixing bath, the silver compound sensitive to light had been perfectly removed, so that the hyposulphite had in five minutes perfectly done that portion of its work, there was another insensitive compound left, which continued regularly to diminish in quantity by continuation of the action of hypo. That is, whilst the portion of paper which had been in the hyposulphite but five minutes stood a severe test of sunshine under a negative absolutely as well as a piece fixed for half-an-hour, nevertheless, the piece which had been in ten

\* *Philadelphia Photographer*.

minutes gave a less brown streak with hydrosulphate of ammonia than one treated for five minutes; one treated for half-an-hour showed less indications than one treated for twenty minutes; and so on.

A prolonged exposure to the action of hyposulphite, where allowable, has therefore a very plain advantage. For that this silver in the whites has something to do with fading seems pretty clear; it would at most appear that the chemical action connected with fading starts with it.

A comparison of these results was extended to sulphocyanide of ammonium. Paper immersed in a solution of that substance (sulphocyanid., 1; water, 2) for different periods—from five minutes up to twenty—were tested in the manner just described. The result was altogether different from that obtained with hyposulphite. The brown stains produced by the hydrosulphate of ammonia were all equally strong, and without reference to the time of action; the stain on paper left for twenty minutes was no lighter than on that left in but five.

It appears, then, that this substance is not soluble in sulphocyanide. As the pieces which had been immersed in sulphocyanide exhibited about the same strength of colour under the hydrosulphate test as the piece which had been acted upon by the hypo for five minutes, it would seem that not very much of this substance had been removed by the hypo in the first five minutes, and that the whole quantity of this compound originally in the paper was but small.

Finally, I may remark, that the extended series of experiments which I have made upon the properties and permanence of paper positives seem only to place in a stronger light the great uncertainties connected with silver printing. The solutions in use are continually undergoing changes which, whilst they are of paramount importance to the keeping qualities of the print, are invisible to the eye, and can with difficulty be guessed at. Such considerations enhance the importance of those processes which avoid the use of silver, and give the unstable compounds which silver renders it necessary to employ.

Since the above was written, I have noticed a fact which seems of interest in connection with the fading of positives.

A portion of a print was subjected, more than a year ago, to a simple sulphur toning—that is, hyposulphite of soda and chloride of lead, without any admixture of gold. This was marked and put away. About the same time a line was drawn with hydrosulphate of ammonia across the whites, which produced a brownish stain. The stain, though a decided light brown, was, of course, much lighter than the dark portion of the print. Now, after the lapse of about sixteen months, matters have materially changed. The sulphur-toned print has nearly faded out, so that the streak of sulphide is now much darker than the print.

This is an interesting fact, and one which seems fully to confirm the view which I expressed long since—that the popular idea that the fading of a print depended upon the production of sulphide of silver was erroneous. Here the print had almost faded out; whereas the sulphide of silver alongside had not (so far as could be noticed) suffered any alteration. Sulphide of silver is, in its chemical relations, rather a stable substance, and not one from which we should expect such changes.

Again, there seems another very strong reason: In a faded print the whites generally turn yellowish. If a conversion of silver into sulphide is taking place, why should that darken the light parts whilst it lightens the dark parts?

Again, in the prints in question, although the whites are fairly yellowish, they are not nearly so dark—not the tenth part—as the stain left by the sulphohydrate of ammonium. If a complete conversion into sulphide has taken place, and if such a conversion can almost efface the print, it ought to have completely affected the white also. For the reasons above given, I do not conceive that faded prints are converted into sulphide, but rather into some much less coloured silver compound.

## Proceedings of Societies.

### LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of this Association was held on Tuesday evening, the 25th ult., the President, the Rev. G. J. BANNER, in the chair.

The minutes of the previous meeting were read and confirmed.

Mr. FORREST said that at a recent meeting he had promised to bring forward a new kind of dull glass suitable for focussing. He had placed a piece of the glass in question in the hands of the Secretary, and would be glad to hear his report.

Mr. BOLTON said he had tried the glass, which, in appearance, was very similar to fine ground-glass, and found that the image formed upon it would bear magnifying to a greater degree than upon ground-glass of the finest grain.

In answer to an inquiry, Mr. FORREST stated that the dull surface was obtained by the action of vapour of fluorine acid.

Mr. SLEDDON passed round a number of pictures by the quassia process, some of them taken under very unfavourable circumstances; and gave a *resumé* of the process, which, however, did not differ from the details already published.

The pictures entered in competition for Mr. Green's prize were then given in for adjudication, Messrs. A. and R. Cooko being chosen judges. The prize was awarded to Mr. Henderson, for a dozen stereos by the collodio-bromide process. Indeed, the whole of the pictures entered were taken by the same process.

Several prizes were announced for future meetings, and there is every hope that the admirable system instituted by Mr. Green will, by giving birth to a spirit of emulation amongst the members, tend to raise not only the number of workers, but also the standard of quality of results produced. In addition to Mr. Green's prize for the best year's work, there are others promised by Mr. Hughes, for the best picture not exceeding 25 square inches, and by Mr. Henderson and others, object not announced.

A discussion arose as to the advisability of having another excursion. Several rather remote localities having been named without finding favour, it was finally decided, in consequence of the unfavourable weather experienced on the occasion of the last Saturday afternoon excursion to the "Old Hut," to repeat that excursion on Saturday, the 5th of September.

The meeting was then adjourned.

## Correspondence.

### SUGAR IN THE PRINTING BATH.

MY DEAR SIR,—Enclosed are two photographs from the same negative: they are of no account except in illustrating a little matter.

When Bovey's formula for printing-baths appeared in your YEAR-BOOK last winter, I thought it would be a considerable benefit to me if I could prepare sensitized paper to keep for a few days. I had always been in the habit of using it immediately on preparation. Accordingly, I added the quantity of sugar recommended to my 80-grain bath, and have been using it during the spring and summer, and been well pleased with it. About seven weeks ago I left my studio for my summer ramble. On my return lately, and beginning to print, I found some sensitized paper left from my last printing. It was not a good colour by any means, but I printed, toned, and fixed a few cartes, and No. 1, enclosed, is one of them. Forty-five days elapsed between the sensitizing and the printing and toning. The colour is not good—the negative will not give that under any circumstances. No. 2 is a carte from the same negative, the sensitizing, printing, and toning done on the same day; and the colour is very little better.

Another point I may mention in connection with this. Your contemporary, the *B. J.*, in No. 423, deprecates the use of sugar in the printing bath. He says, in winter it may be allowable, but

in summer the chances are that it decomposes and becomes useless. All through this hot summer I have used sugar in this bath, having it slightly acid, as he also recommends; but my experience leads me to consider it perfectly reliable, and by no means subject to change. At the end of last week I printed six dozen cartes in the printing bath made in winter last, with the quantity of sugar recommended, and in no way can I see any difference between the cartes printed then and now.

No. 2 is one of those last printed.

September 14th, 1868.

Yours very sincerely, KENT.

[The cards sent admirably illustrate the value of sugar in the printing bath in permitting the paper to be kept, without yielding discoloured prints. Our correspondent speaks modestly of his pictures when he says the colour is not good. They are both above the average in general qualities, and are of a rich warm sepia tint—that on paper upwards of six weeks sensitized scarcely appreciably less pure in the lights than the other.—ED.]

### AUTOMATIC SYPHON.

SIR,—I had not long been employed in photographic manipulations before I became convinced that an *automatic syphon* would be of the greatest service to photographers and all others using corrosive fluids or valuable metallic solutions.

At the first glance the construction of such a thing as a really automatic syphon appeared to me (as it perhaps may, sir, to you) an impossibility; but four years persistent endeavours have enabled me to surmount the difficulty, and to produce a syphon so perfectly automatic that it may be used to transfer prussic or boiling nitric acid, and so simple that it can be made more cheaply than a syphon of ordinary construction.

Photographic apparatus makers to whom I have offered the invention are some of them of opinion that such a thing would not be of any use to photographers, whilst others express their belief that, however useful it might be, the greater number of photographers would be "too mean" to purchase it.

Some of these gentlemen, however, appear to be getting so good a living out of their "moan" patrons that I am induced to appeal from the makers of apparatus to the users thereof, and to beg of you, sir, to allow your readers an opportunity of judging for themselves as to the probability of their finding a use for such an article, and of expressing for themselves their unwillingness to invest a sixpence in its purchase.

Judging from my own experience, there are, I believe, many assistants who would, if necessary, spend such a sum from their own pockets to possess the means of emptying a large positive bath without risk or trouble.—I am, sir, yours truly,

JOHN SMITH.

9, Rue Royale, Boulogne-sur-Mer, France, Sept. 10th, 1868.

### Talk in the Studio.

THE ABYSSINIAN EXPEDITION.—We are glad to learn that Serjeant John Harrold, late chief photographer to the Abyssinian expedition, was one of the six non-commissioned officers of the Royal Engineers to whom was awarded silver medals for "distinguished services in the field" before Magdala. General Simmons, C.B., distributed the decorations at a full-dress parade of the corps at Chatham on Saturday last, and in his speech made special mention of Serjeant Harrold, whom he complimented on the efficient manner in which he had discharged his photographic duties.

PORTRAITS OF THE ABYSSINIAN PRINCE.—We have received from Mr. Jabez Hughes, of Ryde, a series of very admirable portraits of Alamayou, the young Abyssinian Prince, and of his attendant, Kassa; also of Captain Speedy, in his Abyssinian costume, to whom the little Prince has especially attached himself. All the portraits are technically fine, and where groups have been taken we have some exceedingly fine pictorial effects. We have the little Prince in various forms of native costume, and also in European costume, all good, and admirably rendering the semi-Egyptian, semi-negro type of features. The

attendant, Kassa, although black, possesses features of a fine, straight, European type.

HARNECKER'S DRY COLLODION.—We learn from M. Romain-Talbot that Mr. Solomon, of Red Lion Square, has been appointed London Agent for Harnecker's Dry Collodion, to the value of which reference has recently been made in our columns. We hope shortly to have something to say on the subject. Mr. Solomon is also agent for the Carrier Sensitive Albuminized Paper, which has, we are informed, been reduced in price and improved in quality.

TEMPORARY VARNISH FOR NEGATIVES.—Many negatives only require to be used once or twice. In order to protect them, they may be coated with a temporary varnish, made, viz.: Take 4 ounces of white glue and dissolve it in 4 ounces of acetic acid, add a pint of water, and, when properly mixed, it is ready for use. Coat the plate as with collodion. It is easily washed off, and saves much time and trouble.—*Philadelphia Photographer*.

THE AMERICAN BROMIDE PATENT.—It is estimated that if a renewal of the bromide patent had been obtained, the photographers in the United States would have been taxed during the seven years of its continuance to the extent of 1,750,000 dollars, or nearly £350,000 sterling. It is estimated that there are 5,000 photographers in the States. It was the intention of the patentees to impose a licence, costing 10 dollars a year (about £20), upon such studios as they considered first class, and 50 dollars on those regarded as second class. The above estimate of taxation is calculated in the second class rate for the whole.

WAXING THE PLATE-HOLDER, &c.—A correspondent of the *Philadelphia Photographer* says: "I use pure beeswax to protect my plate-holders from the action of the silver solution. Warm them, and rub it in with a piece of wash leather. For mounting photographs I dissolve equal parts of bonnet glue and gum arabic in enough water to secure the consistency of maulage; strain through muslin, and, when cool, it will be about right for hot weather, but in cold weather it must be warmed. A few drops of alcohol will keep it from changing. It sticks, dries quickly, and leaves the cards elastic, and not apt to curl." [This mixture has already been described in our pages by Mr. Spiller.—ED.]

### To Correspondents.

G. H. M.—There are two French photographic journals, "*Le Moniteur de la Photographie*," edited by Mons. Ernest Lacan, published fortnightly by M. Lieber, 13, Rue de Seine, Paris. You can obtain it direct from the publisher for twenty francs per annum. The "*Bulletin de la Photographie*" is the organ of the French Society, and is issued monthly to members of the Society. It contains the proceedings of the Society, and other matters; the subscription is fifteen francs a year; the publisher, M. Gauthier Villars, 55, Quai des Grands-Augustins, Paris.

YENDIS.—The plan of your studio seems to be very good indeed, and we do not see any need for modification of the plan already laid down. It is probable that you will not suffer inconvenience from the houses, painted white, at fifteen feet distance; nevertheless, if the distance can, without inconvenience, be made greater, it will be wise to increase it. If the walls of the passage which turns at right angles be made black, or some very dark colour, so as to reflect no light, there will be no need to have a door to the dark room. The position of the door of the studio is more a matter of convenience than of anything else; we see no objection to its present position.

W. J. A. G.—Messrs. Robinson and Cherrill's address is 1, Grove Villas, Upper Grosvenor Road, Tunbridge Wells. We have no doubt that Mr. Robinson will supply you with studies on the terms you name. The portrait of Mr. Solomon was not taken for publication; its excellence and interest have suggested that course since. Is your copy of the *News* sent direct from our Publishing Office?

E. L. (Cambridge Heath).—Various formulæ for printing enlargements on canvas by development have appeared in our pages. Perhaps the most complete formulæ and instructions for manipulation appear on page 138 of our Ninth Volume. We regret that the press of our imperative engagements does not leave us time for writing private answers to questions of this kind.

J. H. R.—We have not heard of or met with any tendency in the gelatino-iron developer to cause the film to split from the plate,

nor can we see any necessary reason why it should do so; except, indeed, that as a rule a little longer exposure is generally necessary with a gelatine-developer, and, when there is any trace of under-exposure, and the development requires pushing, there is always a greater tendency in the film to split up on drying. The best remedy, when the tendency is, from some unknown cause, manifestly present, is to treat the film before drying with a dilute solution of gum-water, which will generally check the tendency to split.

**ADRIET.**—We can suggest but one of two reasons for your gelatine solution not assuming the condition of a jelly on cooling. Either the gelatine is at fault, or you have boiled it too long, and it has assumed the character of meta-gelatine. We are assuming, of course, that you were careful to add only the proper quantity of water. To test whether the gelatine is good, soak a little in cold water. If it be good, it will swell up without dissolving; if it show any tendency to dissolve in the cold water, it is bad, and unfit for the purpose.

**H. S.**—We will examine the varnish and collodion at our earliest convenience. We have recently been closely engaged, and have not had much time for experimental examinations of the kind. 2. It is a somewhat dangerous expedient to endeavour to get rid of the dark shadows arising from the use of vertical light, by reflectors placed underneath. The unnatural reflection is apt to produce unpleasant effect on the eyes. Try it by means of sheets of white paper or calico before taking any definite steps. It is only by experimental essays that you can hope satisfactorily to modify your difficulties.

**B. L.** notices that we commend Mons. Adam-Salomon for appropriating an idea from Sir Thomas Lawrence; whereas, if he had understood the art teachings in our pages, he would have noticed that imitation of the works of others is condemned as a pernicious practice. B. L. seems to have arrived at a curiously erroneous conclusion, indicating very imperfect knowledge of the subject. The kind of imitation which has been denounced in the art articles in our pages consists in the slavish copying of common-place models, merely because they save the photographer the necessity of thinking for himself. Such a practice never leads to excellence. But we have constantly urged upon our readers the careful study of the works of great masters as affording the best possible art culture. One of the chief aims of Mr. Robinson, in his lessons on Pictorial Effect, is, besides teaching some principles, to bring under the attention of the student good models, and to point out in what their excellence consists. Wherever you see a good idea in a great master, seize upon it, and make it your own by understanding it perfectly. Any reproduction of it will then be your own embodiment of that idea, and not a slavish copy of it. Bear in mind that there is an enormous difference between adopting the idea of a great master, and imitating the work of unknown photographers, bad, good, and commonplace, selected and rendered by an incompetent man working with an imperfect process.

**THOMAS LEWIS.**—See answer above to E. L. 2. The canvas is not sold ready for photographic use. 3. If the operations are carefully conducted, we do not see much reason to doubt the permanency of the results. 4. The simplest method of printing on ivory which we know, is by using our collodio-chloride process; the formulae, &c., given in our last YEAR-BOOK, answer well.

**J. T. B. (Lydd).**—The chloride of silver may be removed by filtration. 2. If your bath does not decrease in bulk in such ratio as to render necessary the addition proposed, only add half the amount, or only add it every other day; but, in making the addition, keep the proportions of gold and of water indicated. 3. It is always well to keep prints moving whilst in either toning or fixing bath. 4. The method you adopt with your washing waters is right. We cannot tell you with certainty the price you will obtain for chloride of silver; if pure, you will probably obtain about a similar weight of nitrate of silver. 5. The chief advantage in obtaining the NEWS direct from the Office is a saving of time. If you get it in good time, there is no reason for changing. 6. We cannot suggest any reason why you found it required such long exposure to get an image on Niello paper, except some imperfection in the sample you used. We are glad that you find Mr. Bovey's formula so satisfactory.

**DETERMINED.**—It is scarcely possible that you should add to any solid substance its own weight of a solvent, and that after mixture it should remain as firm and solid as before. It is almost equivalent to saying that you poured an ounce of water on an ounce of salt, and that the salt remained as dry as at first. Nevertheless, after the solvents have been added to the melted wax, it may, on cooling, form a firmer paste than you desire; in which case again melt it, and add such proportion of the solvents as you may think requisite to produce the result you wish. Add (say) one-fourth of the original quantity of solvents, mixed in the due proportions as stated in the recipe. For our own use we prefer a somewhat firm paste; others like it in the consistency of a soft pomade. In either case, place a few patches of it over the surface of the print—say

in half-a-dozen places. Rapid friction with clean flannel will quickly spread it all over, and continued friction will produce the rich depth and polish desired.

**AMATEUR.**—It is somewhat difficult to make a paper print quite transparent and free from any mottled effect, because the paper itself is not quite free from mottled inequalities in texture. It is desirable, however, to soak the print well in boiling water to remove the size first of all. They may then be treated with wax, or a mixture of a wax and a resin (such as dammar) applied warm. It is possible that one of the encaustic pastes we gave last week, applied warm, so as to thoroughly saturate the print, may answer. The effect, if properly managed, is pretty. It has often been done.

**SWAN RIVER.**—Of the lenses you quote 3 B is the quickest with open aperture. 2. It will cover the size plate named for most subjects without stopping down. It is of the same quality and character as the No. 2 by the same maker, which you possess. 3. We cannot give you the absolute ratio of exposure between 2 B and 6 D, but the latter would require much longer—probably four times as long. 4. For a full-length standing figure of good proportions in a cabinet picture about 30 feet between sitter and camera would be required by 6 D. 5. You can best judge of the relative cheapness of the lenses yourself. If the D lens suit your purpose, it is undoubtedly a cheap lens; but if you require rapid work, you must remember that it is least rapid of those you quote. The quality of pictures it gives is admirable; and where the studio is well lighted it answers well. If you wish to use it for cabinets, No. 3 or 4 of the same series will answer better, and they all cover more than the catalogued size. We are glad that you find the NEWS so useful to you in your far distant home.

**H. V. C.**—Any of those you mention will serve, probably No. 1 or 3 best; but each will be better for the purpose after the addition of from half a grain to a grain of bromide of cadmium per ounce. 2. Spring water cannot be depended on for washing without a preliminary rinse in distilled water after the plate first leaves the silver bath. 3. The method described is better than redipping. 4. Much depends on the weather, and care in storing. Mr. England has kept them upwards of a month, whilst some persons do not find them keep much more than a week. 5. Unless there is mismanagement, such plates have not a tendency to crack or peel. The albumen checks such tendency, even if otherwise present.

**VENATOR.**—If you, as you state, carefully follow instructions whereby others succeed, and you altogether fail, it is a somewhat difficult thing to say why you fail, or to point out a remedy. Any good bromo-iodized collodion generally succeeds; but most commercial samples are better for dry plates after the addition of a little extra bromide. 2. The Liverpool Dry Plate Company's plates are exceedingly good, and may be used for interiors if they are not very dark; but some interiors require an hour or two of exposure with wet plates. You could not hope in such case to succeed with dry plates requiring at least three or four times that exposure. 3. Mr. Bovey states that he uses the double chloride of gold and sodium; an ordinary commercial sample will serve. If you follow his instructions you cannot fail. Many photographers have written to say that it is the most satisfactory formula they have used. If, from some peculiarity in your manipulation, you find the chloride of calcium formula answer better, stick to its use. 4. No. 3 will probably answer your purpose best. The rapid is the most valuable lens.

**W. H. M. (Bristol).**—Oil of spike is the brief or familiar term for the essential oil of spikenard, a plant of the lavender family, but different. The essential oil slightly differs from that of lavender, and is generally cheaper. It is well known in commerce, and is generally kept by chemists. If you cannot procure it, another essential oil—such as that of lavender or rosemary—will serve.

Several Correspondents in our next.

### WET COLLODION WITHOUT WATER.

In speaking of wet collodion without water we do not, of course, mean without the use of aqueous solutions of the various chemicals employed, but of the practice of the wet collodion process in the field without the use of washing water, leaving the negative in a state for further intensifying if, on deliberate examination after returning home, it be found necessary.

Every photographer who has worked the wet process in the field, especially if he have worked large plates, is familiar with the fact that the necessity of procuring and carrying washing water is often one of his most serious troubles, and that carrying hypo amongst his chemicals forms one of his most serious risks. And he is further familiar with the fact that even if water be at hand, and the negative have been finished, he has often, when examining the negative at leisure, felt that the only thing some charming subject required was the development carrying a little further to obtain harmony. A multitude of other reasons might be adduced to show the advantages of intensifying if necessary, and of fixing certainly, at home instead of in the field; but it is unnecessary to multiply arguments to enforce a position which the landscape photographer will admit without question.

Many photographers have for years adopted the custom of finishing at home wet plate negatives. Glycerine, or glycerine diluted with water, has generally been employed to keep the film moist, and in many cases with great success. But it is necessary here, generally, to use a little water to remove the developer of mixed iron and silver solution, otherwise fog would often be the result. One of the most common objections, indeed, to the use of glycerine in this way has been the frequent tendency to fog which plates so treated have shown, if any further development or intensification were necessary; nevertheless, the use of glycerine in skilful hands has minimized the amount of water which might be employed, and materially diminished the trouble of field-work with the wet process.

The method to which we are about to refer will, we believe, remove all risks and troubles, and will permit the photographer to dispense with washing his negative in the field altogether, whilst it will preserve the image in a condition for further development or intensification without risk. For the thorough working out of this method we are indebted to Mr. H. P. Robinson, who has worked plates 16 inches by 12 inches in the field during the exceedingly hot weather without a drop of water, in every instance with perfect success, and without in any instance having a trace of fog. The material employed is a mixture of golden syrup and distilled water in equal parts. Such a preparation for such a purpose is not entirely new; it has been used before; but in the same manner as glycerine, after slight washing, in

order to minimize the amount of water necessary, not to dispense with it altogether. A few words of explanation will be necessary to indicate the difference between the action of glycerine and that of golden syrup, and why the latter may be employed without washing the negative at all, and with perfect immunity from the risk of fog.

About three years ago, when the subject of organico-iron developers was receiving special attention, we made a series of experiments, in conjunction with Mr. Robinson, with various substances added to the developer, a record of which will be found in our Ninth Volume, on the 517th page. We then found that when the development was prolonged with an iron developer to which glycerine had been added, a tendency to fog was the general result. But when golden syrup was added, even in very minute proportions, it had a singular tendency to arrest development, the shadows being remarkably clean and transparent. The glycerine slightly aided reduction, the golden syrup retarded it. It will be readily seen, then, that if glycerine be applied to the film whilst it still contains traces of the iron solution and of the silver solution present in development, a tendency to fog will be the natural result. If, on the contrary, golden syrup be applied, development is arrested at once, and all tendency to fog prevented. Both preparations preserve the film moist, and permit the negative to be kept in that state, but the action on the image is widely different.

It is only necessary, then, in operating in the field, to develop the image as fully as appears necessary, and then apply the mixture of golden syrup and water without washing at all. Development is at once arrested, the iron and silver producing no further action. The negative is then placed in the box, where it will remain moist for hours or days. It can then be thoroughly washed and examined at leisure. If further development or intensification be required, it can be effected without any risk of fog; or, if no further treatment be necessary, it can be fixed with, in either case—other conditions being right—a tolerable certainty of an especially bright negative.

We shall be glad to learn the experience of landscape photographers with this preparation, which promises a considerable relief in field operations. Our own experiments have not been very extended, but perfectly satisfactory; those of Mr. Robinson, with very large plates under trying conditions, have been numerous as well as satisfactory, results fully confirming what theory had suggested.

### OBERNETTER'S APPLICATION OF THE COLLODIO-CHLORIDE PROCESS.

WE have recently devoted some time to further experiments with our collodio-chloride process, and to Herr Obernetter's commercial application of it, in his sensitive-prepared paper. We are indebted to the courtesy of our friend Dr. Liesegang

for some examples of the materials, and details of the manipulation and formula, employed by Herr Obernetter, which have given additional interest to the experiments.

The paper employed by Herr Obernetter is described in a letter to Dr. Liesegang as follows:—"I take fine porcelain paper, coat it with glue, and, after drying, make the glue insoluble by dipping the paper in a certain solution. Then I dip this paper in a very dilute solution of gutta-percha in a mixture of chloroform and ether. This is a very disagreeable preparation, but I cannot use any other substance but gutta-percha, nor any other solvent than chloroform, or that and ether. The paper is then coated with collodio-chloride of silver."

Porcelain paper is that known in this country as enamelled or surface-paper. Collodio-chloride of silver applied on such a paper gives an exceedingly smooth, glazed, and delicate surface. The reason for the preparations it undergoes before receiving the coating of collodio-chloride is found in the fact that if it be applied to the paper in its ordinary state a number of minute bubbles are formed in the film which mar the picture. The solvents of the collodion are absorbed by the layer of pigment which coats the paper, and air being displaced in the operation causes the bubbles. The solution of glue—or, properly, gelatine—subsequently made insoluble by alum or some similar substance, will tend to make the surface non-absorbent, and will thus keep the image perfectly on the surface, and prevent the formation of air-bubbles. The object of the second coating of gutta-percha is not stated, but its intention is probably to secure adhesion of the collodion film to the paper.

Dr. Liesegang favoured us with a sample of the paper prepared for the reception of the collodio-chloride, which we tried, both with a sample of the sensitive preparation made by our own formula, as given in our last YEAR-BOOK, and by the formula employed by Herr Obernetter, of which we have yet to speak. In the prints produced on this paper as prepared with collodio-chloride by ourselves, we have found none of the difficulties which some have found with the Obernetter paper, and to which we found a tendency in the sample we tried. We refer to a disposition in the film to leave the paper during the manipulations, or in drying, or a disposition in the film when dry to crack. The prints produced on the sample of paper we tried were all good. The formula for collodio-chloride with which Dr. Liesegang has favoured us, and with which in the letter to which we have referred Herr Obernetter expresses his satisfaction, stands as follows:—

Alcohol	...	...	200 cubic centimetres
Ether...	...	...	250 "
Soluble cotton	...	...	12 grammes
Nitrate of silver	...	...	8 "
(dissolved in water, 4 grammes.)			

To this is added a chloride solution as follows:—

Chloride of lithium...	1 gramme
Alcohol ... ..	50 cubic centimetres
Glycerine ... ..	6                   "

This may be roundly stated as follows: plain collodion containing nearly equal parts of ether and alcohol, with 12 grains per ounce of soluble cotton. The cotton should be good, and not too horny in character, or this proportion will be too much. We used some soluble paper prepared by Mr. Blanchard, which answered well. To the collodion, nitrate of silver must be added at the rate of eight grains per ounce, dissolved in half its own weight of water. Unless the temperature of the water is raised a little, it is difficult to dissolve nitrate of silver in half its own weight of water; but it will readily dissolve in an equal weight, and if the solvents of the collodion are tolerably free from water, this quantity will not produce any injurious result. Dr. Liesegang recommends chloride of lithium in preference to other chlorides, on account of the low atomic weight of lithium, which is 6.50, a sufficient proportion of chlorine being thus introduced to form chloride of silver by the use of a very small proportion of the lithium salt, which is also very

readily soluble in alcohol. It is added to the collodion in the ratio of one grain to an ounce, which is one grain of the chloride salt to eight grains of nitrate of silver. About seven minims of pure glycerine are to be added to each ounce, with the object of giving pliancy and toughness to the film.

We made some collodio-chloride by this formula, using a sample of chloride of lithium for which we are also indebted to Dr. Liesegang. The lithium salts are extensively used in photography in Germany, but as yet they have been used but very little in this country. The collodio-chloride gave us exceedingly fine pictures, inclining, however, with soft negatives, to excess of softness in the prints. With very vigorous negatives, it gave good harmonious prints. It will be observed, however, that no organic body readily combining with the silver is added, so that no organic salt of silver—commonly desirable as an element of vigour—is present; and by the addition of such a substance we at once gain greater depth, richness, and contrast.

We tried, therefore, a portion of the same collodio-chloride, to which we added citric acid in the proportion of 1 grain to each ounce, and coated one half of a piece of paper with this, and the other half with the collodio-chloride as first made. On exposing the paper to light, the difference in behaviour of the two samples was well marked. At first the tint acquired by each was similar—a lavender tint—but that containing the citric acid darkened most rapidly. As the tints grew deeper, that with acid acquired a reddish purple colour, whilst the other continued of a lavender tint; and finally, that with the acid rapidly bronzed, acquiring a decided green tint, whilst that without acid slowly acquired a slightly bronzed olive tint. On toning and fixing this piece of paper, the half containing acid acquired a rich deep black in the same time in which the other half assumed a somewhat weak greyish black tone.

The advantage of this citric acid was most marked, both in the increased sensitiveness and the increased vigour and rich colour of the print; but the dried collodion film, it is worth noticing, was of a somewhat more horny and brittle film than the other, although both were identical in composition, with the exception of the addition of the acid to one of them. It is probable, therefore, that where citric acid is used, a still larger proportion of glycerine might have a beneficial effect.

We have not tried a sufficiently extended series of experiments as yet in the keeping qualities of the prepared paper to enter into the question at present. As we have already recorded, the paper sent out by Herr Obernetter appears to keep well.

## SHORT ESSAYS ON PHOTOGRAPHY AND ART.

### No. 3.—"NORTH OR SOUTH."

BY NELSON K. CHERRILL.

I REMEMBER, a long time ago, reading an account of a very scientific experiment, to be made with an empty pill-box. It was somewhat as follows. Procure a pill-box of small dimensions, and having disposed of its contents in any manner which may seem desirable, paint it black inside; now with a red hot needle make a very small hole on one side, and with a blunt skewer make a somewhat larger one on the other side; stick a pin through the bottom of the box, and upon the point of it impale any small animal, such as a flea (humanity suggests that the victim should first be slain or rendered insensible); the lid is now to be placed on the box, and then comes the point. Carefully holding the box in one hand, apply the eye to the small hole, you will probably see nothing; but now approach a candle very carefully till the flame is quite close to the larger hole (it is exceedingly difficult to do this without setting fire to one's hair, eyebrows, &c., but that is a trifle), and when the light is "well arranged," you will see the small animal impaled on the pin in a "singularly beautiful manner." For

my own part, I prefer to think that the "singular beauty" of the animal in question would be quite as advantageously examined in ordinary daylight, omitting the blackened pill-box. Now whenever a photographer begins to assure me of his faith in south light for a photographic studio I am always reminded of the blackened pill-box and the attendant horrors of a half-stupified little animal on the point of a pin. Can anything be more exact than the parallel between the two cases? The enthusiastic south-light gentleman says, "I close all the windows with dark curtains;" the medicinal experimenter says, "Paint the inside of the pill-box black." "But then," says the photographer, "I leave one small space through which I get a beam of intense light;" that is represented in the experiment by bringing the flame of the candle close to the big hole in the side of the box. Also the sufferings of the wretched flea while roasting in such close proximity to the candle, in the pill-box episode, are an exact type of the horrors of a sunlit studio, where an almost unbearable temperature reigns throughout the summer months, to the untold discomfort of the unhappy sitters. But mark, I pray you, the conclusion of the whole matter. It must be left to each person's judgment to decide whether, under these distressing circumstances, the poor little wretch under examination looks really more "singularly beautiful" than when viewed in the way in which ordinary men would view such a creature. For my own part, as I have already mentioned, I do not like the pill-box plan of examining insects, and still less do I like the pill-box plan of taking portraits. No doubt it is very scientific, much more so than any other plan; but then science is not the foundation for portrait photography, but art is, or—perhaps more accurately—should be.

There is no worse plan of aping to be great than being mysterious; and there is certainly no worse plan of being mysterious than that of pretending to do something grand when there should be in fact nothing at all to do. A well-arranged studio should have the light always right; in fact, it should be quite impossible to have it wrong at any time; the skill of the photographer should consist, not in arranging window blinds, but in posing the sitter; not that some slight alteration of light may not be of advantage sometimes, especially when turning from one style of picture to another, as from vignettes to whole-plate pictures, for instance. The amount of attention which the light requires should occupy only the fraction of a minute, while the sitter should be ever in the chief thought of the operator; and that is the very worst form of studio in which every square inch of glass surface needs to be as much thought of as the sitter. But few photographers as yet know how to manage their sitters, much less their light and their sitters.

I do not, of course, wish for a moment to deny that very clever men may produce excellent work in the studio when it faces the south instead of the north. But what clever men can do, and what ordinary men do, are—perhaps fortunately—two very different things.

"Some effects, however," it may be said, "can be produced by south light better than by north." What a charm there is in that word "some"; change it rather, and the word is *sun*, for—only excepting the effect of direct sunlight—there is emphatically no effect of lighting which cannot be produced by north light; and as to the comparative comfort of two studios, one in which the sun strikes direct on the glass, and the other in which glass is only presented to the north sky, it is only necessary to try: "One trial proves the fact" that the north light will win the day.

If, then, comfort, convenience, and common sense are in favour of the north light being used, why are not all studios made so as to give this most desirable arrangement? It is pleasing to find that where so much is to be said in favour of the northern aspect of the studio, so many of the best photographers, both at home and abroad, have adopted it in favour of any other. If Salomon's force and Rentlinger's softness can both be done with a north light, what else cannot be done that is worth the doing?

## SKETCHES OF TRAVEL FROM A SUN-PAINTER'S PORTFOLIO.

BY S. THOMPSON.

### No. 4.—FLEMISH CITIES.

"In the market-place of Bruges  
Stands the belfry old and brown."

—Longfellow.

*Bruges and its Belfry.*—Time has dealt hardly with the Liverpool of the middle ages. Its harbour is no longer crowded with richly laden argosies from Venice, Genoa, and the far East. Time was when chartered companies of merchant princes from seventeen kingdoms dwelt within the walls of Bruges, and its court was crowded with foreign ministers, and men of eminence in science and art from all parts of Europe. Its river is now no longer navigable, being almost absorbed by canals for small craft, appropriate to its fallen fortunes. Its population is less than one-sixth in number to what it once was; consequently good dwellings may be had for almost nothing, and not a house has been built in Bruges for more than a hundred years. Yet there is no air of ruin or decay about Bruges. Speculative builders were not in those days. The public buildings are well preserved, and afford, like all the chief towns in the Low Countries, fine subjects for the camera. Belgian Gothic retained its purity to a very late period—with one exception, later than any other. It has also peculiar claims. Belgian Gothic exhibits, more than any other variety, the Gothic style applied to other purposes than ecclesiastical or sacred buildings. The town halls or *hotel de villes*, and other civil or domestic edifices, in which Belgium is richer than any Continental state, are subjects specially adapted for successful photographic rendering. The clean well-kept streets of Bruges and its pleasant walks only indicate, by the sparseness of the population, the absence of all commercial activity. Southey's lines embody an accurate word-picture of Bruges as it now is—

"Fair city, worthy of her ancient fame!  
The season of her splendour is gone by,  
Yet everywhere its monuments remain:  
Temples which rear their stately heads on high,  
Canals that intersect the fertile plain  
Wide streets and squares and many a court and hall  
Spacious and undefaced—but ancient all,  
When I may read of tilts in days of old,  
Of tournaments graced by chieftains of renown,  
Fair dames, grave citizens, and warriors bold—  
Which of such pomp fit theatre may be  
Fair Bruges! I shall then remember thee."

The *belfroi*, or belfry, makes a good photograph from the Grande Place, but the view of it from the canal, taken earlier in the day, about noon, when the light is "on the turn" (with a wide-angle lens), makes a picture. Associations blended with our own past, and memories of surpassing interest, are crowded around and beneath the shadow of that old Gothic tower, and lend an additional zest to the quiet beauty of the scene. The chimes (carillons) are the finest in Europe, and their music recorded the flight of the hours with the same dreamy, unobtrusive melody, while the Van Ecks were painting their imperishable works, as long ago as the fourteenth century, as they do to-day. Those walks around once glittered with the splendid costumes of the courts of Charles the Bold and the powerful Dukes of Burgundy, the ancient Counts of Flanders, the swarthy cavaliers of Medieval Spain, and the knights of the once-famous order of the Golden Fleece, established at Bruges in the fifteenth century by Philip the Good. We must fain pass over all this, and much more than this. Is it not to be found in the chronicles of Froissart and the book of Murray? One episode only which helps to fill up a gap in our own history may I linger over and attempt to broadly sketch.

Time—the great scene-shifter to the world's drama—presents many spectacles on the same stage. The accessories are somewhat altered—new dresses and differently-fashioned costumes provided, as well as fresh actors and a new star—

but the background is often substantially the same. Before it they come and fret their brief hour, and give place in their turn to others. Now it is a comedy, now a heavy piece, and, not unfrequently, a terrible tragedy that is enacted. After long periods the scene of action generally altogether changes: the old arena decays, and is deserted. The scene changes in locality as well as in events, and heretofore unimportant places grow up to be the stage of great things in the world's history.

The waves of time had engulfed two centuries since Charles the Bold was laid in the aisle of the choir of the Church of Notre Dame; the old beffroi still rings out its carillons with wildering sweetness in the clear night air, when the curtain rolls up once more. This time the background is Flemish, but the figures are English. From a house (which still bears the Royal Arms of England, and is little altered) in the Grande Place, or Market Square, almost beneath the shadow of the old tower, might be heard snatches of roystering cavalier songs, the noise and clink of glasses, the loud jest and louder applause, floating out on the stillness of night. This was the residence of the *Merrie Monarch* Charles II., not yet enjoying his own. This was the "Over the water to Charlie," and what it meant. Here was passed some of the long years of exile, and hither repaired the loyal, the disaffected, the ruined patrician, the proscribed royalist, bringing news elevating or depressing of the state of things at home; here they sang their Jacobite songs and cavalier roundels far into the "small hours," and then, joining arms with the witty king, who never said a foolish thing, sallied out from the festive board to cool their heads in a saunter round the old Market Square, awakening the quiet burghers with the noise of royalist songs sung with nasal twang to the tune of Puritan canticles, the generally expressed burden of which was a desire to see "Old Nick gae hame wi' Charlie's foes before him."

Cherie, volatile, and goodnatured, a young man of some twenty-five summers, Charles won the hearts of the honest burghers, and they elected him King of the Company of Cross-bowmen (*Roi des Arbalétriers*).

He mixed freely with them, and when funds run low—which they often did—found some of them generous enough to discount his apparently almost worthless paper. Many an old burgher, as he sat in front of his quaint gabled house smoking an evening pipe, watched the gay prince trip lightly along, heeding every pretty face, for which same, Bruges was famous then as now, and thought the Stewart had small chance of ever enjoying his own again. And, indeed, appearances were all against it. Cromwell was at the full meridian of his power, and England, under his strong rule, was making herself feared and respected, both on sea and land, in a manner to which she had long been a stranger. So years passed on.

A glance at what was doing in the world of art at this period is interesting. Rubens was just dead. His great pupil, Vandyke, possessed of a more delicate physique than his robust master, followed him one short year after, prematurely old at forty-two. But nearly all the great names of the Dutch and Flemish schools were then simultaneously engaged in painting those works that are household names to us, and every fresh dispersion of which draws crowds to Christie and Manson's to offer prices that would fairly take away the breath of the painters who executed them. Teniers was painting in a quiet street in Antwerp. Rembrandt at Amsterdam, together with Van Ostade, Brauer, Gerard Douw (formerly Rembrandt's pupil), and young Paul Potter—some twenty years their junior—happily oblivious of how short was to be that career of his which closed at the early age of twenty-nine. Cuyp, born in the same year as Rembrandt, was quietly painting at sleepy old Dortrecht on the banks of his favourite Meuse (which he never could be induced to quit, save for an occasional visit to his contemporaries in the neighbouring city of Amsterdam) things which he could scarcely have dreamed would ever make the noise in the world they have done.

Wouvermans was at Harleem, which he never quitted. Claude, and Nicholas Poussin were then at their busiest periods; and a glance at Spain shows that Salvator Rosa and Murillo—a few years younger—were also hard at work, presenting altogether a galaxy of talent seldom flourishing at one time.

Time rolls his ceaseless course! Two or three revolutions of his wheel had taken place, and things seemed little changed. But one day there was great commotion and a great packing of portmanteaus in the old house in the Market Square. Messengers had arrived with weighty tidings. Cromwell was dead! The well-known events recorded in history had taken place. The old house was quickly deserted, and the belfry chimes sounded never more upon the royal ear of Charles II., of Great Britain and Ireland King.

### A RAPID ENLARGING PROCESS.

BY M. C. STERNBERG.\*

The continuation of fine weather we have recently experienced has, no doubt, called to mind to many photographers the fact of their having stored away in some out-of-the-way corner an enlarging apparatus of some kind or other, which might at the present season be employed with very great advantage. At the same time, the necessity of having to make a choice among the many known processes often causes them to pause. To those who are already acquainted with a good working method I would counsel to keep to the same; but to others, who desire to be informed of a rapid and reliable process, I can recommend the following with a good conscience. It is by no means new, but to whom it belongs I am unable to say, although I believe it was first practised by M. Selbach; it may, however, be relied upon to give excellent results.

The operation of enlarging by this method is so quick, that with negatives of ordinary intensity an enlargement of not very large dimensions may be obtained without any movement of the mirror during the process. The paper is coated with a sensitive material compounded of the following ingredients:—

Rain water	...	...	1 litre
Brazilian tapioca	...	...	20 grammes
Iodide of potassium	...	...	10 "
Chloride of potassium	...	...	40 "
Lemon juice	...	...	250 drops.

The tapioca is softened in a small quantity of cold water, and then added, by degrees, to the other materials which have been previously dissolved in the litre of rain water, and boiled together in a porcelain dish; the heating of the liquid must be continued during the addition of the tapioca, and so long afterwards as is necessary to clarify it. When perfectly cool, the preparation is laid upon the paper by means of two pieces of sponge in the manner suggested by Dr. Liesegang in his instructions for the production of arrow-root-paper.

When exposed to the atmosphere the paper rapidly assumes a reddish tint, and streaks sometimes become visible upon its surface; these faults disappear, however, on sensitizing the material. The last-named operation takes place in the dark, the paper being treated in a bath made up according to the undermentioned formula:—

Rain water	...	...	1 litre
Nitrate of silver	...	...	60 to 100 grammes
Citric acid	...	...	5 "

The softer the negative the more silver should be employed, and the harder the less quantity.

The exposure is continued until the outline of the picture to be copied appears upon the sensitized paper, when the latter is at once developed in a solution composed of 1 part of a saturated solution of gallic acid to 4 parts of rain water.

\* *Photographisches Archiv.*

The picture is then immersed in the liquid, and will be found to become gradually more vigorous, and to assume a dark-brown tone. It should be raised by the edges now and then for inspection, and, as soon as it appears to be sufficiently vigorous, taken out and floated upon clean water, to prevent the gallic acid from impregnating the paper; after a few minutes the picture may be wholly immersed in the water and well washed, and then passed into an old gold-toning bath, and finally fixed in the ordinary manner.

After retouching, the prints are either polished or varnished, to impart a greater degree of brilliancy.

## PRACTICAL HINTS IN WORKING TANNIN PLATES.

BY M. P. JOHANN GRAUS.\*

HEREIN I beg leave to communicate a few details of the manner in which I operate with tannin dry plates. The principal conditions of success are :—

1. *A collodion film which has been properly applied, and is perfectly adherent to the glass.* The choice of a good tenacious collodion is here an important consideration. Among those with which I have experimented, I have found Dr. Szekely's thick body collodion the most suitable; that of Kleffel gave less satisfactory results in its application to the glass. To render the film more adherent to the glass, I roughened the surface of the plates at their extreme edges by means of a sharp stone. Care must be taken not to allow the formation of air-bubbles in the collodion, as they invariably give rise to comets or circular spots on the application of the developer.

2. *Ample washing of the sensitized film.* I place the plate in a horizontal water bath filled with rain water, and afterwards incline it in a sloping position under a rose of ordinary water for the space of about three minutes; for the latter operation the use of distilled water appears to me unnecessary.

3. *Uniform action of the tannin solution.* The washed plate is well drained, and placed edgewise for a minute or two upon blotting-paper; the tannin solution is then poured on and off the plate several times before it is allowed to remain on for any length of time; or a better plan is to place the plate in a porcelain dish containing the solution, and to tilt the utensil backwards and forwards for about thirty times, allowing the negative afterwards to remain quietly in the solution for two or three minutes, when it is taken out, and, after rinsing with fresh water, drained and dried. In those parts of the plate where the tannin has not acted uniformly, dark streaks or stains will be produced when the negative comes to be developed. The preservative liquid that I use is made up by mixing 15 grains of tannin solution with one ounce of rain-water; after filtration, one-third of a drachm of glacial acetic acid is added, for the purpose of preserving the liquid, which may then be employed as frequently as desired, provided it is filtered every time that it is used.

4. *Proper exposure and development conducted according to the nature of the object.* The most important operation in connection with a dry plate process is the development. Under-exposure and over-exposure may be herein counteracted and corrected, provided the error committed is not too grave. Of invaluable assistance is the system of moistening the plate with a mixture of alcohol and water prior to its treatment with the developing solution, as by the omission of this operation most collodion films are apt to become covered with twig-shaped markings. The alcoholic mixture should be allowed to remain upon the surface an appreciable time, for in hot weather the plates sometimes become very dry, and are then exceedingly liable to the defects just

mentioned. For development I use, for an ordinary stereoscopic plate (exposed, say, five minutes before a usual landscape with No. 5 diaphragm), 3 drachms of distilled water to which 7 to 12 drops of concentrated alcoholic pyrogallic acid solution have been added, together with not more than 2 to 4 drops of silver solution\* in the first instance, in order that the picture, when first developed, may be thin and full of detail. As soon as the details in the shadows are perceptible, more silver is added to the mixture, and the picture intensified to the requisite degree. When manipulating with reproductions of interiors, requiring an exposure of one or more hours, I add to the 3 drachms of distilled water 30 to 50 drops of the pyrogallic solution, and pour this first upon the moistened plate without any addition of silver whatever. Often a few black outlines of the lights are by this means developed, but very slightly, similar to those seen on negatives treated with an alkaline solution. In this manner the hard appearance sometimes worn by pictures of interiors is easily avoided.

## REPRODUCTIONS OF WORKS OF ART OF ALL COUNTRIES.

A CORRESPONDENCE has recently been published between the Prince of Wales, President of Her Majesty's Commissioners for the Paris Exhibition, and the Duke of Marlborough, in which the aim is to popularize art education by promoting art reproduction. The Prince of Wales states that during the Paris Exhibition a Convention was entered into by several princes of the reigning families of Europe, whereby they agreed mutually to assist the museums of Europe in procuring casts and copies of national objects for the promotion of art, and asks the co-operation of the Science and Art Department.

The Duke of Marlborough replies, giving his cordial adhesion to the project. The following are the conditions of the

### CONVENTION FOR PROMOTING UNIVERSALLY REPRODUCTIONS OF WORKS OF ART FOR THE BENEFIT OF MUSEUMS OF ALL COUNTRIES.

Throughout the world every country possesses fine historical monuments of art of its own, which can easily be reproduced by casts, electrotypes, photographs, and other processes, without the slightest damage to the originals.

(a.) The knowledge of such monuments is necessary to the progress of art, and the reproductions of them would be of a high value to all museums for public instruction.

(b.) The commencement of a system of reproducing works of art has been made by the South Kensington Museum, and illustrations of it are now exhibited in the British Section of the Paris Exhibition, where may be seen specimens of French, Italian, Spanish, Portuguese, German, Swiss, Russian, Hindoo, Celtic, and English art.

(c.) The following outline of operations is suggested :—

1. Each country to form its own Commission, according to its own views, for obtaining such reproductions as it may desire for its own museums.

2. The Commissions of each country to correspond with one another, and send information of what reproductions each causes to be made, so that every country, if disposed, may take advantage of the labours of other countries at a moderate cost.

3. Each country to arrange for making exchanges of objects which it desires.

4. In order to promote the formation of the proposed Commissions in each country and facilitate the making of the reproductions, the undersigned members of the reigning families throughout Europe, meeting at the Paris Exhibition of 1867, have signified their approval of the plan, and their desire to promote the realization of it.

Princes of the following countries have already signed the Convention :—Great Britain and Ireland, Prussia, Hesse, Saxony, France, Belgium, Russia, Sweden and Norway, Italy, Austria, and Denmark.

\* The silver solution here alluded to is the following :—

Nitrate of silver	...	...	...	20 grammes
Citric acid	...	...	...	20 "
Water	...	...	...	1 ounce

\* Read before the Vienna Photographic Society.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.

CHAPTER XXXV.

As the composition of family or social groups is so difficult, I introduce yet another example, this time with most of the figures standing. It is by Wilkie, and represents "Sir Walter Scott and his Friends," the figures being dressed in rustic costume, and treated in a picturesque manner: a subject on which I shall have something to say in another chapter. The fact of the design being by Wilkie, of whom it may be almost said he never misplaced a line, is sufficient to recommend it to the attention of the student. The chief object in the composition is Sir Walter Scott, and he is placed near the centre; but the artist has avoided the

error of getting the head precisely in the middle, which is the weakest place in any picture. He is also further distinguished from the surrounding figures by being the only one represented seated; this gives the figure a dignity which contrasts well with the others. The pyramid formed by Sir Walter is supported by the flagon and cloth in the foreground. The student will note that these objects—the highest light and the deepest dark in contrast—form the key-note of the group. He will also notice something analogous in every well designed group of figures: "The string shows through all the beads." Many of the pictures selected to illustrate these concluding chapters will be found to have it, although they were not chosen to illustrate this especial point.

It should especially be noticed that every line and form is arranged so that a series of pyramids intersecting each other are created; that the apex of each pyramid is espe-

cially emphasized; see the dark hat of the tall standing figure, which forms the point of one of the principal pyramids, and the milk-pail which caps the other; then notice how the pyramidal groups cross one another, the staff of Sir Walter Scott forming part of the side of the pyramid of which the milk-maid is the principal figure, and whose foot makes one of the base angles of the other group. Another pyramid, which has for its apex the head of the woman in a bonnet, runs into the adjoining similar form; and the black basket on the woman's arm, combined with the dark form of Sir Walter's favourite deer-hound, admirably supports the whole group. Of this dog it may be mentioned by the way, the owner used to say that he always liked to have him with him in his walks, if for nothing else but to

furnish a living object in the foreground of the picture; and he noticed to a companion how much interest was given to the scene by the occasional appearance of the black hound at unexpected points. Sir Walter always talked and wrote of scenery like a painter, yet for pictures as works of art he never pretended to have any regard.

There has been much discussion as to the position of the horizon in a figure photograph, some asserting it may be almost anywhere, even as low as the feet, so that it is conducive to pictorial effect, while others hold that it must be level with the head of the figure, because the horizon is always level with the eye of the observer; but for this to be true the eye of the artist must be on a level with the head of the model, which never need be the case; in fact, a photo-

graph of a standing figure taken with the lens level with the head would, if the lens were not of very long focus, be considerably distorted and out of drawing in the legs and feet; on the other hand, if the lens were very much lowered, as would be the case when the horizon is represented low, the face would be shown at a great disadvantage, presenting the chin and the nostrils as the most prominent objects. A middle course appears to be best, where the lens is stationed opposite the breast, and its focus requires it to be not less than sixteen feet from the model; the horizon would then be a little below the shoulders, and leave the head clear against the sky; in our illustration Wilkie has placed it rather higher, but he has made it so indistinct that it does not interfere in the least degree with the figures.

It may be taken as a rule that, other things being equal, the lower the horizon the larger will the figure appear.

Even in his humblest subjects Wilkie composed gradually. In noticing this fact Burnet observes: "Many who may notice these remarks will perhaps conclude that Wilkie, in familiar subjects, may be compared to Raffaele in the great compositions of historical painting, and that he may be subjected to the same chilling critical expression: that he arrived at excellence, not so much from his power of genius, as his long study and application. But nothing great or lasting can be achieved without minute investigation into the works of nature, and as we perceive the means she takes to produce the endless variety of effects, we are rendered more capable of imitating her." It was not so much the overpowering impulse of genius that made Wilkie a painter, as hard study. Genius is not to be despised, but it is of very little use if it be not supplemented by that success-compeller—work.

#### OBSERVATIONS ON THE CARBON PROCESS.

BY M. JEANRENAUD.\*

THE process which I am about to describe is that made known to us by M. Poitevin, M. l'Abbé Laborde, M. Fargier, and M. Swau. It is based upon the action of light on gelatine impregnated with bichromate and mixed with certain colouring matters, upon the necessity of washing the impression thus obtained from the reverse side, upon its transfer to a support by means of a cementing material insoluble in water, and upon its final re-transfer to a definite basis.

The beautiful examples produced by M. Braun demonstrate the perfection to which this process may be brought, and in order to induce a more general employment of the methods I have deemed it desirable to make an investigation into the subject for the purpose of discovering the most suitable formulæ, and thus aiding the operator in the practical manipulations. At the same time it must be remembered that the process is a patented one, and that all desirous of practising it commercially must first purchase the right so to do.

I have been assisted in my researches by M. Gobert, who had already made a large number of experiments in this direction, and with his help I have sketched out the following mode of operating, which was included in M. Davanne's *Annuaire* for the present year.

*Preparation of the gelatine.*—The best gelatine for the purpose is that of ordinary quality, which is sold in commerce in thin sheets. The superior colourless qualities are not at all suitable, but that description of material which possesses a yellowish appearance, and costs from three and a half to four francs per pound, has been found to yield the best results. If the finest gelatine only is procurable, then a small quantity of good glue should be added, in the proportion of one part of the latter to three of gelatine; by this means a compound is obtained possessing the requisite degree of solubility. Glue employed alone does not set readily, and, notwithstanding the reaction of the bichromate

of potash and ammonia, remains in too soluble a condition. Take of—

Gelatine	...	...	60 to 70 grammes
Water	...	...	1,000 cub. centimetres
Glycerine	...	...	20 do. do.

If the addition of glue is necessary, substitute a portion of the gelatine (say 20 to 25 grammes) by an equal quantity of glue, which should be allowed to moisten in cold water twenty-four hours beforehand, to facilitate its dissolution. The mixture is placed in a water bath to ensure perfect solution.

*Pigments, or colouring-matter.*—The colouring-matters used must be insoluble, and ground so fine that when mixed they produce tints of the most perfect regularity, similar to those obtained with sepia or Indian ink; they should likewise be of a light specific gravity, so as to remain in suspension in the gelatinous liquid. If a mixture of various colours is prepared, it is necessary that all of them should be of the same density, otherwise they will become separated, and an inequality will be observable in the tints. The colours can only be properly prepared by an operator skilled in the work; and I take this opportunity of thanking M. Colcomb Poignaut for his assistance in furnishing me with a series of tints specially prepared for my experiments.

The pigment which has furnished me with the best results is lampblack to which was added a small quantity of purple (*purpurine*); this mixture was found to counteract the greenish tint imparted to the gelatine by an insoluble oxide of chromium, which becomes formed in the process.

The colouring-matter is added to the gelatine by degrees in such quantities until a few drops of the mixture placed upon paper appear completely black, although, when viewed by transparent light, they are not opaque; the proportion of colouring-matter to be added is varied according to the general character of the negative. When the pigment has been thoroughly mixed with the gelatine the compound is strained through a sieve of fine silk, which keeps back all coarse particles, the operation being facilitated by means of a camel's hair brush, which may previously have been used in mixing the colours. The mixture, when strained, should be placed in a vessel in the water bath.

*Coating the paper with gelatine.*—The most suitable method of applying the gelatine is to place a series of glass plates one above the other in a light wooden frame, the first plate being fixed in a perfectly level position, so that the others, when placed above it, are also quite level. A moistened sheet of paper is carefully laid upon the first plate, care being taken to avoid the formation of air-bubbles, and the excess of water removed by the application of a piece of filter paper. The coloured gelatine is placed in a vessel furnished with a spout (an ordinary porcelain teapot will answer the purpose), the orifice of the latter being contracted to a diameter of about 2 millimetres by fitting to the same a piece of narrow tubing; and the liquid is then poured upon the paper in a series of parallel lines which run into one another, and form, while yet warm, a perfectly smooth film of uniform thickness. If the gelatine is too warm when used, inequalities of a circular form will be produced; but at a suitable temperature of about 30° C. the mixture flows like syrup, and gives a very even surface. It is convenient to facilitate the spreading of the gelatine by means of a glass triangle of the same breadth as the sheet of paper.

A second plate of glass is now placed upon the first, and the operation repeated. At an atmospheric temperature of 12° to 15° C. the gelatine sets so rapidly that one is able, after a series of five or six plates, to remove the first sheet from its position, and to hang it up to dry in the open air, so that the operation of coating may continue in a regular manner without cessation. If the temperature is below 12° C. the gelatine sets too rapidly, and if above 20° C. it takes so long to congeal that it is necessary to work with a large number of frames. The sheets require exposure to the air for twelve to twenty-four hours before they are perfectly

\* Read before the French Photographic Society.

dry, and they should then be piled upon one another, and stored in a slightly damp locality, in order that they may regain their former evenness of surface.

**Sensitizing.**—A solution of bichromate is prepared of three per cent. strength for winter use, and two per cent. for summer; and to this is added one or two per cent. of pure glycerine (according to the dryness of the atmosphere), and one cub. centimetre per cent. of pure ammonia. Each gelatinized sheet is immersed in this cold solution, and after remaining therein for the space of three or four minutes, removed and hung up to dry. The operations of sensitizing, drying, &c., must, of course, be performed in a dark work-room illuminated by a small lamp or a window of yellow glass. When dry they are put away in a box, being laid perfectly flat, and placed in a cool place, so that they may become sufficiently pliant and flexible for manipulation in the printing-frame. It would appear preferable to make use of a new bichromate bath for every fresh batch of paper.

**Exposure.**—The period of exposure varies, of course, with the intensity of the light and the transparency of the negatives, but it may be said to be about a quarter of the time necessary to produce a print with chloride of silver. An over-exposed print becomes sticky, and is difficult of removal, while an under-exposed impression is incomplete when developed; at the same time much may be done in the operation of development by using water in a more or less warm condition.

As I before stated, the fine details and half-tones can only be obtained by washing the print from the back, and it is necessary, therefore, that the gelatine surface which has received the photographic impression should be attached to a sheet of paper by means of a cement insoluble in water: a mixture of india-rubber and resin forms the best cement for the purpose.

**Preparation of the paper with India-rubber cement.**—The following compound is prepared:—

Rectified sulphuric ether	...	...	200 cub. cents.
Native white rubber, cut into thin strips	...	...	20 grammes.

The latter is allowed to moisten in the ether for twenty-four hours, when is added—

Ordinary benzole	...	200 cub. centimetres
Gum elemi*	...	20 grammes.

The whole is thoroughly mixed by frequent agitation, and the result should be a syrupy liquid of thick consistence, which requires straining first through a piece of coarse muslin, and afterwards through flannel, to remove any precipitate that may have been formed. The solution which I have found to answer best is the soft india-rubber cement of commerce, dissolved in benzole, in the proportion of 100 cub. centimetres of the cement to 500 cub. centimetres of benzole.

This india-rubber solution is poured upon sheets of paper in the same manner as collodion, the corners of the sheets having first been turned up to facilitate the operation; the paper is hung up to dry, and if it does not prove sufficiently adherent a further quantity of the solution should be poured on at right angles to the first application, so as to ensure a coating of uniform thickness. The whole operation of preparing this cemented paper may be performed some time beforehand; but, inasmuch as the prepared sheets stick together if piled one upon the other, it is perhaps better to make it as wanted.

When the sensitized gelatine film has been sufficiently printed, it is taken out of the frame and laid upon a flat surface (upon a marble slab or glass plate); a sheet of paper covered with the india-rubber solution is then placed in contact with it, and both pressed firmly together, first by the hand and afterwards by drawing over them the edge of a plate so as to exclude all air-bubbles; if the two surfaces do not adhere perfectly they may be placed under a press and subjected to a slight, even pressure.

\* I have likewise found gum dammar to answer perfectly.

**Development.**—The image, thus imprisoned between two sheets of paper, is put into cold water to soak, the temperature of the same being gradually raised to 30° or 40° C. The sheets soon separate from one another, the image leaving its original support, and becoming adherent to the film of india-rubber. The print is rocked to and fro in the water, the temperature of which is gradually raised, until all the soluble parts of the gelatine compound have been washed away; care must be taken to prevent the warm water being poured over the print, and, least of all, over the half-tones, which are so delicate that mere contact with water of too high a temperature is sufficient to remove them altogether. If the operation has been successful, an image of great purity is obtained, and this is washed rapidly twice or thrice in cold water, and then placed upon a sheet of filter-paper to dry. At this stage the picture is reversed, and requires to be detached from the film of india-rubber, in order to be viewed in its proper light.

**Transposition of the print.**—The best way of performing this operation is to prepare a gelatine solution of one per cent. strength, and to immerse therein the finished print, together with a sheet of paper of good quality; then, placing the two together, and taking care that no air-bubbles are formed between, the sheets are slowly drawn over the edge of the bath, and removed from the liquid and hung up to dry. The operation may also be performed by first coating a sheet of paper with a 5 per cent. solution of gelatine, and then manipulating in the same manner as above, but in a bath of cold water. When dry, the india-rubber may be removed by means of a sponge or dabber impregnated with benzole or ether; but a better and more economical mode of proceeding is to roll up the prints and to place them in a glass tube, together with a quantity of ether, and by agitating the same to remove the rubber; the ether may be used again and again until it has quite evaporated. Any particles of india-rubber still remaining on the print are easily dissolved away by immersing the latter in benzole, and afterwards cleaning it with a soft piece of rag.

The finished print is trimmed and mounted on cardboard in the ordinary manner. The most preferable mounting material is a 20 per cent. solution of gum arabic added to an equal quantity of solution of alum.

## THE COFFEE PROCESS.

MR. JEX BARDWELL, with whom this process is a favourite, gives the following comprehensive account of his operations in our excellent contemporary the *Philadelphia Photographer*.

### No. 1.—Silver Bath.

That which you use in your daily practice, presuming that it gives a clean, clear negative by the wet process.

### No. 2.—Collodion.

Any good sample of collodion containing a fair share of bromide.

### No. 3.—Developer.

Alcohol	...	...	1 ounce
Pyrogallie acid	...	...	96 grains

### No. 4.—Silver Solution for Development.

Water	...	...	1 ounce
Nitrate of silver	...	...	10 grains
Citric acid	...	...	20 "

### No. 5.

Water	...	...	1 ounce
Nitrate of silver	...	...	20 grains
Citric acid	...	...	20 "

### No. 6.—Substratum.

Water	...	...	5 ounces
Gelatine (Coxe's)	...	...	20 grains
Iodide of cadmium	...	...	2 "
Bromide of cadmium	...	...	2 "
Alcohol	...	...	2 drachms

No. 7.—*Coffee Solution.*

Coffee, roasted and ground	...	2 ounces
White granulated sugar	...	1 ounce
Water	...	20 ounces

In making No. 6 put the gelatine into the water cold, and let stand for a few hours, and then add the iodide and bromide, and apply a gentle heat till dissolved; when cool, add the alcohol, and filter till perfectly bright.

In making No. 7, add the coffee and sugar to the water cold, and raise to a boil; let cool, and filter bright.

Perhaps it would be best that I should give an evening's work, supposing that the operator has no especial room set apart for this kind of work. Should he succeed, and make a business of it, it is well to have a room constructed so that plates could be prepared at any time; but we will take, for instance, the kitchen for the workroom; time, when the women folks have gone to bed, the table being your bench, and the stove convenient to finish drying your plates, the sink or slop-pail to receive the waste water from washing, a tin that will hold about a quart of water, having a spout with a rose attached to it in the same manner as a garden watering-pot; two four-ounce wide-mouthed bottles for the substratum; a small glass funnel, two dishes, such as are used by the women folks, of an oblong form with sloping sides, of such a size that the plate may rest on the sides without touching the bottom, a few tennypenny nails, and a cloth to wipe your fingers on, is about all that is necessary.

First take a board about two feet long by one wide, and drive as many pairs of tennypenny nails into it as you have plates to prepare, placing the nails about two and a half to three inches apart for the plates to dry on, and set it on the table with the upper end resting against the wall. Presuming the glass to be clean, you coat the plate with substratum in the same manner as you would flow the collodion, it will flow just as readily. Return the excess into the funnel standing in one of the wide-mouth bottles, and into which is placed a small piece of sponge through which the collodion is filtered, when it will be in a fit condition to use again; then set the plate on the nails, with the lower corner resting on the board, when it will drain and dry quite quickly without fear of a back flow. After having coated as many plates as you wish, take the first one and dry completely by the stove, for should it retain any moisture, it might cause the collodion to slip, either in the bath or the washings; you then coat a plate with collodion which we will call No. 1, and place it in the silver bath for about three minutes, when, on taking it out, you will place it face down in one of the oblong dishes, which should be filled with water; then coat plate No. 2, and put into the bath, fill the tin can with a quart of water, and take plate No. 1 out of the dish (it should be moved in the water of the dish until the greasy lines have disappeared), and gently wash with the quart of water, which runs through the rose, then put it into the other dish, which should contain the coffee solution, coated side down. Now take out plate No. 2 from the bath, and put it into the dish of water. Coat with collodion, plate No. 3, and put it into the bath; then take plate No. 1 out of the coffee, and set it up to drain in the same manner as before described; then take plate No. 2 out of the water, and wash as before, and put into the coffee; take out No. 3 and put it into the dish of water, and so continue till you have all the plates done. As soon as they get surface-dried take plate No. 1 and hold it either before the stove or in the oven till perfectly dry—you might almost say baked. In making tannin plates this would cause a quantity of fine circular lines across the plate, but, in this process, I never have had great difficulty; on the contrary have found great advantage in thus baking. The plates are now finished; put them away in your changing-box.

There is, certainly, no difficulty in thus preparing them; it is easy and sure. So far everything is well. I would recommend that the corners of the glass be well rounded and

the edges ground, as they change in the box with so much greater ease, and I find the sharp corners and edges of the plate are apt to fray the wood-work of the box, thereby causing, in time, a sparkle of dust. Should it be deemed best not to use a substratum, which, in fact, I do not recommend if the intention is to work for quick exposures, and with the alkaline development, in such case you should, just before commencing to develop, run around the edges of the plate a camel's-hair pencil charged with Anthony's diamond varnish, which will effectually prevent the film from slipping; the varnish dries quickly, and is the best thing I know of for that purpose. It may be thought, that in consequence of the coffee containing sugar, that it would cause the plates to be sticky; but such is not the fact, they are remarkably hard. It is of the utmost importance that you keep your fingers clean, and, in order to do so, wipe them after each operation, on the damp cloth kept for that purpose, and try to treat each plate just alike; for instance, should you wash one plate more than another, it may cause a difference in the sensitiveness. After some practice, you get to know just the time to give the plate an exposure, with as much certainty as if in your room.

Now comes the tug of war—the development; it is where so many fail. It requires all your care, patience, and good judgment. By the proper exercise of your judgment, in the proportions of the pyrogallic acid and silver, it is in your power to completely control the development, and make a good negative out of what, under ordinary circumstances, would be a complete failure. It is this power that makes pyrogallic acid so valuable as a dry-plate developer. On taking the plate from the changing-box, you first run the varnish around its edges; this, however, is not needed if the substratum has been used; then flow the plate with water, so has to completely moisten the film; then, into an ounce of water, drop five to ten drops of No. 3, and flow the plate with it, and if the picture begins at once to make its appearance, return it to the glass and add a drop of No. 5, but, if slow, a drop of No. 4; then, if the time of exposure was about right, the picture will come up all right; but if the detail are at all backward in making their appearance, add a little more of No. 3. When the details are all out, wash this plate, and you will have a negative perfect in detail, but lacking intensity; but this latter may be obtained by washing the plate, and mixing in another clean glass half an ounce of water, ten to fifteen drops of No. 3, and about ten drops of No. 5; and, on flowing the plate, it will at once acquire intensity. Care should be taken not to carry this too far, as the color of the plate is very non-actinic, and you may produce a negative so intense as to be useless. Then, after well wash and stand up to dry. Do not varnish till perfectly dry, nor attempt to print till the varnish is hard.

I think there is no person who has had any practice with dry plates, but will be pleased with the ease, certainty, and simplicity of this process; but, to those who are making their first attempts, I would present to them a key to success, which is patience, for, without that, no man may expect to be an expert in the practice of dry-plate photography. It is well to remember that pyrogallic acid fetches up the picture and details, and silver produces intensity and hardness; but upon the proper addition of each (which addition must be ascertained as the picture makes its appearance) will depend the value of your negative.

The water used in making solutions and in washing, is such as is supplied to the city by the water-works. I have never observed any trouble that I could trace to its use; therefore, find no necessity to recommend the use of distilled water.

## Proceedings of Societies.

### FRENCH PHOTOGRAPHIC SOCIETY.

A MEETING of the Society was held on the 7th ult., M. DAVANNE, Vice-President, in the chair.

M. PLACET addressed to the President of the Society the following letter, relative to the photo-engraving process recently patented by M. le Colonel Avet:—

"I find in the last number of the *Bulletin* an extract of a patent for photo-engraving secured by M. le Colonel Avet. The process detailed is no other than my own, patented in 1861 and 1863, and published in the *Bulletin* of the 4th December, 1863. It is to be regretted, therefore, that the researches of M. Avet, seconded by those of his adjutant, M. François Drivet, have merely resulted in the discovery of a process which has been known and applied for some considerable time.

"M. Avet is evidently but ill-informed of previous experiments and discoveries, for the artificial grain which he has likewise just invented is, in my opinion, a very old affair. This grain, produced by means of network, has been experimented with times without number, and has always been rejected on account of its monotonous uniformity. M. Avet's grain, however, be it understood, does not in any way resemble mine, and in this respect I do not wish to assert any claim whatever, for in my process the grain is produced of itself, varying in size on every picture, from the intense blacks to the fine details, where it first becomes perceptible."

M. DAVANNE remarked that in reading the accounts of the two processes as they appear in the *Bulletin*, there was certainly a very great analogy between them.

M. LE COMTE NOSTITZ presented to the Society a specimen picture, showing the result of using an iron developer with dry plates prepared by M. Manners Gordon's gum process; the specimen was a portrait obtained with a very rapid exposure on a dry plate.

M. JULES GIRAUD exhibited a collection of micro-photographs, and read a communication detailing the manner in which they were produced.

M. GRUBB, of Dublin, presented the Society with a series of photographs of the moon, taken by means of a telescope constructed for the Government of Melbourne; the pictures were taken on the 1st February last, with an exposure of half a second to two seconds, bromo-iodized collodion being used for the purpose, with iron and pyrogallie acid development.

M. DECAGNY exhibited a large number of prints taken by the Taupenot process, and read the following communication in regard to them:—"The pictures here produced may be divided into several classes, representing nearly all the difficulties against which the photographer has to contend; they include the following reproductions:—

- "1. White marble statues taken in and out of doors.
- "2. Interiors with strong contrasts.
- "3. Monuments with sky and water.
- "4. Landscapes with strong contrasts.

"An inspection of these pictures will suffice to show that, however strong the contrasts may have been in the original, a satisfactory reproduction has generally been obtained, and with the permission of the Society I will expound my theory of the Taupenot process, a theory which I believe holds good in all dry-plate processes.

"The Taupenot process can never be successful without, as in the wet process, the whole picture is at once developed in one operation, recourse being had afterwards to the intensifier; this may be proved in the following manner:—Let us suppose that we have to secure a picture, at any moment, of a landscape with sky and water, together with an old monument or mossy ruin in the foreground; to effect this, either of two ways is generally employed, the first being to give a good exposure and to employ a slow and mild development. What is the result? If a long exposure is given, the high lights of the picture are very quickly developed, and the operator finds himself with a choice of two evils: he may either finish at once, or he may proceed with a slow development. If he takes the former course, the sky and water become impermeable; if the latter, the image becomes flat, the different planes run one into the other, and distance is lost in the sky, while the latter, together with the water becomes dull, the silver refusing to precipitate itself upon those portions of the negative. When even the details in the shadows are brought out, the effect is not more satisfactory. The second way of operating is to time the exposure for the high lights only, and then, if the negative is treated in such a way as to give details in the shadows, the sky and water become covered with a deposit of silver, which is with difficulty penetrable by light.

If, however, as in the first way, a good exposure is given, and the picture developed in such a manner that the whole of the

details are brought out at once, the silver will be found, when the plate is afterwards intensified, to deposit itself equally over the whole surface, securing a result both soft and harmonious.

M. BRIOIS exhibited to the Society some sheets of collodion tinted at the borders, and uncoloured in the centre, suitable to act as screens for obtaining portraits of graduated tint, and likewise other films of collodion, both coloured and uncoloured, for serving as transports for positives.

The proceedings then terminated.

## Correspondence.

### "LUX GRAPHICUS" ON THE WING.

THE HARVEST IS OVER, THE GRANARIES ARE FULL, YET FAMINE IS IN OUR MIDST—PHOTOGRAPHERS' BENEVOLENT AND PROVIDENT SOCIETIES—PHOTOGRAPHY ENNOBLED—REVIVAL OF THE EBURNÉUM PROCESS—THE SOCIETIES AND THE COMING SESSION—PHOTOGRAPHIC APPARATUS V. PERSONAL LUGGAGE.

DEAR MR. EDITOR,—My quill is as restless as my wing, and as I skim about like the swallows, many things fall under my observation that would otherwise not do so, some of which are noteworthy and of interest to the photographic profession, many are not; but harvest time is interesting to every one, and it is of this I am going to make a few remarks. It is always a subject of grave importance and anxiety to a nation like ours, with a very limited area of cereal land, until it is known whether the harvest has been abundant or otherwise. It is also equally important that the harvest, however plentiful, should be carefully reaped and garnered, so that famine may not fall upon the people before another season of plenty shall come in its course. The cereal harvest is over, and has been wonderfully abundant, in spite of the unusually long, dry, and hot summer. The stack-yards are full, and the granaries are teeming with plenty, and there is bread enough for all that can afford to buy. There, that is the qualification that brings to my mind the most serious part of this subject. Although the season has been wonderfully fine and favourable for a rich harvest of all things, "famine is in our midst." A cry of woe is mingled with our mirth. A glorious summer and autumn have, on the whole, yielded a rich reward to the labourers in the pleasant and profitable fields of photography; yet there is want among some of the workers. In the columns of your contemporary I observe a letter "begging alms" on behalf of a poor widow and her little orphans. It is a case of pure charity, and far be it from me to say to any one, "Do not help her;" "They have no claim on the sympathies of the photographic public;" "Neither she nor her late husband did anything to forward the progress of the art nor advance the interests of photographers in general." I grant the latter hypothesis, and say, "He that giveth to the poor lendeth to the Lord." Nevertheless, I cannot refrain from expressing my opinion that such painful appeals should not be allowed to appear in the columns of the photographic journals; all such private cases could and should be provided for by any of the provident organisations so common to other trades. The subject has been frequently mooted in your own columns, but no action has been taken. Very recently a lady correspondent called attention to the subject again, and now, in the pages of your contemporary, I notice an elaborate plan is laid down as the ground-work of a Photographer's Provident and Benevolent Society. That plan is open to some objections, but it is certainly desirable that such a society should be formed. It is rather late in the season for photographers to make any provision for cases 1 and 2 as the correspondent in your contemporary suggests—this year, at least—but I think his other plan of making a provision, however small, for widows and orphans, is highly to be commended, and if only carried into effect would undoubtedly mitigate the anguish and lessen the fear of want in the minds of many deserving women, and might prevent the recurrence of those painful appeals to which I have just alluded. It is just as important and imperative a duty for every man to make some sort of provision for those dependent upon him, as it is for the husbandman to reap and carefully house his harvest. Knowing the interest which you, Mr. Editor, personally take in this subject, I trust that you will exert your influence, and see if it be possible to found a society *at once* that will grow in after years to

be a monument to photography and to the goodness and forethought of the photographers of the present generation.

Photography, like the fine arts, is honoured with a title of nobility. A baronetcy has recently fallen to the lot of one who for years has followed photography as a profession, taking cartes-de-visite and other photographs in the usual business-like manner. Of all the styles of distinction that are conferred upon men, I think baronetcies have been subject to the greatest number of vicissitudes, and spiced with the greatest amount of romance, from the romantic succession of Sir Robert Innes to Sir William Don, "a poor player;" and now the photographic profession includes among its members one of the baronets of England.

Your description of the Eburneum process, given recently in your "Visits to Noteworthy Studios," has awakened quite a new interest in that beautiful form of photograph, introduced a few years ago by Mr. Burgess. Several photographers whom I know have set about producing them. The specimens which I have seen are very beautiful as cards, but they are particularly suitable for lockets, brooches, studs, pins, rings, &c., being sharp, clear, and delicate, and easily cut to fit any size or shape.

Next month some of the London photographic societies will commence the session of 1868-9, and it might be asked, What are their prospects? It is to be hoped that the North London will do better than it did last session. There was more than one *nil* meeting. The South London will doubtless keep up its character, and exhibit its usual vitality. The personal interest taken in the meetings by their kind, genial, and courteous President is almost sure to develop all the latent force of the members. It is also to be hoped that the Society will make as brilliant a start as it did at the commencement of the session last November. Such an exhibition as that in Conduit Street may easily be repeated, though it may not be such a startling one.

The question raised, whether photographic apparatus be or be not considered "personal luggage" by the railway companies, is one of very great importance to photographers, but particularly to amateurs, for if decided against them it will cause no end of inconvenience, vexation, and expense by delays and extra charges. On the other hand, it must be admitted that the view taken by the railway authorities is technically correct. The very word "personal" shows that they mean such articles as are really and absolutely necessary for the personal comfort and convenience of travellers, which can only rightly include wearing apparel, changes of linen, dressing-cases, ladies' work boxes, and writing-desks. These are absolutely indispensable for the comfort and convenience of travellers. Photographic apparatus, and particularly chemicals, do not come under that classification, and I think it is of great consequence to the railway companies and their passengers to know what should, or should not, be put into the "luggage van." I know a case where an amateur photographer was travelling by rail with a 12 by 10 bath full of nitrate of silver solution packed among his clothes in a box in the luggage van. The bath leaked, the solution spoiled all his shirts, and he was driven to the shift of papering his fronts. Now, supposing the box containing the leaky bath had stood upon some one else's box—say a lady's—it might have run through and spoiled some valuable dresses; at the least, it would have spoiled the appearance of the box, to the great annoyance of the lady passenger, and the probable claim on the company for compensation. There are always two sides to a question, and though few men have travelled more with photographic apparatus in the luggage van than myself, I think, in this case, the best of the argument may be fairly ceded to the railway companies.—Yours very truly,

September 18th, 1868.

LUX GRAPHICUS.

#### CARBOLIC ACID.

SIR,—Carbolic acid is derived from tar. Tar is derived from coal. Coal is wood compressed by the agency of masses of matter, and thereby charred or converted into carbon. Coal was made in many instances thousands of years before the light of the sun dawned upon this earth. The wood of which it is composed flourished and grew under an atmosphere and temperature much hotter than our own. The plants and trees that compose coal grew in an age when carbonic acid gas was in excess. The only light that dawned upon those trees was that of what we call electricity. From tar is derived aniline, and many beautiful colours now used in arts and manufactures.

Query—Whether the latent electricity, as contained in coal,

from whence proceeds and is produced carbolic acid, is conducive and beneficial to our silver baths? Mr. Warner, in a contemporary journal, would lead one to consider that it was. Has this ever struck any of your readers?

Electricity, a wood force, plays a much more important part with our productions than we have any idea of. Let your readers look into these facts.—Yours, H. O.

#### WHAT IS PASSENGER'S LUGGAGE?

DEAR SIR,—The question arises, What is passenger's luggage, photographically?—About seven weeks since I started on a photographic trip, taking a third-class ticket. My luggage being in excess of my allowance, they charged me 5s. 8d. overweight. Upon my reaching my destination and looking after my luggage, I found my dark box streaming out a liquid in such a manner convinced me something was smashed. It was but the work of a few seconds before the straps were undone, and, to my annoyance, I found my glass bath was smashed, and contents gone, thus losing the whole of my bath. I made my claims to the S. E. R. Company, and I enclose you their letter (which please return) for the benefit of travelling photographers. I remained five days doing no work, during most beautiful weather. For the future my bath don't leave my sight. It has travelled hundreds of miles. Its bottom dropped out several times by the rotting of the brass screws, but never such a smash. It was nearly a quarter of an inch thick, and now all in atoms.—Yours truly,—G. B. SHEPHERD.

3, High Street, Tunbridge Wells, Sept. 22nd, 1868.

[Annexed is the letter received from the secretary of the railway company in answer to an application for compensation.]

"Mr. G. B. Shepherd, 3, High Street, Tunbridge Wells.

"SIR,—Referring to your communication of the 1st inst. on the subject, I beg leave to acquaint you I have caused enquiry to be made, from which it appears that on the 28th ult., whilst in course of conveyance for you to Shorncliffe as passenger's luggage, a package containing a photographic bath and chemicals sustained damage in some way.

"In a case of this kind, however much the Company regret the loss to the owner, they cannot, as a principle, admit liability upon themselves in any way in the matter, such things not really being passenger's luggage within the meaning of the act.—I am, sir, your obedient servant,

"C. W. EBORALL, General Manager."

#### Talk in the Studio.

PIRATING MR. WOODBURY'S PROCESS.—M. Levitzky, writing from St. Petersburg to Mr. Woodbury, says that a person styling himself Adolphe Angerer, and announcing himself as brother to the celebrated photographer of Vienna, is offering to sell Mr. Woodbury's process to photographers in Russia, and alleging that he has worked with Mr. Woodbury and acquired the process. His pretensions are altogether without foundation. Mr. Woodbury knows nothing of him, and Herr Angerer, of Vienna, states that he has no relative of that name.

PRESERVING PROTOSULPHATE OF IRON.—M. Wellborn states, in the *Journal de Chimie*, that a small piece of camphor placed in a bottle of protosulphate of iron will preserve it perfectly free from oxidation.

THE COFFEE PROCESS.—Mr. W. F. Morgan, of Bristol, well-known as a skilful dry-plate man, says, in a recent letter: "As a dry-plate amateur—chiefly, until lately, with tannin—I must bear testimony to the superiority and simplicity of the coffee process. It appears to me all that its most sanguine admirers claim for it. The film has a tendency to leave the glass, but an edging of varnish secures it."

FLUORESCENCE.—The *Norfolk News*, speaking of Professor Stokes, the President-elect of the *British Association*, gives some account of his experiments in examining the chemical rays of the spectrum by other than photographic means. It says:—"There are certain substances which, when placed in these feebly-luminous rays, become apparently self-luminous, and shine out in the partial darkness of the room with strange brilliancy and beauty. When most of the luminous rays of

white light are cut off by sheets of manganese glass, by cobalt glass, or by a trough filled with ammonia-sulphate of copper, rays scarcely visible to the eye may be made to pass through the room. Then, when slabs of uranium glass, or screens painted over with a solution of rescoline, are placed in the path of these rays, they appear to be self-luminous, and glow with unearthly beauty. We have tried many of these experiments, and find that when uranium glass is the recipient of the rays, it glows with a yellow colour like the moon, when illuminated with the blue rays of the spectrum; but the nearer the colour of the incident light approaches to violet, the greener and the more ethereal is the glow of the uranium glass. Hence it will be seen that if the new President chooses to break through what we are told is an established custom, and next year gives an experimental, instead of a simply oratorical, opening address, the audience will see something worth observing, and yawns and gapes will not greet his gaze."

## To Correspondents.

H. O.—The formula of Mr. Bovey's printing bath, in which sugar is used, stands as follows: nitrate of silver, 6 ounces; pure nitrate of soda, 3 ounces; leaf sugar, 2 drachms; water, 80 ounces. Full particulars in regard to the mode of using appear in our last YEAR-BOOK; but the above formula may probably be sufficient for your purpose. The formula for the toning bath appears in our issue for June 26th last. Full instructions cannot be given very briefly; but the formula may be shortly stated thus: to 12 grains of double chloride of gold and sodium add 1 grain of common salt, and pour into this 1½ pint of boiling water; when nearly cool, add 2 gallons of rain or river water, or well water which has been boiled. The bath is then ready for use, and improves with age. For mode of replenishing, &c., see Mr. Bovey's article.

W. F. MORGAN.—Permanganate of potash may undoubtedly be used for decolorizing the printing bath, without any fear of injurious results. We are glad that you find the coffee process so satisfactory.

H. H. CUNNINGHAM.—At one time it was the custom of the Photographic Society of London to hold photographic exhibitions annually; but for various reasons this has not been done of late years. It is intended to open the next session of the Society in November with an exhibition, which will probably be kept open for a few days. The Royal Cornwall Polytechnic Society also devotes a portion of its annual exhibition to photographs. It is held at Falmouth, opening on the 29th of the present month. The exhibitions are generally open to the contributions of all photographers. 2. Chloride of platinum may be used in toning in the same way as chloride of gold; some photographers have recorded that a mixture of chloride of gold and chloride of platinum give better tones than gold alone. We have seen many examples of the results; but, on the whole, prefer gold alone. The presence of platinum tends to a blacker tone, which we do not generally consider an improvement. 3. Heat will of course reduce any salt of silver to a metallic state; but it is not customary for this result to be brought about in fusing nitrate of silver, unless the temperature were unduly raised, or the heat unnecessarily prolonged. It is not an uncommon thing to find that in an aqueous neutral solution of chloride of gold, the salt is occasionally reduced, and metallic gold precipitated. We generally keep chloride of gold in a concentrated alcoholic solution.

L.—The object of using dilute albumen instead of pure white of egg is to avoid an unnecessary thickness of varnish over the transparency; and a very small portion of albumen is generally sufficient to make the aniline colours "take" freely to the picture. The albumen should certainly not be coagulated with a salt silver, as a sensitive compound is at once formed. There are various means of coagulating albumen, such as nitric acid, bichloride of mercury, sulphate of iron, &c. Which of these would answer best we cannot say; but we do not think them necessary, as the aniline colours generally work perfectly on the albumen in its natural state. Of course, a little practice in such colouring is necessary, in order to succeed. We regret our inability to answer such questions privately, but a very large portion of our time would be absorbed if we wrote private answers in even the exceptional cases which occur.

W. J. A. G.—The quality of the collodion may possibly be a cause of the tendency in England's plates to split in drying, but we are not familiar with the fault. The use of a preliminary coating on this plate might prevent it. The application of a dilute solution of gum or of albumen to the finished negative before drying would be a tolerably certain preventive.

A. J.—Bromide of cadmium is tolerably soluble in alcohol and ether, and should generally, with a little agitation, dissolve in collodion. Sometimes a little mechanical aid is necessary. Use a glass rod with rounded end to crush the salt, and mix it with the collodion; or mix the salt into a paste with about half a drachm of alcohol, and then add to the collodion. You will find no difficulty if you aid the solution in this manner.

JOHN BEATTIE.—The unfinished and unsigned letter was doubtless yours, as we supposed, but were not quite certain. We will write to you in a few days.

G. B. S.—All the experience which has reached us tends to prove that blue glass in a studio has no advantage whatever, but some disadvantages.

SYBIL.—Your lines shall have our careful consideration.

VENATOR.—Varnish made according to the formula in question would be of a dark colour; but this, we believe, will scarcely be appreciable on the negative. The object of adding essential oil is to aid in dissolving the gum. Such oils have no other special value. We have often considered the suggestion you make. There are reasons for and against, and hitherto the latter have prevailed. The lighting and general qualities of your prints are good.

H. C. L.—The markings of which you send us an example are known generally as matt silver stains. The causes and remedies are various, and have been extensively discussed in our last two or three volumes. For full consideration of all the causes and remedies we must refer you to the articles which have appeared in our pages under the heading in question. A general remedy consists in extreme cleanliness, keeping the inner frames of your dark slides constantly washed, allowing the plate to rest on clean blotting-paper, avoiding delay between exciting and developing the plate, and avoiding the use of a very strong bath, or a very old one. 2. Cockling is always due to unequal expansion and contraction of the print and mounting-board. One remedy is the use of strong mounts; another, sponging the card, so that it may become as damp as the print before placing the two in contact; another, the use of an adhesive material with very little moisture, such as glue. When paste and similar materials are used, the water penetrates the print and makes it expand. If it be placed on the dry board in this expanded state, it will necessarily contract in drying, and this necessarily drags the board and makes it cockle. 3. The simplest method of ascertaining the precise specific gravity of alcohol of which you know the number of degrees over-proof, is to consult a table of the relations between the two. The term "proof spirit," and the mode of determining strength by degrees over-proof, are both clumsy. As a general indication of their relation, we may mention that proof spirit has a sp. gr. of .9200 at 60° Fah. Absolute alcohol, which has a sp. gr. of .8005, is 70 over proof. Spirit 60 over proof has a sp. gr. of .8298. 4. The offensive smell of some albuminized paper is due to the use of decomposed albumen in its preparation, or to keeping the paper in a damp place, causing decomposition.

W. L. S.—There is no especial advantage in exciting your paper in whole sheets, beyond the saving of time. Where a large amount of printing is done it is a good practice, as it saves time and permits the sheet to be cut up as economically as possible, which dividing the sheet into halves or quarters for the purpose of sensitizing does not always permit.

F. F.—Where all the washing waters, hypo, developing solutions, &c., are mixed together, liver of sulphur (polysulphide of potassium) is the proper material for precipitating the silver. The silver will be thrown down, of course, as sulphide of silver, and can then be reduced in the usual way.

VERY OLD SUBSCRIBER.—Your general design is good. We should prefer facility for extending the light a little laterally; 6 feet 6 inches in front of background, in some cases, will be found too much without light. Better have the whole of the 10 feet in the roof of glass. Use ordinary crown or sheet glass. The ribbed glass will obstruct a good deal of light, and should not be used, except where necessary to exclude direct sunlight, or prevent the interior of the studio being overlooked. As a rule, have all your glass continuous, so as to form one extended light, not a series of small ones. If possible, therefore, bring your side-light a little nearer the background instead of introducing small windows.

HON. J. W. STRUTT.—Received. Thanks.

ERRATA.—In the description of M. Reutlinger's studio, the sitting is described, by a clerical error, as thirty-five minutes; it is obvious that it should have been thirty-five seconds. In the article on India-rubber as a Protection for Negatives, the words "pliable resin" are found in the last line but one of the first paragraph; they should have been "friable resin."

Several Correspondents in our next.

### YELLOW SPOTS ON PRINTS.—IMPERFECT FIXATION.

NOTWITHSTANDING all that has been written on the subject of fixing prints, amongst the defects brought under our attention from time to time by troubled correspondents, there is none of such frequent and regular occurrence as the results of imperfect fixation, manifested either by mottled stains of a yellowish green or yellowish brown throughout the print, or by patches or spots of the same colour scattered more or less plentifully over the picture.

The cases of examples of imperfect fixation throughout the whole print are not, happily, of very frequent occurrence. The importance of the plentiful use of fresh strong hyposulphite solution has been so constantly urged of late years, that few photographers are likely to err so far in this matter as to produce the mottled, greasy-looking prints which indicate imperfect fixation in its worst phases; yet several examples of this kind have come under our attention during the last few days, with queries as to the cause of the mottled yellow stains which pervaded the whole texture of the paper. The commoner form of the defect, however, consists in the existence of spots of yellow or yellowish green, or yellowish brown, not seen generally until the prints have left the washing water and are spread out to dry, and sometimes not seen until the prints are mounted. The fact that the print appeared pure and spotless in the various stages of its production, and is only seen a few hours, or sometimes a few days, after a very careful washing, which seems generally the puzzling part of the matter, affords really the certain indication of the cause of the defect.

To make the matter clear to those of our readers who are not familiar with the processes involved in the operation of fixing a silver print by hyposulphite of soda, we may briefly and simply restate the nature of the reactions:—On the first contact of the chloride of silver in the prints with hyposulphite of soda a double decomposition takes place, producing hyposulphite of silver and chloride of sodium. Hyposulphite of silver combines with an excess of hyposulphite of soda, and forms a double salt freely soluble in water. It is on the presence of this double salt that perfect fixation depends, because there is a second form of hyposulphite of silver which is produced when there is not an excess of hyposulphite of soda, and which is comparatively insoluble in water, but soluble in a strong fresh solution of hyposulphite of soda. This sparingly soluble hyposulphite of silver is formed when the fixing solution is nearly exhausted, or when the solution from any cause is prevented from acting freely on the print; and it is to the presence of this salt, and its subsequent decomposition, that the yellow stains of imperfect fixation, either as small spots or universal mottling, are due.

When the process of fixing is going on perfectly, there is

no appearance in the print which presents any peculiarity to the eye; but as soon as the fixing power of the solution begins to be exhausted, or the print from other causes is being imperfectly fixed, on being held up to the light it presents a number of opaque spots of a yellowish tint. If the formation of these spots be discovered at once, they may be at once dissolved, and the print properly fixed by fresh strong hyposulphite solution; but the defect is rarely seen until the decomposition of the hyposulphite of silver issues in yellow stains of greater or less extent.

The single hyposulphite of silver is very prone to spontaneous decomposition, the final products of which are sulphide of silver and sulphur. Its decomposition is still more readily effected by the action of light. Being a colourless salt, it is not, as we have said, observed until it is decomposed; and as the prints are often washed in the dark room during the night, this decomposition rarely takes place until the prints are spread out in the light to dry, and, under some circumstances, at a later period. Sometimes, but rarely, these stains of sulphide of silver will become black; they generally retain the yellow tint of sulphide of silver in combination with a decomposed organic salt of silver. The decomposed salt forming these stains will generally be found in the body of the paper, or between the paper and the albumen, forming opaque patches, as may easily be seen on examining the prints by transmitted light.

The occurrence of imperfect fixation throughout a print is always traceable to the use of weak, exhausted, or acid hyposulphite solution; but the causes of spots or patches of imperfect fixation are often more puzzling to the inexperienced printer. Such spots are, however, generally traceable to one of three causes: 1, the prints sticking together whilst in the fixing bath; 2, the formation of air-bubbles on the prints on immersion in the fixing bath; 3, or the contact of the print with hyposulphite before immersion in the fixing bath.

1. If the prints are immersed in the fixing bath in batches, and are not kept moving, each print receiving separate attention, they are apt to stick together, and some portions of the prints are imperfectly acted upon by the fixing solution. Such prints are liable to irregular yellow patches of imperfect fixation.

2. When a print is first immersed in the hyposulphite solution, air-bubbles are very apt to form on its surface, and adhere with great tenacity, thick horny papers being more liable to this tendency than thin soft papers. If the bubbles are large they are easily seen and removed, and the mere act of turning over the prints will generally break such bubbles; but in many cases minute bubbles are not easily seen, and not easily removed in the ordinary course of moving the prints in the solution. Such bubbles effectually protect the surface they cover from the perfect action

of the fixing solution, and are perhaps the most fertile of all causes of the small yellow spots with which many photographers are only too familiar. The remedy is simple: it is necessary carefully to examine each print as it is turned over in the fixing bath, and remove with a brush or sponge the bubbles as they are formed.

3. The last mentioned cause is not, we hope, very common, but it has come sufficiently frequently under our attention to render a caution to the inexperienced not unnecessary. Young printers who are conducting the whole of the operations themselves are apt to be forgetful of the importance of carefully cleansing the fingers every time they come into any kind of contact with hyposulphite of soda, and a slight taint of this substance on the fingers coming into contact with excited paper will certainly issue in a stain, which will generally become visible before the picture is finished.

Other occasional causes will conduce to imperfect fixation. Occasionally it will result from defects in the paper; and occasionally from the long keeping of excited paper in hot weather, a compound being formed between the silver and the size in the paper not readily soluble in the fixing solution, and eventually issuing in decomposition and discolouration. But our aim has been here to call attention, for the benefit of the less experienced of our readers, to some of the most common and most easily remedied sources of defects which we have reason to believe are only too common.

In answer to the oft-repeated question as to the proportion of hyposulphite of soda necessary to fix a given number of prints, we can only repeat what we have often before stated, namely, that the number which may be safely fixed in a definite quantity of hypo solution cannot be absolutely stated. Much discussion has arisen on the subject, but no absolute certainty obtained. Many circumstances will affect the question, such as the thickness of the paper, the proportion of chloride of silver present, the extent to which it is reduced, &c. Theoretically, about three parts of hyposulphite of soda will be required to dissolve one of chloride of silver. One whole sheet of sensitive paper has been calculated to contain about from 25 to 30 grains of chloride silver. On this theory about half a dozen sheets of paper might be fixed by one ounce of hyposulphite of soda. In practice, however, so many other circumstances interfere, that perhaps not more than one-fourth or less of that number ought to be fixed in the quantity. The rule of keeping the solution alkaline cannot be too strictly enforced, and the use of carbonate of ammonia, as recommended by Mr. Spiller, will certainly conduce to safety. If any trace of acidity exist in the toning bath the prints should be very carefully washed before immersion in the fixing bath.

Observation and experience are, of course, necessary, and form the best guides for the practical printer; and until that experience is gained, the operator should take care never to tread on the heels of danger. As to the time of immersion, the temperature and the quality of the paper will somewhat influence the decision. Thin Saxe paper will generally be fixed in new solution of hypo, or 6 ounces in 4, in about ten minutes; thick Saxe will require fifteen minutes; thin Rive paper about fifteen minutes, and thick Rive about twenty minutes. A slightly albuminized paper will be fixed more rapidly than a highly albuminized sample; the principle being, that the more horny and repellent the surface, the longer the time of immersion.

#### WET COLLODION WITHOUT WATER.

EVERY photographer knows how much of comfort, and even of success, depends on the observation of apparently minor points in manipulating. We have had many scores of letters thanking us for the publication, a few years ago, of a communication by Mr. Russell Manners Gordon, in which he incidentally pointed out the importance of adding the same proportion of alcohol to the developing and intensify-

ing solutions, and to the silver solution to be used therewith, in the process of intensifying. Attention to this permitted the free mixture of one solution with another, or of one after another, without risk of greasy lines, and consequent stains, and at once promoted ease in working and success in result. We have ever since regarded this as a settled canon of manipulation, to be observed in all circumstances in which it can be brought into operation.

In our recent remarks on Wet Collodion without Water it did not occur to us to repeat the injunction in reference to the preparation of the golden syrup solution. To secure an even flow, and obtain entire immunity from risk of stains, it is necessary to add alcohol to the syrup solution; otherwise, on its first contact with the developer containing alcohol, the well-known repulsion of the particles of the two solutions will take place, causing streaks and stains. Mr. Robinson calls our attention to the importance of mentioning this, in order to save a few disappointments to those who may try the process without at first thinking of this point. He says:—

"In your article on this subject last week you have omitted to state that some alcohol should be added to the preservative solution. Without this addition the golden syrup and water presents a very oily appearance when poured on the developed plate, and stains are inevitable. Of course this does not occur to any great extent when no alcohol has been used in the developer, which is seldom the case, except for very small plates, and few photographers now care to use a developer that will not take kindly to the plate. The best proportions are,—

Golden syrup ...	...	...	10 ounces
Water ...	...	...	10 "
Alcohol...	...	...	6 drachms.

Although the negative may be intensified at home, in practice I always perform that operation in the field, by adding a few drops of silver solution to the iron developer, and using it again. The muddiness formed may be disregarded.—H. P. ROBINSON."

#### NEGATIVES TRANSFERRED TO LEATHER COLLODION.

MR. WOODBURY has recently brought under our attention some examples of the transferred negatives treated in the mode which he has recently described in our pages. Considering the simplicity of the means and the excellence of the result, it is a little surprising that the system has not been much more commonly adopted than it is at present. Those we have examined are sufficiently thick and firm to be handled with perfect convenience; and, except by wilful injury, it seems impossible that they can in any way come to grief.

No appreciable difference in definition is visible in prints printed with different sides of the transferred negative in contact with the sensitive surface; but, theoretically, it would seem that a sharper impression could be obtained from the negative when reversed, as required for use in connection with many of the mechanical printing processes, because the image formed in the original collodion film, without intervention of any film of varnish, gelatine, or collodion, is in contact with the sensitive surface.

One or two points worthy of remembrance in connection with the process were mentioned by Mr. Woodbury. The first relates to the intensity of the negative. It is customary, in ordinary operations, to carry the intensification a stage further than is required for printing, because it is generally somewhat reduced by the final varnishing. Most operators like to see the negative, when finished and wet, present to the eye just the proper amount of intensity. On drying, this is considerably increased; and on varnishing, again reduced to about the condition of intensity possessed by the wet negative. As, however, neither the coating of gum, nor the final layer of collodion which is to form the substitute for glass,

in any degree reduces the intensity of the image, it is important to avoid obtaining too much density in the producing the negative.

A second point requiring great care is the levelling of the negative before pouring on the thick film of collodion, otherwise an uneven and unsatisfactory layer is irremediably produced. And, finally, it is of vital importance, after the combined films are removed from the glass, to lay the transferred negative they form between sheets of clean blotting-paper, and allow them to dry under a weight. If removed whilst still in any degree damp, they are apt to cockle, and no subsequent treatment will make them lie perfectly flat.

### VARNISHES FOR NEGATIVES.

THE *Photographisches Archiv* contains some remarks on varnishes by Herr Bienert, in which he expresses a conviction that cracking of the film and varnish is more frequently due to keeping the negative in an apartment subject to changes of temperature than to imperfection in the varnish. He recommends the following formula, stated to be that of Herr Haefstangl. We may remark, in passing, that it appears to us that a varnish so made would be scarcely so hard as the best varnishes in the market. The alcohol employed is to be strong, but not so strong as to dissolve the collodion film. The specific gravity should not exceed 817.

Alcohol ... ..	2 ounces
White shellac ... ..	100 grains
Venice turpentine... ..	20 "
Gum sandarac ... ..	10 "
Gum mastic ... ..	5 "

A varnish which may be used with very little heat, but is unsuitable for carelessly kept negatives, subject to changes of temperature, stands thus:—

Turpentine (common) ..	$\frac{1}{2}$ drachm
Venice turpentine ... ..	$\frac{1}{2}$ "
Gum sandarac ... ..	2 $\frac{1}{2}$ "
Sugar ... ..	3 grains
Camphor ... ..	2 "
Alcohol ... ..	2 $\frac{1}{2}$ ounces

We fear that the film given by such a varnish will very easily scratch.

### ECHOES OF THE MONTH.

BY AN OLD PHOTOGRAPHER.

A PHOTOGRAPHER'S PROVIDENT SOCIETY—PHOTOGRAPHER'S PERSONAL LUGGAGE—TRANSFERRED NEGATIVES—BLUE GLASS IN STUDIOS—INDIA-RUBBER FOR MOUNTING—TOUCHING NEGATIVES—ENCAUSTIC PASTES—SOCIETIES.

I HAVE often wondered to what singular cause the fact was due that, notwithstanding the repeated discussions which have occurred on the importance of establishing some Provident Fund, or Benevolent Society, or combination of both, for the relief of the aged, the sick, or unfortunate amongst photographers, so little practically—in fact, nothing—has yet been effected. It cannot be that any notion exists that photographers possess immunity from the ills of life; it cannot be that less care prevails amongst them for the sufferings of their fellows; it cannot be that as a community they are too poor to establish a fund for the relief of each other; it cannot be that they are not sufficiently numerous to require a separate provident or benevolent organization on their behalf; it cannot be that there are not sufficient intelligent and capable men amongst them to carry out such a purpose; surely it cannot be, as some assume, that the men most capable of carrying out such a scheme are the least likely to need its aid, and are too supine to take action in a matter which does not touch their immediate interests.

Possibly some light may be thrown on the question if I record some observations I recently heard in the course of a conversation on the subject amongst some photographers.

"It was a fatal mistake," remarked one, "that the first appeal to the benevolence of photographers should have been made for an individual instead of a general cause. If the same effort had been put forth for the relief of all the needy and deserving in the photographic community, it is likely enough that a very large sum would have been secured at once, which, augmented by annual subscriptions, might, if carefully administered, have met with some efficiency all cases of need for years to come. Unfortunately it was not so, and the trouble which those having charge of the Goddard Fund seem to have had with the recipient himself and with his executors, and the attempts to cast discredit on their conduct by men of no credit, will probably check many in any effort to establish a general fund."

"The expenditure of so much effort for an individual fund was clearly a mistake," rejoined another; "but it is easy to be wise after the event. But the aim was a good one, and the troubles in the way could not have been anticipated. As for the attempt to malign those who did the work in the Goddard business, I should hope that no men of sense would be deterred from doing a good thing because of the snarling of two or three pariah curs."

After some further conversation, another gentleman remarked: "The real difficulty is a common one: what is required is, a beginning. Many will be willing to work and give when once the thing is begun, if the project be begun under satisfactory auspices. If a committee of a dozen trustworthy men were formed, with an active secretary, or two secretaries, also men of standing and reputation in the profession, I feel satisfied the project would soon become a success. Find the men willing to take the first steps, and all required steps will soon follow in due course."

I must confess that I am much disposed to agree with the last quoted speaker. Who will begin? Perhaps none is so fit as the long established editor of a long established journal. Will our Editor, the first projector of such a scheme, undertake the duty, and at once invite subscriptions?\*

The somewhat interesting question recently raised, "What is personal luggage, photographically considered?" possesses, like most questions, two sides. It seems undoubtedly natural enough, at first sight, to say, that provided the proper weight has not been exceeded, it cannot be a matter of consequence to the company whether the luggage consists of photographic apparatus or of boots and tooth-picks; yet, on second thoughts, it is clear that it does matter much, as two of your correspondents last week illustrate. It is, I fancy, pretty clear that the photographer ought not to claim compensation for broken nitrate baths. Such things would require, as a rule, much greater care in transit than a trunk of clothes; and if, when treated in the same manner as the latter, a bath breaks, it does not seem unnatural that it should be at the photographer's own risk. If the nitrate solution running out of such broken bath leak into some case containing a lady's valuable wardrobe, from whom should she recover compensation—from the company, or from the photographer?

I have recently seen some of the negatives transferred by the process Mr. Woodbury described a short time ago in your pages. Nothing could be more perfect or convenient for use; they were quite sufficiently stout to be convenient for use—limp and elastic, so that there was little risk of cracking or scratching them, and wonderfully convenient for storage, besides possessing the especial advantage, in

\* We scarcely agree with "An Old Photographer" here. A journalist has rarely sufficient leisure to permit him to undertake such duties and responsibilities. Our sympathy and aid may always be calculated on in such a matter; but we have long made it a rule not to accept the charge of moneys in any such case. Besides, the first step is organization, in the course of which a treasurer will necessarily be appointed. If necessary, we will, at all times, aid in transmitting money to such an officer, but we cannot undertake his office.

relation to photo-engraving processes, of permitting either side of the negative to be placed in contact with the sensitive surface. I fancy that the time will come when the use of transferred negatives will be much more common than it is now.

I have noticed recently a tendency to revive the question of the advantages of blue glass in studios. I see from your pages that an elaborate paper was recently read before one of the German photographic societies on the subject, giving countenance to the notion that some advantage was to be gained by its use. I should not like to be guilty of discourtesy or dogmatism, but I cannot help remarking that this seems to me one of the greatest absurdities ever propounded. White glass admits all the rays of light, the blue, or most actinic ray, amongst the rest; blue glass only admits the blue ray; but it does not admit of anything which the white glass excludes, nor can it exclude anything which can be injurious: whence, then, the advantage? If I have a sovereign and a handful of silver, and copper besides, I am surely richer than if I had only the sovereign. If the other rays which go to form white light had any injurious or retarding effect, something might be gained by excluding them; but nobody has ever pretended that the other rays were injurious. It is known, on the contrary, that although blue is the most actinic ray, some of the other rays have also a degree of actinic power. Whilst nothing is gained by the use of blue glass, I am not equally sure that something is not absolutely lost in rapidity, besides the displeasing and gloomy effect of the blue-lighted studio.

My experience decidedly confirms that recorded in the News as to the uselessness of india-rubber for mounting prints. From the large number of examples I have already seen in my own possession, and in that of others, curling off the card, I am satisfied that it is most untrustworthy as an adhesive material, or as a "mountant," as some would affectedly phrase it. I have not tried it as a means of preventing negative films cracking, but I have used it as a preliminary coating for dry plates. So far as my own observation is concerned, it has not suffered any change when used in this way.

Since you first introduced the practice of touching negatives with black-lead pencil to English photographers, I have frequently used it with advantage, and where light, delicate touching is required, I desire nothing better; but I recently saw in the studio of a friend a bottle of the mixture recommended in your pages a short time ago by Mr. Bell, I think, consisting of silver precipitated from a nitrate solution by means of pyrogallie acid rubbed up in essential oil of lavender as a vehicle. The negatives touched with it were admirable; the touched spots were so perfectly homogeneous in colour and material with the deposit of which the substance of the negative was formed, that nothing could possibly be better; and my friend assured me that it was the most pleasant mixture to work with upon a varnished negative which he had tried.

In the preparation of encaustic pastes the use of a large portion of an essential oil as a solvent for the wax will generally be found, I think, preferable to the use of benzole only, which, by its quick evaporation, renders the task of applying the paste sometimes difficult. Essential oil of lavender—although, apparently, from its strong perfume, a very volatile material—is not so in fact, and answers admirably as a somewhat slowly evaporating solvent for such materials as wax. Paraffine, I find with you, does not answer.

Many of the societies will commence their sessions before I write again; and so far as the London societies are concerned, all, I believe, with prospects for activity and interest. I hear of good papers on the *tapis* for each of these already. Next month I hope to speak of their performance instead of their promise.

## Foreign Miscellanea.

M. Bisson has recently made a second ascent of Mount Blanc for the purposes of photography, and has been exceedingly successful in his results. When he made his first ascent, several years ago, he was so hampered with the large apparatus, dark tent, and necessities that he was compelled to take for working the wet collodion process, that the undertaking proved to be one of serious difficulty and enormous expense; the obstacles to be overcome, the large body of guides and porters requiring control, and the cares and troubles inherent to the wet process, were subjects demanding the possession of great courage and skill on the part of M. Bisson. When Mont Blanc was scaled a second time by this intrepid photographer, the circumstances under which the ascent was made were very different. M. Bisson provided himself with a stock of dry plates prepared by MM. Léon and Lévy (the successors of MM. Ferrier and Soulier), according to the albumen or collodio-albumen processes. Four views were taken from the summit of the mountain, the whole number of plates exposed at different points of the route being from sixty to eighty. The negatives were developed by M. Lévy on the return of M. Bisson to Chamounix, when the success of the expedition was found to be most complete.

In some of the Paris theatres are sold photographic programmes containing portraits of the principal actors. The cards of this description sold at the Variétés, during the performance of Offenbach's "Bridge of Sighs," were five inches high by three broad, and contained, in three rows, twelve ovals, of which eleven were filled with portraits, and the twelfth with the title of the piece, &c.; at the back were advertisements, and the names of the leading photographers of Paris. The cards are to be purchased inside the theatre for the sum of one franc.

A German journal states that the reproduction of summer freckles on the face may be prevented in portraiture by the sitter briskly rubbing his features until they are red.

MM. Geymet and Alker are the authors of a book entitled "Emaux Photographiques," at present in the press. The work treats of all the formulae, operations, and hints necessary to the production of photographs upon enamel. It likewise gives details for preparing the enamel, the method of retouching the pictures, causes of insuccess, &c.

The *Bulletin* publishes in *extenso* M. Davanne's report upon photographs and photographic necessities exhibited at the Paris Exhibition of 1867.

In the *Photographische Correspondenz*, M. Alois Nigg discusses at some length the best method of lighting studios, and criticises Dr. Vogel's remarks in reference to the height at which a glass roof should be built.

M. F. Lamberg, of Odessa, recommends the following gold-toning bath for albuminized paper as being durable, rapid, and economical. Two solutions are made as follows:—

- 1.—Double chloride of gold and  
potassium ... .. 1 gramme  
Water... .. 400 grammes.
- 2.—Phosphate of soda ... .. 2 grammes  
Acetate of soda ... .. 20 "  
Fresh chloride of lime ... 1 gramme  
Water... .. 1600 grammes.

The first solution is added slowly and by degrees to the second. This gold bath will be found to preserve the whites perfectly pure and beautiful.

The *Archiv* states that a very beautiful gloss may be given to photographs by first polishing them with wax dissolved in ether, and afterwards coating them with an alcoholic or enamel varnish.

Dr. Jacobsen recommends the following method of clarifying shellac varnish. He states that besides the soluble resin which may be dissolved by cold alcohol, shellac likewise contains a waxy material, soluble only in hot spirits of wine. If, therefore, a solution of shellac has been prepared in boiling alcohol, the liquid will, on cooling, become quite turbid, owing to the minute particles of wax in suspension; the solution may be cleared by allowing it to stand for some time in a cold locality, and then filtering it through felt or filter-paper. The durability of the filter may be increased by the addition to the solution of very finely-ground glass. If it is desired to bleach the solution, it is boiled previously to filtration, for a short time, with freshly burnt bone-black, and then allowed to become perfectly cold.

M. Grasshoff recommends the coating of prints with normal collodion, and, when this has dried, the further application of an alcoholic varnish by means of a broad camel's hair brush; if the varnish is poured upon the picture instead of being applied with a brush, the effect produced is not so brilliant. If it is desired to retouch the print with water-colour, M. Grasshoff suggests that this operation should be carried out after the collodion has been poured on; by this means the retouching is easier to perform, and the print may afterwards be varnished either with dammar, mastic, or copal oil-of-turpentine varnish, prepared by mixing equal parts of oil-of-turpentine and commercial varnish. Pictures thus treated require from one to two days for drying.

In reference to colouring of photographs, the Hamburg correspondent of the *Archiv* states, that if the colours are rubbed on the palette with gum, and then applied to the photograph, the latter will, after being varnished with collodion, appear very much as if it had been painted in oil. Many photographs finished in this way are sold, says the correspondent, as veritable oil-coloured photographs, which, however, have never seen any other oil than that in the lamp by whose light the artist has painted them.

For facilitating the application of water-colours to the albuminized print, the same correspondent recommends a coating of the following mixture:—

Absolute alcohol	...	...	...	8 parts
Ether	...	...	...	4
Gum, dissolved in a little water	...	...	...	1-16th
Glycerine	...	...	...	1-8th

By applying powdered colours to albuminized prints which have been varnished with a solution of wax in oil of lavender, in the manner in which Daguerreotypes are coloured, a very beautiful effect may be obtained, resembling very much a picture upon porcelain.

M. J. Wothly, of Aix-la-Chapelle, recommends the employment of ordinary hydrochloric acid instead of a soluble chlorine salt, in the preparation of collodio-chloride; by substituting the agent in question a finer precipitate of silver is said to be produced.

M. de Constant states that he has obtained very good results with M. Carey Lea's bromide of silver collodion, by substituting balsam of Tolu for tincture of aloes.

Dr. Liesegang publishes in the *Archiv* a very interesting account of a visit he paid to Mr. Woodbury's establishment during his recent sojourn in London.

M. Béchamp publishes an interesting paper in the *Comptes Rendus*, the result of a long investigation into the circumstances of the decomposition of eggs and their liability to spontaneous alcoholic and acetic fermentation.

The *Zeitschrift für Analytische Chemie* recommends the following method of detecting hyposulphite of soda, which is so delicate that if the latter is contained in a solution in the proportion of 1 part in 500,000, its presence is at once discovered. A few small pieces of aluminium wire (which is preferable to zinc, as being more likely to be purer) are added to the solution to be tested, together with a little dilute

hydrochloric or sulphuric acid, and the mixture is then warmed slightly; if hyposulphite is present, lead-paper becomes blackened after an interval of at most five or ten minutes. As the aluminium dissolves but slowly, the wire may be afterwards washed and put aside for further experiments.

The *Correspondenz*, in alluding to Mr. Spiller's paper on the presence of hyposulphites in mounting boards, remarks that some time since MM. Szekely and Massak caused a large quantity of mounted and unmounted photographs, produced at the same time and in the same manner, to be stored away for the purpose of ascertaining their keeping qualities. After an interval of some time the prints were examined, when it was found that the unmounted copies were still in a perfect condition, while those on cardboard betrayed all those symptoms which are regarded by photographers as evidence of fading.

The same paper warns its readers against a certain process-monger, who claims to be a cousin of the MM. Angerer of Vienna, and assumes the name of those gentlemen; he states that he has worked for some time with Mr. Woodbury, and is anxious to effect the sale of that gentleman's process. He likewise endeavours to dispose of formulae for making cheap sensitizing baths, the following recipe being one for which he charges the sum of forty-five shillings, viz.:—

1.—Water	...	...	...	8 ounces
Nitrate of potash	...	...	...	1 ounce
Nitrate of uranium	...	...	...	7 grains
Ammonia	...	...	...	3 drops.
2.—Water	...	...	...	9 ounces
Acetic ether	...	...	...	20 drops
Nitrate of silver	...	...	...	1 ounce.

When both solutions have been made, they are mixed together.

## SHORT ESSAYS ON PHOTOGRAPHY AND ART.

### No. 4.—"ON DISTORTION AND PERSPECTIVE."

BY NELSON K. CERRILL.

A VERY ingenious artist, who, by the-way, gets his living by photography, tried the other day to argue me into the belief that all photographs are wrong. And the reason for their wrongness was, he said, that you could never get so far from the subject you were taking, as to avoid distortion in the lines or exaggeration in the perspective. It is quite evident to my mind that this gentleman was under a great misapprehension as to the real state of the case, and, in consequence, his remedy for distortion, or bad perspective, was not one calculated to prove of much avail, and I propose to open the subject in the present chapter in order that it may, if needed, be ventilated by others whose opinions will be of more value than my own. I will first premise that though exaggeration of perspective may, when carried to great excess, produce distortion, when speaking strictly, distortion should be considered as quite apart from perspective; it may occur in many other ways, as from the lens giving curved lines, and not a flat field, and so on. Properly speaking, then, the difficulty which my artist friend had stumbled against was one of perspective only, and I purpose to treat it as such.

So far from wishing to avoid the effects of perspective, I greatly rejoice in them, because I consider that "relief" is as much, or almost as much, to be obtained by it as it is by light and shade; but it is said that any part of the figure—as the hand, for instance—being projected at all towards the lens in taking a picture, is too much enlarged, and that when, on the other hand, any part of the figure is behind the rest, it is in turn too small. That when the hand is held forward it is *large*, and when held back it is *small*, is a matter almost too obvious to need mention; but it is as to the degree of this enlargement or diminution that I would direct attention. It is, I contend, not essentially and necessarily wrong

to have the hand either on an enlarged or a diminished scale; it may be so in fact, and facts are not always wrong.

The best way to consider the matter will be to take an example. Thus, stand before a looking-glass at twelve feet distance: for all practical purposes, the image that you see of yourself reflected in the glass is just the same as would be seen by a spectator at a distance of twenty-four feet (the image reflected being always, apparently, as much behind the reflector as the real object is in front of it). Now close the hand, and put it up by the side of the face, and note exactly its apparent size as seen in the glass; next stretch out the arm to its full extent towards the glass, and note how much larger it is now in proportion to the face than when held up close to the head. From this it will be seen (as, indeed, it did not require much showing) that as an object approaches the eye of an observer (or, which is the same thing, the lens of a camera) it is increased in size, and, therefore, it cannot be said to be wrong to represent it as larger. Now let us continue our experiment with the looking-glass. Let us go only six feet off instead of twelve, place the hand again by the side of the head, and it will still maintain the same proportionate size to the feature as it had in the first instance. Not so, however, when it is again extended to the glass, for now it is apparently larger than it was before, even larger in proportion than when held forward from a greater distance. The same experiment being repeated from a much shorter distance will show the same result in a more marked manner, so that it will be quite evident that the nearer any object is to the eye of a spectator, so much greater will be the apparent enlargement of any part of it which is projected forwards. And thus it will be seen that it cannot be wrong to represent the nearer parts of a picture larger in proportion than those which are more remote.

But then there is another matter to be considered, namely, the relation of the amount of apparent increase in the size of projecting portions of the figure and the focus of the lens producing the picture; and here I venture to think a mistake is commonly made. Long focus lenses, requiring to be placed at a considerable distance from the sitter, will produce less apparent enlargement of projecting parts than one of short focus, which will have to be brought very near the sitter; but at the same time I apprehend that in any case, the amount of enlargement will bear the same relation to the focus of the lens as it does to the distance between the observer and the object seen. This is evidently the case, as with short focus lenses the apparent enlargement is always more than with long, and in just the proportion which may be observed in the looking-glass experiment. It must always also be remembered, that there are two things besides the true effect of perspective, which tend to increase the apparent enlargement of prominent parts of the figure. If any part of it comes out of focus it will be inevitably enlarged beyond the proper degree due to the projection; and if, though still in focus, there is any movement, the same effect will take place. These two cases need not, however, be taken into consideration, because they are merely the result of bad technical photography, and it is not my object to defend bad work, but only good.

There are now a few very important points to be considered.

Firstly, what is the proper relation between the focus and the lens, and the size of the picture? It is evident that much depends on this, for if the enlargement of near objects must take place, and if the proportionate amount of this enlargement is dependent upon the length of focus of the lens employed, it seems evident that one lens must be better adapted than another for the pictorial rendering of any subject; all lenses may be mechanically right, but all may not be so good practically. A short focus lens seems most suitable for small pictures, and one of long focus for larger ones; and I think that probably that focus lens which needs to be placed at the same distance from the plate as the eye is from the picture, when seen to best advantage, is the one best suited to each particular size; this may be open

to some exception on part of short or long-sighted people, but, as a rule, I think it is correct.

Another point must not be left unmentioned. If it is at times a disadvantage to find portions of the picture enlarged, there ought to be also occasions on which this peculiar property of perspective might come into very valuable service; as if, for instance, a hand is too large in nature, it may be reduced by being kept in the background, and the same with a figure of "rude" dimensions in a group.

There is also another curious point: the necessity to avoid exaggerating the natural perspective (if one may so call it) which exists in almost every face; in almost every face the mouth and the eyes are converging, not parallel, as one would suppose, but the mouth is almost always rather up at one corner and down at the other, or else the eyes are not quite straight with the two lines of the mouth. If, then, a three-quarter face portrait be taken, looking the wrong way of the face, the most absurd result will follow; though the near side of the face will, by the law of perspective, be the larger, the actual distance between the eyes and the mouth will often be greater in the side of the face remote from the camera than in the side nearest to it, so that almost a pseudoscopic effect will be produced; this is wrongness and false perspective, if you will; but to make those objects which are nearer the camera larger in proportion than those which are behind is not a fault at all, but a most necessary consequence of true perspective, without which pictures would look as flat and unrelieved as do objects seen at a great distance.

#### ON GILDING GLASS.\*

THE gilding of glass is by no means so certain a process as that of silvering, inasmuch as there exists at present no efficient method for applying gold to a vitreous surface. The Liebig process, in which an alkaline solution of gold is reduced by means of a mixture of spirit and ether, is somewhat uncertain in its results, and by no means so efficient as the earlier method of Wernick, which has been simplified by Professor Bottger in the following manner:—

Three solutions are prepared, all of which are endowed with good keeping qualities, and are mixed together in certain proportions previously to their employment.

No. 1.—One gramme of fine gold is dissolved in *aqua regia*, and the solution placed in a water bath to evaporate, for the purpose of separating the superfluous acid; it is afterwards diluted with water to the extent of 120 cubic cents. A better plan, perhaps, is to dissolve  $1\frac{1}{2}$  grammes of chloride of gold in 120 cub. cents. of water. It is necessary that the gold solution should be absolutely free from any metals which are precipitated by the reducing fluids—as, for instance, silver; if the chloride of gold contain a trace of chloride of silver, the greater part of the gold is precipitated in the form of powder, and the thin coating of gold very soon becomes dissolved from the glass. A slight trace of acid in the chloride is less injurious.

No. 2.—Six grammes of caustic soda dissolved in 100 cub. cents. of water.

No. 3.—Two grammes of ordinary grape sugar are dissolved in 24 cub. cents. of alcohol, of 80 per cent. strength, and 24 cub. cents. of commercial aldehyde of 8.870 specific gravity are afterwards added.

If this reducing fluid is kept longer than a day its action becomes weaker.

The fluids are mixed immediately before employment in the following manner, viz., of No. 1, four volumes; of No. 2, one volume; and of No. 3, one-sixteenth of a volume. The mixture quickly assumes a greenish tint, owing to the gold becoming precipitated. The glass to be gilded is cleaned first with soda lye, and afterwards with alcohol, but on no account is any acid to be used, as in that case the gilding is very liable to leave the glass again. The

\* *Photographisches Archiv.*

liquid is poured into a flat dish, and the glass plate to be coated is placed upon two strips of glass in such a manner that the liquid covers only the thickness of the plate. When the gilt surface has been produced, it is carefully rinsed with water, and placed in a sloping position against the wall upon blotting-paper, prepared side innermost; it is then allowed to dry in an atmosphere of ordinary temperature.

The greater portion of the gold remains behind in the bath in the form of light flakes in suspension; this is filtered off and heated, and may be again converted into chloride of gold.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.

CHAPTER XXXVI.

One of the most effectual means of impressing truths on a pupil's mind is to reiterate them again and again from many points of view. It is for this reason that I have introduced several illustrations showing how the pyramidal form—that of most use in figure composition—has been the ruling idea in the several artists' minds in the construction

of their groups, and how no group is allowed to exist without a contrasting balance or support. These principles are further plainly illustrated in the wood-cut from Elmore's fine picture of the "Invention of the Stocking Loom." The fault of the picture, in the eyes of some critics, is that the subject is not sufficiently evident, but requires explanation. This, in my opinion, is a very small matter, although it certainly is an advantage when a picture explains itself, and does not necessitate any reference to a catalogue. If I went into a description of the details of the composition I should only be repeating what I have said of other groups; I will therefore pass to an extension of the same principles in a more complicated subject.

Everybody knows West's great picture of the "Death of General Wolfe;" I have therefore not thought it necessary to occupy space with a large illustration of it, but content myself with a diagram of the leading lines, which will bring its various parts to the recollection of the student. This picture is a very perfect example of a hollow group, or circular composition, so called from the figures and objects forming it being placed nearly on the circumference of a circle, and which arrangement is applicable to the highest works of art, from its simplicity and extensive sweep, and to the lowest, from its being finely adapted for the purposes of light and shade.

Mr. Lake Price has carefully analysed this picture in his lessons on composition in the early volumes of the PHOTOGRAPHIC NEWS, and as the volume containing it has become scarce, I cannot do better than avail myself of his analysis of the composition.

"We observe the stricken hero prostrate in the centre of the picture, the sympathy of his officers and soldiers in the fall of their general being well expressed. The 'red man,'

hard of nerve himself, looks on with interest to see the resignation of the white chief to his fate; whilst the cry from the battle-field, 'They run! they run!' is perfectly given by the panting figures on their right, and the more episodal

one in the distance. The arms of the pointing figures cross each other, thus composing. The animated figure of the trapper or huntsman is most necessary, and gives the foil and sentiment to the still repose of the group immediately round the dying man. The grenadier, standing rather apart, judiciously separates the grouping, and prevents it being monotonous and crowded. The colours and their straight staff carry up and break the top line of the composition, and give value to the action. The advancing figure is prevented over-balancing by the crouching Indian beneath,

which makes a mass with him. The balancing line of the Indian's gun cannot be dispensed with, though the artist has judiciously broken it by the intervening knee; nor the cap of the grenadier on the ground, which composes with the lines of his figure, and completes the group; whilst the dark hat under Wolfe finishes the circle, and gives distance to the lighter parts behind. The gun on the ground completes the base-line carried through the foreground. This is a most perfect composition, and should be well studied. We have first the story, told in a touching and distinct manner; next, we have the main lines, traversing the subject horizontally, balancing each other, whilst the lines of the figures, as seen in the analysis, reply perfectly, and balance with each other; at the same time each figure either composes with its own base, or forms part of another mass, the whole arrangement, in its linear composition, being admirably susceptible of subsequent chiaroscuro."

It was with this picture that common sense in historical painting in England commenced. Before this period the most ridiculous absurdities were perpetrated in the costume, not only in historical pictures, but in every other class of painting. The picturesque dress of the day was thought too barbarous for the sham classical taste of the time of James the First. This taste, revived by Verrio and Laguerre, was in the height of fashion when West commenced his "Death of General Wolfe." A portrait painter seldom allowed his sitter to appear in his own dress; if his subject was a lady, she was transformed into a shepherdess with a spud in her hand, tending sheep in Arcadia; if a youth, the distinction of sex was indicated by giving him a crook instead of a spud, and pandean pipes in his hand. Men were dressed in armour of an earlier period, and it appeared to be a law as binding as those of the Medes and Persians that in historical subjects (which should be treated allegorically, if possible) the figures should be dressed in Greek or Roman costume, or not so much the costume of the actual Greeks and Romans, as a dress in which they were supposed to appear. If a battle-piece was represented, the king or general, "the noblest Roman of them all," was set in the front, bearing no possible proportion to the rest of the combatants. Thus, if the dubious costume were to be believed, actions of Englishmen in the seventeenth and eighteenth centuries were performed by the people of extinct nations. But to make the thing still more absurd, although the dress was exchanged for Roman armour, the enormous wigs of the period were retained! Fine examples of this false classicality are to be found in the statues about London, especially in Westminster Abbey and St. Paul's Cathedral, where, by-the-bye, there is evidence of a further decadence in artistic truth; the classic heroes of the early Georges were at least dressed, if dressed absurdly; but passing by Dr. Johnson and others who are wrapped in blankets, we come to the monuments erected to the memory of those who fell at Waterloo, and find that some of them, with that enthusiasm which disregards appearances or cares for uniform, actually went into battle *in puris naturalibus*, without any clothes at all. West, much against the advice of his friends, dismissed this pedantry, and restored nature and propriety in his noble work. Cunningham, in his life of West, speaking of this picture, says:—"The multitude acknowledged its excellence at once; the lovers of old art, the manufacturers of compositions called by courtesy classical, complained of the barbarism of boots, and buttons, and blunderbusses, and cried out for naked warriors, with bows, bucklers, and battering-rams." Sir Joshua Reynolds was so blinded by the fashion of the time that he entreated the artist to recollect the danger which every innovation incurred of contempt and ridicule, and urged him to adopt the costume of antiquity, as more becoming the greatness of the subject than the garb of modern warriors. West's answer was, that the same truth which gives laws to the historian should rule the painter; if, instead of the facts of the action, fiction was introduced, what would posterity think of the truth of

the painter? Reynolds afterwards acknowledged, when he saw the completed picture, that the artist was right: "West has conquered," he said to a friend; "he has treated his subject as it ought to be treated. I foresee that this picture will not only become one of the most popular, but will occasion a revolution in art." At that time, truth of effect in art was so little regarded that Garrick thought it right to play Macbeth in a full court suit, and murdered Duncan in a bag-wig with a dress-sword!

I have gone at such length into this subject in order that I may point out a similar error in our practice of to-day—one not so glaring and absurd as the classical armour appears to us now, but which seemed quite right to our ancestors, but one which is but a new application, only in a less degree, of the same error—I mean the practice of dressing a sitter for a portrait in fantastic garments, for the purpose of making him up into a picture. The object of portraiture is to make a resemblance of a man as he is, and very little liberty should be allowed or taken in doing it. I am not now speaking of photographs of which the object is to make a picture apart from portraiture—in these anything may be done, so that general truth is observed—but a portrait professes to represent a prosaic fact, and should fulfil its function.

#### ON THE EMPLOYMENT OF COLLODIONIZED PAPER.

BY LUDWIG SCHIRANK.\*

THE introduction of carbon printing, causing as it did so great a stir in the photographic world, and giving rise to the hope that by its means perfect durability might be obtained, has for a time distracted attention from the endeavours which have been made to substitute gun-cotton, or rather collodion, for albumen in the printing process. The gentleman to whom belongs the honour of having first introduced collodion as a material for printing is the celebrated German experimenter, M. Wothly, of Aix-la-Chapelle; for although at an earlier date developed collodion positives were transferred to chalk and gelatine paper, still we believe that in M. Wothly's uranium printing process collodion was employed for the first time as a sensitive coating for paper in the form it is used to the present day.

The failure of the uranium printing process was partly owing to the fact that the consumer himself was expected to prepare his own sensitive material by coating the paper with collodion, a manipulation requiring, of course, more care and attention on the part of the operator than is demanded in the employment of albuminized paper.

For the same reason Mr. Wharton Simpson's collodion-chloride process, during the early days of its existence, made but little progress, until several manufacturers introduced into commerce the sheets of paper ready collodionized.

But even now that collodion paper is obtainable in commerce, photographers are slow in adopting it, and not until it is more generally known that the carbon process is ill adapted for universal practical employment will attention again revert to the old methods. It must be admitted by every impartial observer that the prints upon collodion paper greatly surpass in brilliancy and detail the albuminized picture, and these qualifications, although possibly of no importance in large pictures, are invaluable in prints of lesser size, viz., in stereoscopic, microscopic, and other reproductions in which fine details are depicted. Of these advantages must every practical photographer be aware; and yet on many sides has the introduction of collodion paper been prevented. The first reason for this we have already touched upon, namely, the hope that the carbon process would bring about a total reform in the process of printing. The second reason was that the manufacturers of the collodion paper were at the commencement not perfectly *au fait*

\* Photographische Correspondenz.

at their work, and furnished a material, therefore, which was of such mediocre quality that photographers who had resolved to give the new product a trial were at once frightened away altogether. The paper possessed all the faults inherent to glass plates coated with collodion, such as streaking and fogging caused by the bursting of collodion bubbles, these faults giving rise to dark spots whenever the paper was printed. Besides, the collodion employed for coating was often of unequal composition, and the paper not sufficiently glazed, so that pictures were sometimes produced upon the collodion paper which were inferior in point of brilliancy to those furnished by good albuminized paper. At another time a whole batch of the prepared paper was sent into the market, and became unserviceable after a short time, owing to the addition, during its manufacture, of too large a quantity of resin.

M. Obernetter, of Munich, who has built a factory on purpose for the preparation of collodionized paper, experienced with his first products, made at the new manufactory, the greatest difficulties, arising, in his opinion, from the damp walls of his workshop. The paper when freshly prepared was perfectly good, but after a fortnight, or three or four weeks, a change came over the material, and rendered it quite unserviceable. For some time he was unaware of this serious evil, and every batch was tested, and being found of proper quality was at once sent off; but in a short time from every part of the world came complaints. As soon as the cause of injury was discovered, the workrooms were continuously heated, but without result; and it was not until the heat of the summer had perfectly dried the walls of the factory that the evil disappeared of itself.

"I have found out," wrote M. Obernetter to us at the time, "that the application of a preparation of gutta-percha prevented the peeling off of the film and its liability to become damaged, and at the same time increased the durability of the picture to such a degree that sulphuric acid or a solution of cyanide of potassium might be poured upon the prints without injuring them in any way."

All these experiences are undoubtedly of value, although it is to be deplored that they were acquired so late and at a time when many photographers had relinquished their trials of the material. A third cause of failure was due to the employment of old used-up gold and hyposulphite baths of the ordinary strength in the manipulation of the collodion paper, a course of proceeding adopted in direct opposition to the directions given by the manufacturers, who stated distinctly that no other solutions than those indicated by themselves should be employed; the consequence was, that in many cases the sensitive film was found to become detached from the paper during the processes of toning and fixing. Although we have on a previous occasion already made known the instructions drawn up by M. Obernetter in regard to the employment of collodion paper, we consider it desirable to recapitulate the same with a few important additions.

#### *Instructions to be Observed in the Use of Collodion Paper.*

The printing is to be done in the shade, the pictures being copied to a degree but slightly more vigorous than that desired for the finished print.

The toning is conducted by placing the prints first of all in ordinary water, without addition of common salt, to remove the superfluous nitrate of silver; three changes of water in a quarter of an hour will be amply sufficient. The toning bath is most conveniently made by keeping in stock two solutions, thus composed:—

- |                              |            |
|------------------------------|------------|
| 1.—Distilled water...        | 50 ounces  |
| Sulphocyanide of ammonium... | 40 grammes |
| Hyposulphite of soda ...     | 3 "        |
| Bicarbonate of potash ...    | 1 gramme.  |

If the gold compound used is neutral, the last-named may be suppressed.

- |                           |            |
|---------------------------|------------|
| 2.—Distilled water...     | 50 ounces  |
| Pure chloride of gold ... | 2 grammes. |

By chloride of gold is meant a pure compound, free from acid and water, and not salts of gold; if the latter is employed, about double the quantity should be taken, as it contains but half the amount of gold. If, after five minutes' immersion in the gold bath, the pictures still remain red, and do not assume a beautiful violet tinge, there is not sufficient gold present, and more solution must be added until the prints tinge quickly; the bath must on no account give an acid reaction.

Both solutions are endowed with good keeping qualities. For use they are mixed in equal proportion, only so much being taken as is required for immediate employment. In this way a couple of pictures may be at once toned without delay in quite as economical a manner as a large batch; moreover, no chance of the prints becoming yellow need be feared by using these solutions, for it is this bath, and this only, that can be relied upon for the production of faultless pictures. Other baths have a tendency to dissolve off the film of collodion.

When the prints have attained the desired tone, which occurs in from two to ten minutes, they are washed in ordinary water, and fixed in a solution which should be compounded exactly in the following proportions, viz., 40 grammes of hyposulphite of soda dissolved in 32 ounces of distilled or ordinary water. The fixing will be completed in five or ten minutes, and then a subsequent washing of two to three hours will suffice to remove the weak solution of hyposulphite.

In all the manipulations care must be exercised not to bend the paper or to injure the surface with any sharp instrument, as by this means the collodion is easily torn; no cutting or trimming should be done before printing. When the prints are laid in the first water bath, after their exit from the pressure frames, they are inclined to curl themselves up: this is of no material importance, and if they are laid, face downwards, in the toning bath, they again become straight in a few minutes. Too many prints must not be allowed in the toning or fixing bath at the same time, as red spots are thereby caused. When the pictures have been thoroughly washed, after fixing, it is as well to lay them one upon the other, face downwards, on a plate of glass or clean board, and to press them with the hand, so as to expel the water; they may afterwards be placed in an upright position, so as to drain thoroughly. While the pictures are yet damp they are trimmed and mounted; or, if it is deemed inconvenient to place them at once upon cardboard, they are again heaped upon one another to prevent their becoming completely dry. In order to facilitate the trimming of the prints, it is best to mark upon the negative, either by means of a needle or a black line, the size to which the print should be cut. As a mounting material, ordinary starch paste, freshly boiled, is recommended. Rolling the finished print conduces much to its beauty, and a coating of paper varnish is advisable, inasmuch as the film is thereby protected from injury.

These instructions are so clear that a close observance of them cannot fail to ensure success. Our honoured colleague, Professor August Freund, has nevertheless suggested several improvements which we cannot withhold from our readers, especially as they are designed for producing greater durability, one of the principal arguments in favour of the adoption of collodionized paper in place of that prepared with albumen.

"The rolling up of the picture when placed in contact with water is only to be avoided by employing at first just sufficient water to moisten the print, and, after a few minutes, when the same has become perfectly sodden, to add a larger quantity of liquid. That the sulphocyanide of gold bath only can be used I have likewise found out, although the papers prepared by myself in Vienna some time since could be toned in any ordinary bath. The collodionized paper at present manufactured does not give good results with any toning bath but that of sulphocyanide; and I have likewise found it necessary, besides washing the

prints three or four times to free them from any free nitrate before being brought into the toning bath, to treat them in a mixture of equal parts of spirits of wine and water, to which, for every twenty parts, one part of caustic ammonia is added. The pictures are immersed in this mixture for a few minutes, then washed again in water, and afterwards toned and fixed in the ordinary manner. If this treatment is omitted the pictures are not capable of being perfectly fixed—that is to say, they become altered in direct sunlight.\* Although, however, the omission of the spirit bath does not allow of their being perfectly fixed, the prints so produced do not undergo any alteration in diffused light, at least as far as my experience goes, which now ranges over a period of nearly two years.

(To be continued.)

## Correspondence.

### INDIA-RUBBER, ENCAUSTIC PASTE, ETC.

SIR,—Some very important articles in your paper lately, respecting the use of india-rubber in photography, and also the application of encaustic preparations for improving the appearance of the finished picture, induce me just to trouble you with a few lines on these subjects.

In a paper I read early in this year before the South London Society, I expressed my belief that photographers who used india-rubber as a mountant would find it to their loss, and I have had abundant further evidence, since that time, that such is really the case. Vignettes are speedily stained and spoiled, and other pictures, within periods varying from a few months to a few years. I doubt if anything else is equal to Glenfield starch for mounting pictures on cards; and a very few drops of carbolic acid added to it when made will cause it to keep a considerable time.

I also adverted in the same paper to the use of encaustic paste, expressing a belief that whilst greatly enhancing the beauty of the print, it gave every hope of increased longevity. Wax is one of the most permanent and most unchangeable substances from atmospheric influence, and not only does it contain no element of decomposition within itself, but, from its repulsion of fluids, it acts strongly as a preservative from any deleterious substances from without. It is also unaffected by most chemicals. Previous to Mr. Blanchard's formula of bees-wax in benzole, the encaustic paste made for sale to photographers was far too hard and brittle, often quite chippy. I adopted Mr. Blanchard's suggestion at once, and after adding a few drops of an essential oil, to give a little more elasticity and prevent the preparation drying up too quickly, it was found all that could be desired. You have now given us M. Adam-Salomon's recipe, and a very capital one it is. I made up a supply at once, and had a large number of pictures done with it. Whether it is superior to our former one when properly made with essential oil of lavender is a matter of difference of opinion; those who are employed in doing the pictures say they have no choice, that one applies to the prints just as well as the other. On looking over a hundred pictures of various sizes which have been finished indiscriminately with the two preparations, there is nothing to lead one to a preference, although I confess that on carefully scrutinizing prints done with M. Salomon's encaustic I certainly fancied there was a little more depth given, just a *soupeon* more of liquid transparency than with the other; but after repeated trials of the fairest nature, it was not found that it was possible to pick out from the bulk pictures treated with either preparation, on account of any difference in their appearance. There is no inducement on the part of dealers to adulterate bees-wax; but it is believed that white wax, from its price, is, to a considerable extent, mixed with other and cheaper substances. I have made up M. Adam-Salomon's formula, substituting bees-wax for the white article, and from the result of the last few days' use am rather inclined to look to it as the right thing. If this is manufactured for sale, a good

large bottle should be sold for a shilling, and in a convenient shaped bottle too.

In conclusion, I most strongly advise the use of encaustic paste; those who have begun it are not likely to discontinue, whilst those who have not, have a pleasure in store.

SAMUEL FRY.

### WET COLLODION WITHOUT WATER.

DEAR SIR,—In the NEWS of September 25th you give a method of working wet plates without water, and as I have, by a different method, been doing the same thing for more than a year past, perhaps the result of some experiments may interest some of your readers. I had just invented and completed a new dark tent upon small (11-inch) wheels, having the following advantages:—1st. It is so light—only about two pounds upon each hand—that a boy twelve years old can get along as fast with as without it. 2nd. It can be taken to pieces for railway travelling in about one minute, is about the size of a child's perambulator, and can be set up as a dark tent in less than thirty seconds. Having completed the tent, I thought what a useful thing it would be if the wet process could be worked without water, and I set about trying it. Knowing that a negative may remain in contact with hypo soda for many hours without injury, I poured hypo soda solution containing a little golden syrup upon a developed but unwashed plate, and I obtained a negative clear in the shadows, and without any stains; but the decomposition between the hypo and the pure nitrate of silver created a few minute floating particles, which adhered to the plate, and were difficult to remove in the after washing, which was generally postponed until the next day. I next tried chloride of calcium applied to the developed but unwashed plate. This converted the free nitrate into chloride, stopped further developing action, and kept the plates moist. The negatives were clean and bright, but if the chloride of calcium was used too strong, it sometimes produced a little discolouration of the white parts of the negative.

I finished my efforts in this direction by trying a strong solution of common salt, with sufficient alcohol to prevent its running greasy upon the plate, and have used it ever since with perfect success. It stops developing action, and keeps the plates moist for several hours, merely with the addition of a pad of wet blotting-paper at the bottom of the plate-box.—Yours truly,

W. CALLAWAY.

Lucerne Villa, Torquay, Sept. 26th, 1868.

PS.—The salt produces a quantity of chloride of silver upon the plate, every trace of which dissolves in the hypo.

SIR.—With reference to your article, in last week's Journal, on "Wet Collodion without Water," allow me to make a few remarks. Being myself a landscape and architectural photographer, I have for my convenience a eas or portable laboratory, fitted with racks that swing to and fro, so that it answers every purpose of a dark room. I think we are greatly indebted to Mr. Robinson, who has brought out the use of golden syrup. I may mention that I always take a 10 by 12 plate, proceed to my laboratory, and develop it with iron developer as follows:—

Iron	...	...	...	...	120 grains
Liquid ammonia	...	...	...	...	1 to 2 drops
Glacial acetic acid	...	...	...	...	½ ounce.

As soon as I find the picture sufficiently out in detail I pour over a mixture of equal parts of golden syrup and water. I find the syrup stops the action of the developer altogether, and by placing the negative on a rack inside your dark room while you are preparing another plate, you will find it sufficiently drained to place in your negative box, the bottom of which I always keep wet. In this way I have kept plates for a week, and obtained some splendid enlargements, of which you are aware plates must be very clear and transparent to obtain a direct enlargement without any working up. I shall be happy to forward you one of the enlargements from plates a week old, should you wish it.

All that the above requires, after getting home, is to carefully wash, and, if necessary, you may intensify and fix without injury to the plate. I shall be glad to furnish you with further particulars as I proceed.

\* Professor Freund's experience here is exceptional. We have prints in our possession produced at the time we first introduced the process, toned and fixed in the usual manner, which have been exposed to sunlight for months without change.—ED. PHOTO. NEWS.

Trusting I have not taken up too much space in your valuable columns—I remain, sir, yours obediently,

*Lyham Road, Brighton.*

JAMES BLANE.

### CARBOLIC ACID.

SIR,—The startling affirmations contained within the letter of your correspondent, "H. O.," last week, are like many other startling affirmations; *i.e.*, more sensational than either reasonable or demonstrable. Having affirmed how carbolic acid proceeds from coal, he says:—"Coal was made in many instances thousands of years before the light of the sun dawned upon this earth." This assertion is totally destitute of evidence in favour of its truth, and is, moreover, as your correspondent will see upon reference to any standard work on geology, enormously improbable.

Further on he says:—"The only light that dawned upon those trees was that of what we call electricity." More and more improbable still, and equally destitute of evidence.

Finally, he asks, "Whether the latent electricity, as contained in coal, from whence proceeds and is produced carbolic acid, is conducive and beneficial to our silver baths?" Until it has been shown—first, that carbolic acid is the peculiar seat, in its latent form, of that electricity which, without evidence, is asserted to have played so important a part at a time in reference to the sun, which neither geology, astronomy, nor common sense indicate as even possible; and, secondly, until electricity, either latent or dynamic, has been *proved* to influence the silver bath, such a question is, I think, as supremely ridiculous as the groundless assertions by which it is preceded.

DIODENES.

### Talk in the Studio.

NORTH LONDON PHOTOGRAPHIC SOCIETY.—The first meeting of the session of the Society will be held in Myddelton Hall on the evening of Wednesday, the 7th. Mr. Nelson K. Cherrill will read a paper on the Relation between Intensity and Tone. Various presentation prints will, we believe, be ready for distribution.

ROYAL CORNWALL POLYTECHNIC, FALMOUTH.—The thirty-sixth annual meeting of this Institution opened on Tuesday with more than usually encouraging prospects. In the photographic department there are upwards of two hundred entries, with about double that number of specimens. The local photographers of the West of England contribute well, and with contributors from a distance the exhibition in this branch is the most satisfactory and brilliant display yet made by this valuable Institution. There is a good display of photographs by the Palestine Exploration Society, which have a distinct and peculiar interest of their own. Portraiture, large and small, is well represented. Among the miscellaneous entries of fine art subjects are some brilliant specimens of wood engraving, with a variety of most creditable art specimens from Devouport, Truro, Torquay, Tavistock, Penzance, and Plymouth.

PHOTOLITHOGRAPHIC REPRINTS OF RARE BOOKS.—A society has just been projected in Manchester for the reproduction, by means of photo-lithography, of rare and old illustrated books. The issues for the first year by the "Holbein Society" will consist of Holbein's *Dance of Death*, and Holbein's *Figures for the Old Testament*. Other works of similar interest and character will follow. The subscription will be a guinea a year, entitling the member to the two volumes mentioned, and volumes of similar value will be issued in other years. The photo-lithography will be executed by Mr. A. Brothers, of Manchester, who, some time ago, reproduced in a similar manner Whitey's *Emblems*.

PHOTOGRAPHS OF THE ECLIPSE.—Mr. W. L. H. Skcen, of Colombo, Ceylon, has favoured us with ten photographs of the Eclipse on the 18th ult., taken with an ordinary 12 by 10 view lens, the exposure being instantaneous. The work is very excellent, and the gradual progress of the eclipse admirably shown; but the images are, of course, too small—about the size of a pea—for astronomical purposes.

COLLODIO-CHLORIDE PAPER.—A correspondent sends us a very charming 10 by 8 landscape on Obernetter's collodio-chloride paper. Nothing can exceed the delicacy and beauty of the definition rendered. He says: "I have been much interested in the notices, which have from time to time appeared in your journal, regarding the paper prepared by Herr Obernetter; and, being desirous to try it, I procured a supply, and have been experimenting with it, with great satisfaction to myself. I find it superior to any of the albuminized paper I have met with, in giving tone, brilliancy, and detail. I send you a print in which this paper is used, and would like your opinion of it. I must, however, call your attention to a rather curious defect, arising from a cause similar to one given in the PHOTOGRAPHIC NEWS some time ago. A broad pencil mark on the back of one of the sheets had come in contact with the prepared side of another, and though both were kept in the dark, the impression must have been conveyed from the one to the other, although invisible on the prepared side till the picture was developed, when it came out as you see. I may send some smaller prints, in 'Obernetter,' another time."

BEWARE OF THE COLTS.—A correspondent, J. D. W., sends us an account of "An Amateur's First Trip," and the mishaps attending it:—"Having selected a spot on the slope of a beautiful hill, the tyro, with an assistant, went at six a.m. and prepared for operation, having first planted his tent near a brook some 150 yards below. After adjusting the lens, the youth looked towards the locality where he had left his tent, which, to his surprise, had disappeared. Rushing back, he found, to his great mortification, his tent prostrated, his silver bath wasted, and his hopes of success on that occasion frustrated. When recovered from his consternation, the question arose, Who or what has done the mischief? The miscreants were near in the shape of two frisky colts, which had come to give the tent a Frenchman's salute, or to be reveuged on the invader of their territory. Many a hearty laugh has the young amateur and his friends had over his misfortune, and he has resolved never again to leave his tent before he had placed an armed sentinel to protect it."

A NEW CAUSE FOR VARIETIES IN THE QUALITY OF COLLODION.—A correspondent writes: "The other day the representative of a collodion maker, in soliciting an order, was eloquently showing the difficulties in the way of home brewing in regard to collodion, and enlarging on the varying nature of soluble cotton. The latter was to be attributed, in his opinion, to the different pastures on which the sheep producing the cotton wool were fed!"

COLLODION AND TOOTHACHES.—The *Lancet* says:—"Toothache can be cured by the following preparation of carbolie acid: To one drachm of collodion add two drachms of Calvert's carbolie acid. A gelatinous mass is precipitated, a small portion of which, inserted in the cavity of an aching tooth, invariably gives immediate relief."

BALLOON PHOTOGRAPHY.—A contemporary says:—"M. Toumachon, the photographer, recently performed a feat worth recording. Having ascended to the height of nearly a thousand feet in the captive balloon at the Hippodrome, Paris, he succeeded in taking several photographic views, accurately representing the city from a birdseye view. The chief difficulty he encountered was the rotary motion of the balloon. His success shows the practicability of obtaining correct representations of the positions of military forces safely and rapidly." It should not be forgotten that Mr. Black, of Boston, some years ago successfully performed a similar undertaking.

### To Correspondents.

YORK.—There is a little unnecessary complication in the formula you have been using; but the excessive bleaching is chiefly due to using, too soon after it was made, a very strong bath. Time and dilution will improve it; or you may use it at once if you dilute it with an equal bulk of hot water. Try an ounce of the solution; add to it an ounce of very hot water, and, when quite cold, try it for toning. The probability is that it will work quite satisfactorily.

J. B.—The passage you enclose is an amusing illustration of the mode in which outside journals speak of photography. It should

be borne in mind, however, that instantaneous exposures depend quite as much upon the light as upon the subject, and upon the lens as upon the process. We have ourselves produced instantaneous marine subjects on Dr. Hill Norris's rapid dry plates, and we have seen Mr. R. Manners Gordon take groups of cattle in two seconds with his gum plates.

**M. B. B.**—The object of the preliminary coating of india-rubber in the patent albuminized paper was to partially render the paper waterproof and non-absorbent, and so to keep the albumen on the surface. When that office is served, it becomes of little comparative consequence whether the india-rubber changes afterwards or not, if its first purpose has been subserved. We have heard good accounts of it, but cannot speak of its advantages from experience.

**W. M. S.**—The Kinnear camera is an excellent, light, and convenient camera for field work. The lenses you name can with convenience be used with this camera. We cannot with propriety recommend any special lens by name here, but if you will make a list of those from which you wish to select, and attach to each one a number, we can then indicate, by its number, that which we think will suit your purpose best.

**W. J. A. G.**—We believe it is intended to open the next session of the Photographic Society with an exhibition of pictures in the rooms at Conduit Street, as on the last occasion. It will be opened on the evening of the second Tuesday in November. 2. We have not yet had any personal experience with Harnecker's dry collodion, but have heard various good accounts of it. 3. In preparing dry plates in cases where a long immersion in the nitrate bath is necessary, bear in mind that it is not all waste time, as, whilst one plate is in the bath others can be washed, coated with the preservative, &c.; and, if necessary, two baths may be kept going. Precision and perseverance are the only aids to success in dry-plate working which we can recommend.

**C. A. C.**—To proceed against any one who has infringed the copyright of one of your pictures, it is necessary to apply for a summons to a magistrate. When the case comes to hearing you must be prepared to prove satisfactorily that the copyright is yours, and that all the steps necessary to secure it to you, laid down in the statute, have been carried out; and next, that the person charged has infringed your copyright. It is wise, in such a case, to employ a respectable attorney to conduct the business for you. He will tell you if you have not a good case, and save you the trouble and expense of going further; and if you have a good case and succeed, his expenses will probably be allowed by the Court.

**NORTH LIGHT.**—Your letter is scarcely so clear as it should be, to enable us to give you efficient advice in such a case. You speak of the "lighted end" of your room, but your description refers to a lighted side, which, of course, would be the right thing, as the end should not be lighted. In the studio of the gentleman you mention, it is possible to take both sides of the face, but it is more convenient and effective for one side than the other. The proportions you describe for your intended studio are good, and if you can build it so as to allow the 12 feet by 9 feet of side-light to face the north, the result will be good. You need not then have any glass but that in the side and skylight on the north side; you can then use either end of the room, and so get a perfect light on either side of the face.

**J. CARTER BROWNE.**—When an old dry-plate photographer meets with difficulties like those you describe, which he cannot overcome, the case is serious, and we are by no means certain that we can name a remedy. Our own experience with the process you name is small; but if you have not found blistering inherent in the process, it must be due to preventable causes. The use of a thick tough collodion would conduce to the end. The use of ground glass for the transparencies would undoubtedly conduce to it, for two reasons: one, the difficulty of getting a perfectly clean ground surface, and the other the fact that the film rests rather on a series of points than on a continuous surface, a condition which would conduce to the formation of blisters. The use of nitric acid for cleaning the glasses would, if any trace of it remained, undoubtedly tend to the formation of blisters. In the little experience we have had with gum and tannin as a preservative, we found the formation of blisters a serious trouble, which was somewhat modified by the use of alcohol and water to moisten the plate before development. 2. Mr. Smith, of Negretti and Zambra's, is the inventor of a printing frame for transparencies, rendering transposition unnecessary. It can be had at the establishment in Fleet Street; the price we do not remember. 3. The difference in the results to which you refer is most probably due to the difference in the collodion. Let us hear further from you as to whether you get rid of the blistering.

**PETER SIMPLE.**—The heat of an ordinary oven would not be sufficient to burn in a picture on porcelain. It might be possible with some ingenuity to manage with a kitchen fire. The absence of detailed information as to the nature of a muffle arises from the fact that it is presumed that few will undertake such a process as

enamelling without some previous knowledge of the technical details. The chief duty of photographic journals is to describe the photographic part of the business. We shall have pleasure, however, in aiding you in this part of the matter. A "muffle" or "muffle furnace" is practically an oven with arrangement for the fire to surround it perfectly, and so bring the interior to a white heat without contact with smoke or ashes, &c. For experimental purposes, you may construct a substitute. Take some fire-bricks, and arrange them in a large kitchen range so as to form a hollow chamber, the interior about the size of a brick; then, by means of a pair of bellows, get up a white heat. Now place a piece of fire-brick about an inch thick inside, and on this place the enamel to be burnt, and close up the aperture for a few minutes, varying, according to the requirements of the materials used, from three to ten minutes. With a soft enamel a red heat may be sufficient. If you have had no experience in this art you must expect some failures; for, besides photographic difficulties, you must remember that the art of enamelling is a delicate and difficult as well as a beautiful operation, and sometimes requires the devotion of years to ensure the highest success. In your earliest attempts you must be content to produce your arms in a monochrome, and substitute a goose vert for a goose argent.

**B. L.**—Thanks for your well-meant remarks, but the matter is not worth further attention. We hold with Popo's lines in relation to the statements which have excited your indignation:—

"One half will never be believed,  
The other half ne'er read."

**II. W. P.**—To get more equality of illumination in your enlargement, use either a lens of longer focus, or stop down that you now use. 2. For lining a cistern for collecting rain water for photographic purposes you may use either lead, or zinc, or gutta-percha without much hesitation; the latter is, however, the safest. 3. We fear that any society combination for the purpose of maintaining prices would be difficult to organize and carry out; but something analogous is at the present time being attempted in America, the result of which we watch with interest. We strongly deplore at all times the competition of cheapness, and recommend that of excellence as something far better. As a rule, they who initiate a competition in lowness of price are conscious of their inability to succeed in a competition of excellence. 4. The only means of overcoming the difficulties of colour in photography consists in full exposure, the free use of bromides, and the exercise of judgment and taste.

**SILEX.**—We have no reason to suppose that gelatine forms a combination with silver, insoluble in hyposulphite solution, like the combination of albumen and silver, and plain paper prints (in which the sizing material is gelatine) do not usually show any trace of silver in the whites, except the paper be kept a long time between exciting and fixing. In the latter case a decomposition at times occurs, which leaves in the body of the paper a compound not easily removed in the fixing bath. Mr. Rouch is now at home, and doubtless can attend to your proposal.

**O. G. MASON (New York).**—We send the back numbers you require. 2. The cyan process is making steady progress in this country, and thousands of prints have already been produced by it. We have just received some dozens of very fine results from one of our most enterprising professional photographers, who is going into it extensively. So far as we can judge at present, there will be no difficulty or uncertainty wherever the thing is gone into in earnest; but on a small scale it will be more trouble than silver printing. In our experimental operations we have found no uncertainty or difficulty of any kind not easily overcome. 3. We have not received any copies of the moon photograph to which you refer. We shall have pleasure in receiving the prints you kindly offer, and to forward copies to our societies. Thanks for the communication, which shall appear in our next.

**W. T. BOVEY and J. MARTIN** received.

Several Correspondents in our next.

## THE STABILITY OF NEGATIVES INTENSIFIED WITH IODIDE OF MERCURY.

THERE are few modes of intensifying more simple and certain, none which produce more perfect results, than that in which printing vigour is secured by the precipitation on the negative of a layer of iodide of mercury. At one time this method was a great favourite amongst many able photographers. The card negatives of Mr. Lacy—a name almost forgotten now, but once a name of mark—were all intensified by this means, and few finer have been produced. Such negatives, however, possessed one fatal drawback: they were liable to change. The deposit acquired in the process of intensifying was sensitive to light, and in the process of printing the negatives gradually became more and more dense, until, finally, they became so black and hard that it was almost impossible to print through them, and the prints obtained were flat, coarse, and worthless. Negatives which, on their first production, gave delicate, soft, harmonious prints in fifteen minutes, eventually failed to yield anything presentable in as many hours.

At a time when prints were ordered in single copies, such a defect in a negative was rarely noticed, as it had no opportunity of being developed, and if it were known to exist, the fact would have been regarded with little apprehension. Even when the card mania began to set in, and prints were ordered by a dozen at the time, the defect was not at first appreciable; but when such orders began to be repeated from the same negative, and, still more, when, for publication, hundreds and thousands were required, this fatal defect was quickly detected, and felt to be intolerable, and the process was generally abandoned.

A puzzling circumstance remained, however: whilst the instability described was the common experience, there were exceptions. Some photographers declared that they never found any alteration in such negatives. In our own experience some changed, and some did not. The uncertainty was, however, sufficient to render the process untrustworthy, and unless the causes of instability and of permanence could be traced, and the conditions clearly laid down, few persons familiar with the possibilities would voluntarily risk the gradual deterioration of a negative of any value by submitting it to the treatment in question.

We have recently been led by observation and experiment to arrive at certain conclusions on the subject which tend to its elucidation. We have been induced to examine anew the conditions under which the negatives which have remained stable in our own hands were produced, and we have had opportunity of ascertaining the *modus operandi* employed by some photographers who, having habitually used iodide of mercury for intensifying, have experienced no change or instability in the results. The better to explain the causes in operation which lead to instability,

we will first briefly describe the common mode of applying the process.

A negative developed with iron in the usual manner was fixed and washed. At this stage it should be clean, and with the usual amount of vigour which an iron negative, produced in the usual way, without any attempt to intensify it, would possess. In some instances it was now dried, some photographers preferring the effect of intensification upon a negative which had been dried. The late Mr. Lacy, for instance, had a profound belief in the advantage of drying. His argument was, that if the intensification were conducted upon the film when it was in the soft spongy state in which it was first produced, there was generally some lateral deposit which marred the delicacy of the finest lines; but that when the film had been once perfectly desiccated, it never acquired the spongy, absorbent condition it had at first; and that the deposit the image acquired in the process of intensifying would be more strictly vertical, increasing the density of the image without making fine lines thicker or coarser. But whether the negative were dried or not, it was not intensified until after fixing. It was then treated with a weak solution of bichloride of mercury, say of five grains to the ounce. This was applied until an even grey tint was obtained, care being taken to avoid the white stage which the complete action of the mercury solution would cause. Having reached the grey stage, the plate was rinsed, and a one or two-grain solution of iodide of potassium was applied. By means of this solution the exact degree of intensity to be secured could be considerably governed. A slight application produced a greenish grey tint; a further application produced greater intensity and a more non-actinic colour, the image acquiring an olive tint, continued action producing a dingy yellow or citrine tint. The half-tones acquired value exactly in due relation to the high lights, and the negatives, when properly managed, were at once delicate, harmonious, and brilliant. If they had not changed, nothing could have been better.

To gain an idea of the cause of the change, let us examine the action of bichloride of mercury alone on the silver image. If a collodion picture, negative or positive, be treated with a solution of bichloride of mercury until it is partially whitened, then rinsed, and exposed to the light, it will rapidly darken. A portion of the silver forming the picture has been changed into chloride of silver, and a deposit of subchloride of mercury has been precipitated on the image. The chloride of silver formed is clearly sensitive to light, and becomes darkened when submitted to its action. But if, instead of stopping the action of the bichloride solution when the whitening process is only partially effected, it be continued until an opaque dead white image is produced, the whole of the silver image being converted into chloride, and a thick layer of subchloride of mercury deposited on it, light will be found to have no action upon it. We have

some examples in our possession which have been exposed to light for years without any diminution of the pure white tint they possess. The only explanation of this we can offer is, that chloride of silver—or, at least, dry chloride of silver—is not sensitive to light when in the presence of excess of chlorine or of a chloride.

It will be seen, then, that the negative, intensified with iodide of mercury in the mode described, is in the condition for change to which we have referred. A portion of the image is converted into chloride of silver, and left in a state in which it will readily darken by the action of light. The layer of subchloride of mercury deposited is converted into subiodide of mercury; whether it is changed at all by the action of light we cannot with certainty say, but an impression prevails that it is. If the action of the iodide solution were continued, it is probable that a portion of iodide of silver would be formed, and thus another element of instability be provided.

There are two or three modes in which, from a consideration of these facts, we might arrive at probable immunity from liability to change in negatives intensified by the method in question; and it so happens that the methods from which we should have anticipated stability are in practice found to give perfectly the required results.

The first method consists in continuing the action of bichloride solution until the image is perfectly whitened, and the insensitive stage of which we have spoken is attained. If a solution of iodide of potassium in any degree too strong (say one of even six grains to the ounce) be applied, or even if a weak solution be applied too long, a bright yellow layer of proto-iodide of mercury is obtained, and these yellow negatives, although at times very good, are apt to give flat, hard, unsatisfactory prints. But if a weak solution of iodide of potassium, not exceeding one or two grains to the ounce, be employed, and used with care, the greenish grey negative, characteristic of subiodide of mercury, is obtained, and this generally secures the fine printing qualities of negatives produced by the first method described.

Another method, which we find, from the experience of others, yields negatives which do not change, and which, in the brief verification we have had opportunity of making, seems to give stability, consists in the use of a solution of iodide of mercury direct. Iodide of mercury is soluble in a solution of bichloride of mercury, or in a solution of iodide of potassium. The simplest mode of making the preparation is to make a five-grain solution of bichloride of mercury, and a five-grain solution of iodide of potassium, and mix them together in equal parts, or, rather, at the rate of an ounce and a quarter of the latter to an ounce of the former. A red precipitate will be formed, which will redissolve on gradually adding more to the iodide solution. The resulting mixture will intensify vigorously, giving a greenish grey or an olive tint to the negative, which, as those who have tried it for years assure us, undergoes no change by the action of light.

#### MEDALS AT THE CORNWALL POLYTECHNIC EXHIBITION.

THE Royal Cornwall Polytechnic Society, which possesses especial interest to photographers as being the only body which has an annual exhibition of illustrations of the arts and sciences generally, which gives to photography a prominent position, and awards medals for especial excellence in the contributions, has just issued its report, an extract from which, so far as it will be interesting to our readers as relating to photography, we subjoin. It says:—

"In the collection of photographs this year the judges were particularly struck with the amount of uniform excellence exhibited, thus leaving less room for great contrast between the productions of different artists than they have sometimes noticed, and rendering selection between them often exceedingly difficult. Prominent amongst the landscapes stand the four beautiful pictures by Nelson Cherrill,

in which the clouds and the aerial perspective are rendered with a truth seldom seen. To these the judges award a first silver medal. The first bronze medal they give to George Wardley, Manchester, for views in the English lake district; also, a first bronze medal to W. H. Warner, Ross; and a second bronze medal to R. P. Yeo, Plymouth, for views and interiors. These, though of small size, exhibit great delicacy and skill. In the amateur class a fine series of views taken on dry plates by J. Beasley, London, show great artistic taste and manipulative talent, comparing favourably with the best of wet plate productions, and the judges awarded to him a first class bronze medal. The second bronze medal they gave to T. M. Brownrigg, Dublin, and a prize of £1 to J. H. Morgan, Clifton. Coming to portraiture, the judges found great difficulty, where all was excellent, in arriving at a decision. After a long comparison, they determined to award a second silver medal each to R. Faulkner, Torquay, and Briggs, Leamington; to the former for some beautifully posed and delicately soft portraits printed by Swan's carbon process, and to the latter for a finely-modelled portrait of a gentleman, and cabinet portraits, with natural background. They also award to R. Slingsby a first bronze medal, for the portrait of a lady and a fine little life study, "Rest." To R. F. Barnes, London, they gave a second bronze medal, for photographs burnt in on enamel. For three capital enlargements made on albuminized paper by direct printing in the solar camera, a first bronze medal is awarded to J. F. Trull, Falmouth."

There are two or three facts of interest in connection with these awards which are worth mentioning. The first prize, it will be noticed, is awarded to our esteemed contributor, Mr. Nelson K. Cherrill, for landscapes with clouds, the finest of these being "Rusthall Common," which was selected a few months ago by the Committee of the North London Society as a presentation print, the selection of the Committee and the judges thus singularly corroborating the correctness of each others' taste. As this picture is now in course of distribution, it may be worth while to mention that it illustrates the possibility of obtaining very perfect results in the field by means of the wet process without water, the golden syrup solution which we recently described having been used by Mr. Cherrill, who, with Mr. Robinson (his partner), has largely applied it during the past summer.

Another point worth noting is the fact that in the landscape department, with a limited list of prizes, medals are obtained by pictures illustrating at least four different processes. Mr. Cherrill's work is by the wet process; Mr. Wardley's by the collodio-albumen; Mr. Beasley's by the Fothergill process; and Mr. Morgan's, as he recently informed us, by the coffee process. Mr. Brownrigg, if we remember aright, uses the Fothergill process. Mr. Warner and the other medallists all use, we believe, the wet process.

Mr. Barnes, who receives a medal for enamel portraits, has been quietly working for many years in this direction, working out processes of his own. Some years ago we examined many of his experimental works, which were interesting, and had much promise. From the fact that he has here obtained a medal, we infer that he has made great progress, having, in this instance, had to compete with the enamels of Mr. Henderson, some of which we have recently seen, and which are admirably perfect.

#### OVAL MASKS FOR PORTRAITS.

WHERE the best effect in a portrait—especially if it be small—is secured by cutting the picture of an oval form, it is much more convenient and effective, as most photographers know, to mask the negative so as to print it through an oval aperture of such shape and size as may be most suitable. It has been a moot point amongst photographers, as to whether black paper, yellow paper, excited albuminized paper blackened by light, or tinfoil, formed the most convenient and useful masks, and the various suggestions and discussions on the subject, as well as the queries

which reach us from time to time, sufficiently attest that a very large number of photographers undertake the somewhat troublesome task of making such masks for themselves. It is by no means an easy task to cut the oval apertures true and clean, and we have not unfrequently seen the effect of a very good picture spoiled by the irregular edge or imperfect shape of the mask with which it had been printed.

Until very recently, we were not aware that such masks, of different sizes and shapes, very perfectly cut, could be obtained ready for use, and we doubt not that a large number of our readers are in a similar state of ignorance, from which they will be glad to be relieved. Whilst in Mr. Burgess's studio, we noticed that he used some excellently made masks in contact with the negative in producing his burnum prints, all of which are thus printed through oval masks. We learnt that the masks were supplied by Mr. Mander, of Birmingham, who, in reply to our enquiries, informs us that he makes them of all sizes. We have examples before us of nearly a dozen different sizes of oval apertures for card pictures, ranging from one inch to upwards of three inches in the longest diameter. The apertures are cleanly cut by means of punches, the material being glazed black paper, quite opaque. Nothing can be better for the purpose, and nothing more convenient. We presume that they can be obtained through dealers generally.

### CARBON REPRODUCTIONS.

WE have recently been favoured by Mr. Sarony, of Scarborough, with some very admirable examples of the value of Mr. Swan's carbon process for reproducing works of art. Whatever tardiness may be manifest in its introduction to portraiture or landscape work, there is little doubt that carbon must soon supersede silver for photographic reproductions. The possible instability of silver prints has always been used as a strong argument against the use of photography as a means of popularizing art, by many really anxious to diffuse good examples of the great works. The introduction of the carbon process, and the especial facility with which it lends itself to the faithful reproduction, in various tints, of monochrome, of all kinds of pictures, has been gladly recognised and applied, and will doubtless shortly give a completely new impetus to art education.

The pictures we have just received from Mr. Sarony illustrate in a special manner the value of the carbon process, reproducing not only the drawing, but the colour of the original in the very material employed by the master. The subjects consist of a series of masterly sketches by the well-known marine painter, Carmichael, who recently died. The original sketches are in sepia, and the photographic copies are in sepia, so perfect in their rendering of every touch and tint, that in many instances an expert might be puzzled to distinguish the drawing from the photograph.

The boldness, freedom, and spirit of Carmichael's sketches give them great value both to the art student and the collector. Fine in composition, firm and accurate in drawing, they seize with rare truth and beauty the fleeting phases of the landscape which struck his fancy. They comprise a good selection of sea pieces, and some fine landscapes, the majority being about 15 inches by 10 inches in size. The reproduction is admirably done. The negatives are evidently very perfect, and nothing can exceed the excellence of the carbon printing. Mr. Sarony is extending his arrangements for carbon printing, having ordered a larger engine with a view—having tested the process—to carry out the arrangements on a very complete and extensive scale. Hitherto, notwithstanding that much good carbon work has already been done in this country, the process has received its largest development in France by M. Braun, of Dornach. We hope shortly to see, in the hands of the Autotype Company and their licensees, the carbon process, which has been developed and perfected in this country, carried out with a degree of enterprise equal at least to that which M. Braun has with so much success devoted to it.

### DIFFUSION OF FOCUS.

BY THE HON. JOHN W. STRUTT.

IN a review of a work by Dr. Monckhoven in a late number of the PHOTOGRAPHIC NEWS, a passage is quoted on the subject of what is called diffusion of focus. I have not seen the work itself, but I think an erroneous impression is likely to have been produced on the minds of those who read the extract. Some time ago, when the subject first began to attract the serious attention of photographers, there were many discussions in the journals, and it was generally admitted that true depth of focus was to be attributed to spherical aberration; but very little was said on the manner in which spherical aberration produces this result. As the matter is an important one, and not very easy to those who have not made optics a special study, I have thought that a few remarks on it might be acceptable to photographers.

In most applications of optics to the formation of images the point of greatest importance is, that the definition should be the best possible at the centre. Thus, in a telescope, that object-glass (aperture and focal length being given) is the best which most accurately collects to a point the rays from the star or small portion of the sun's or moon's surface. The distinctness of the image off the axis, its curvature, or distortion, are matters of comparatively little importance. The spherical aberration, then, of a telescopic object-glass must be reduced to its smallest possible amount. In a certain sense this result might always, in any object-glass, be attained by limiting the aperture, but it would be at the sacrifice of light, and the increased effect of diffraction would in many cases more than counterbalance any advantage arising from the reduction of spherical aberration. The real problem is to effect this reduction with a given aperture.

When photography was first introduced, and the attention of opticians was turned to the construction of photographic lenses, it was natural that too much should have been thought of the importance of securing freedom from spherical aberration; but soon the necessity of a flat field and absence of distortion appeared, and to secure these a certain sacrifice of definition was essential, though far more remained than was necessary in an image not required to stand the test of magnifying. Another point of difference between the requirements of photography and astronomy was also obvious. A photographic object-glass has to form images of objects comparatively near and at different distances, and that not only at different times, but frequently at one and the same time. Now if the lens collects accurately to a point on the ground-glass or plate the rays from an object at one distance from it, it is clear that the rays proceeding from an object at a different distance, tending, as they do, to meet at a point before or behind the plate, will actually meet the plate in a circle of small diameter; and it is important to notice that this circle will be equally lighted; that is, the rays will be uniformly distributed over its area.

If, then, it be required to photograph on the same plate objects (say A and B) at different distances from the lens,

supposed to be free from spherical aberration, there are notably three distinct ways in which the adjustment for focus may be made. First, it may be made so that the light from A is accurately collected to a point on the plate, in which case A is perfectly defined, but B, being represented by the above mentioned small circle, is badly defined in proportion to its diameter. Secondly, the adjustment may

be made for B as in the first case for A. One of these arrangements would, of course, be adopted when the definition of one of the points is required to be the best possible, while that of the other is of comparatively no moment. Such occasions arise, but in pictorial photography it would be generally desirable that both objects should be fairly represented, and that the definition of one should not be entirely sacrificed in order to improve the other. In such a case the focussing would not be made on either A or B, but on a point (approximately) half way between them, so that neither A nor B would be perfectly defined, but would be represented on the plate by circles of light equal to each other, but of only half the magnitude of that which represented one point in the first and second cases. This readily suggests the question, would not a lens affected by spherical aberration be capable of giving as good a representation as this of A and B on the screen? It is true that in actual photography there would be generally some third object, and so situated that the peculiar power of the lens would be brought out in perfectly defining it; but this would be rather a drawback than an advantage, as a tolerably uniform definition is usually desirable. We are thus naturally led to enquire what effect the introduction of spherical aberration would have on the definition of objects situated at various distances from the lens. With this end in view it is necessary to examine carefully the nature of the bundle of rays which proceed from towards the screen after refraction by an uncorrected lens.

In the first place it is to be noticed that the rays which are refracted by one part of the lens do not, in general, reach the axis at the same point with those which come from a different part; so that if we divide the lens into rings, proceeding from the centre outwards, each small ring may be supposed to act as a perfect lens; but there is a variation of focal length in passing from one ring to another. Thus the focal length of the outermost ring C A, and that of the central part C F, the intermediate rings having intermediate focal lengths. The least section of the assemblage of rays is at Q, where the curve F Q H, touched by all the rays, and called in optics the caustic, meets those from the edge of the lens, which, having cut the axis in A, again diverge. But it does not follow, as might at first be supposed, that the screen should be placed there in order to get the best possible definition of the object O. The reason of this will appear presently.

Between the lens and Q the space occupied by the rays is bounded by the curved caustic surface, but beyond Q by the cone, whose vertex is at A, formed by the above, refined to extreme rays.

A second radiant point, O' nearer the lens (say) will produce an approximately similar system of rays to the above, only displaced somewhat towards the right, or from the lens. But instead of considering the two systems of rays as cut by a fixed screen, as in actual practice, it is allowable and more convenient for explanation to confine ourselves to one system, and conceive that intersected by parallel planes at varying positions along the axis. This substitution proceeds on the assumption that the objects are not at very different distances from the lens in relation to its focal length.

In order to avoid continual reference to them, it will be supposed in what follows that the *aperture* and *focal length* of the lens are given, or do not vary under the circumstances contemplated, which of course does not prevent the aberration changing its amount within certain limits. The distances between the two cutting planes which we have to consider is given as soon as the positions of O O' are fixed. And as, in the case of a corrected lens, the definition of objects slightly out of focus may be measured by the diameter of the small circle which represents a point, the question is suggested, where must the sections in the present instance be taken to make their diameters equal? In Conington's Optics there is a remark to the effect that such a quality as definition cannot have a measure. Thus I

suppose one definition could not be said to be twice as good as another. But neither could the same be said of two temperatures, at least, prior to modern discoveries, which does not prevent the ordinary thermometer from being a very useful measure of temperature.

The planes will evidently lie on opposite sides of Q, but not equally distant from it, inasmuch as the obliquity of the caustic surface to the axis on the left is less than that of the cone which bounds the section on the right of Q. A definite result can of course be obtained by the application of mathematics, and it will, I believe, be found that the magnitude of the aberration may be so chosen as to make the diameters of the section smaller than it is for a corrected lens; so that it would appear that for the *equal* definition of O O' a corrected lens is *not* the best. On referring to the original calculation I find that this statement is not quite correct. As the aberration increases from zero up to a certain point, the definition (as measured by the size of the section) would remain unaltered, and after that point would deteriorate. The correction in view of what follows is of no moment.

About a year ago I went through the calculation alluded to, but I was aware that it would give no adequate idea of the advantage of an uncorrected lens, on account of the fundamental assumption on which it proceeds, namely, that the diameter of the section of the pencil made by the screen may be taken as a measure of the distinctness, or rather indistinctness, of the image.

This, though admissible enough for a corrected lens, is by no means equally so when there is a spherical aberration, for then the light is not impartially distributed over the area of the section, nor according to any other fixed law, the same for all sections. There is, in fact, a series of points where the illumination is *much* (according to the ordinary theory of rays, infinitely) greater than it is elsewhere, such points being situated on the caustic surface, and also in a line along the axis between A and F. That this is so will be admitted when it is remembered that *all* the rays pass through the line A. The result is that a section taken between H and A has a bright rim, but nothing peculiar about the illumination at the centre. On passing A, however, while the bright circumference continues, a spot of intense light makes its appearance at the centre, and this state of things remains until Q is past. At this point the bright circle leaves the boundary of the illuminated area, continuing to contract, while the latter begins to expand. Soon after passing F the illumination becomes comparatively uniform over the whole area of the section.

All this may be easily observed by admitting the sun's rays into a darkened room through a hole in the shutter in which is fixed a lens of short focus. If the rays diverging from the small image of the sun thus formed be allowed to fall on a lens which possesses a considerable amount of spherical aberration (such as a microscopic or magic lantern condenser), the circumstances of the preceding paragraph are sensibly realized, and the construction of the refracted pencil can be examined by receiving it on a movable paper screen.

A very beautiful modification of this experiment has been made by Professor Stokes, who avails himself of the power possessed by certain substances of rendering visible and dispersing the blue and ultra-blue rays of the spectrum, a phenomenon to which he gave the name of fluorescence. The sun's rays, reflected horizontally, by a mirror placed outside the window, are admitted into the darkened room through a blue glass, and, after refraction by the lens, pass into a glass trough filled with a weak solution of osculine placed close behind it. The blue glass is not absolutely necessary, but much increases the brilliancy of the experiment. A solution sufficient for the purpose may be made by soaking a few chips of the inner bark of the horse-chestnut in a jug of water, but it soon decomposes. The path of the rays is marked by the luminosity of the liquid, somewhat as in a smoky atmosphere, and the bright line along the axis is

very evident. But if the light be limited to one plane by a slit placed in front of the lens, it disappears, as might be expected. The experiment may be varied by placing before the lens an opaque diaphragm, such as a piece of cardboard pierced with a number of small holes, by moving which about the composition of the pencil may be easily studied.

Inasmuch, then, as the light is so variably distributed over the section—sometimes concentrated on the circumference, sometimes at the centre, or both—the question arises, What is to be taken as the measure of the distinctness of the image? How far would a concentration of light towards the centre compensate for an increased diameter of the section? Although the answer is essential to a complete theory of the image formed by an uncorrected lens, I am not aware that it has ever been given. Possibly the nature of the original object would have to be taken into account. In the mean time, photographers will not hesitate. The choice practically lies between a flat-headed pencil with which no fine line or delicate tracing can be made (except over a limited portion of the picture), and the sharp central point of light, with the condition imposed that the ground must be gone over with a stump, softening, but not obliterating, the details. In fact, the image formed by an uncorrected lens, *properly used*, may be regarded as compounded of a multitude of images superposed on one another of all degrees of distinctness, the first roughly sketching the principal masses of light and shade, the intermediate ones giving all but the minute details, which are at length filled delicately in by the last perfect component image.

Some time ago it was proposed in the PHOTOGRAPHIC NEWS to submit the exposed plate for a short time to the action of weak diffused light, with a view of thereby giving additional softness, and of reducing the time of exposure in the camera. This method of procedure was not altogether unsuccessful in cases where, for some reason, it was impossible to allow the full time required for the formation of the invisible image. But it will be seen at once how far preferable it is to increase the aperture of the lens, *even though the rays from the added part be not in focus on the plate*, for instead of a uniform action fogging the shadows at the same time that it strengthens the lights and half-tones, we have, at the worst, the same uniform action over the lights of the picture, while the masses of deep shadows are spared.

I have confined myself entirely to the subject proposed, and have made no reference to chromatic aberration, although what has been said is in great measure applicable to it. When the question is examined with that object, it may possibly be found that the importance of perfect achromatism has been also exaggerated, although the difference in average refrangibility between the luminous and chemically-acting rays will always be an impediment to the employment of chromatic lenses. There would be very little difficulty if the lens were always used under the same conditions, as a *fixed* difference of position between the ground-glass and sensitive plate could be easily secured by a suitable arrangement of the plate-holder.

#### PHOTOGRAPHS OF THE ROYAL CORNWALL POLYTECHNIC EXHIBITION.

(FROM OUR OWN CORRESPONDENT.)

The thirty-sixth Annual Exhibition of the Royal Cornwall Polytechnic Exhibition, which has just closed, afforded the inhabitants of the west counties a sight of the finest, largest, and most varied collection of photographs that has ever been exhibited under the auspices of this valuable Society. The first number in the department was H. P. Robinson's. "Returning Home," representing a girl in humble life crossing a lonely heath on returning to her dwelling in the gloaming, after her day's labour at gleanings, is certainly the finest work of the kind we have seen, the timid, scared expression of the girl being forcibly portrayed, the landscape being excellent, and the whole composition of the

entire picture admirable. A likeness of Adam-Salomon stands pre-eminent among the portraits, not only from its fine manipulation as a photograph, but also the fine artistic treatment of pose and lighting, its general effect being that of an impression from a high class mezzotint engraving. The next exhibitor we notice is Briggs, of Leamington, who sends some pretty cabinet pictures, a frame of emolliotypes, and a fine 10 by 12 portrait, a good example of careful manipulation, somewhat marred by the roll of paper held in the hand. Four whole-lengths on 10 by 12 plates, by Clark, of Bristol, were most charming productions, the figures being bold and vigorous, and the accessories judiciously in keeping, sufficiently prominent without being obtrusive. Slingsby, of Lincoln, exhibited four portraits, and "Labour" and "Rest," two clever studies from the life. Stephen Thompson had four pictures—two English and two Swiss scenes. Much interest was manifested in two small frames of medallions, burnt in on enamel, by R. J. Barnes, of London; and also in another frame of enamel pictures, by Mr. Henderson. A frame of cabinet pictures taken in the studio, with backgrounds from outdoor scenes from nature, by Robinson and Thompson, of Liverpool, were very effective, and good examples of this class of combination picture. Some most excellent portraits, printed in carbon, as well as some studies, also printed in carbon, sent by Mr. A. Faulkner, so closely resembled prints from engraved plates, that a good many people could hardly believe they were in reality specimens of photographic art. This gentleman also exhibited some charming carte specimens of studies of children.

Of enlargements there were several exhibitors, the most noticeable of whom were J. F. Trull, of Falmouth, who showed three specimens, untouched—two busts, life size, and a half-length of a military officer—which would favourably compare with any others sent to any exhibition whatever. Of coloured enlargements, the only exhibitor was Mr. T. M. Douglas, of Edinburgh, whose name is appended to six pictures in the catalogue. Two of these pictures were really very fine specimens of art, being far superior in execution to what are generally shown as "photographic enlargements, coloured in oils," and might take fair rank among the higher class of portrait painting.

Of landscape, the most noticeable among the professionals were George Wardley, of Manchester, who exhibited some fine large examples of the lake and country scenery, and Nelson K. Cherrill, Tunbridge Wells, who sent half-a-dozen fine pictures, in one of which—"Rusthall Common"—the massing of the clouds was particularly grand. Of smaller subjects, W. H. Warner, of Ross, and R. P. Yeo, Plymouth, sent some very brilliant specimens of interiors, as well as out door scenes, on the cabinet size.

Mr. F. Beasley, jun., although in the amateur list, exhibited fifteen pictures 10 by 12, by the Fothergill process, which very few professionals could surpass. The value of this gentleman's contribution was enhanced by every picture stating the time between preparation and exposure, and exposure and development. Mr. J. H. Morgan, Clifton, another amateur, exhibited some remarkably good pictures, particularly one or two of Tenby Harbour. Some views and groups taken during the late campaign in Abyssinia, sent by Major Holland, R.E., gave the visitors to the exhibition some idea of Theodore's stronghold, and other points of interest in the late war in that country.

On Friday evening a conversazione was held, during a portion of which an account was given of Solomon's magnesium lamp, and its application to the purpose of enlarging from carte negatives. After the lecturer had minutely explained the properties of the lamp and the metal, and showed the audience enlarged images on the screen, he retired from the larger hall to the smaller one, and, after a comparatively short time, returned with an enlargement he had made in the interim, thus giving strong proof of the value of this invention to photographers. In the hall I perceived a worked-up enlargement, in monochrome, of Mr.

Solomon himself, as well as some other untouched pictures, and I should think many followers of the art who do not feel warranted in going to the expense of a solar camera will gladly avail themselves of this much less costly apparatus."

Another correspondent, after some remarks on the unusual excellence of this year's photographic exhibition, says:—

"There is a prospect of the Cornwall Society becoming migratory, and holding its meetings in other parts of the county; this will prove of much benefit to art in general, and photography in particular." He adds "a word in conclusion to photographers generally, and the Exeter local committee in particular. Next year the British Association hold their meeting in the ever faithful 'city of the red earth,' when a most excellent opportunity occurs for a great art display, graphic and photographic, to those interested in the proceedings of the exploration society. Further information may be obtained from Mr. A. L. Fox, one of the acting honorary secretaries of the Cornwall Polytechnic. For the British Association, Mr. H. S. Ellis, of Exeter, will furnish any particulars that may be required."

The official report of awards will be found in another column.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XXXVII.

MR. FRUWIRTH'S useful process of phototype, which not only reproduces engravings for the press, but also enlarges or reduces them, enables me to present one of the most perfect compositions of modern times, which, happily, belongs to the nation, and will remain an object of study as long as it exists.

Perhaps nothing in the whole range of art can be brought into comparison with the works of Mulready for technical perfection. In truth of drawing, elaborate finish, and exquisite colour, he excelled long before the works of the modern pre-Raphaelites made these qualities indispensable in pictures, and to these perfections he added most supreme skill in composition. His subjects were not always equal to his powers, and one cannot help regretting that he wasted such splendid art on themes such as "Boys firing a Cannon," "The Loan of a Bite," "Bob Cherry," and others; but even these incidents become, under his hand, elevated, and redeemed from the commonplace and vulgar. The nation is rich in possessing—through the

generosity of Mr. Vernon, and, more especially, of Mr. Sheepshanks—a large collection of his works, illustrating his progress from the commencement to the end of his career. Painted in his best period, "Choosing the Wedding Gown," of which an illustration is given in this chapter, is one of his finest creations, and is an admirable example for the student to have constantly before his eyes.

During the earlier chapters of this attempt to teach the

laws of art to photographers, when I had to deal chiefly with principles, and to enforce their use, I abstained as much as possible from giving long quotations from well-known works, well knowing that nothing tires a reader more than numerous extracts, often ill-adapted to the purpose for which they are intended; but in the later chapters, in which examples are introduced showing how these laws have been applied by others, I prefer, when possible, using the

criticisms of other writers, because they confirm, in a measure, the principles I have endeavoured to teach. For this reason I here introduce some remarks on the design and colouring of this picture from the *Art Journal*:—"As an example of Mulready's strictly domestic pictures, 'Choosing the Wedding Gown,' exhibited in 1846, is admirable; as a specimen of brilliant colouring it is superlatively excellent; nothing in modern art—it may be said in the art of any age in this class of subject—has surpassed, or even equalled it. This splendour is not reached by the free use of positive colour, but by the most subtle and delicate application of tints, both in the lights and shades, worked up from the lowest to the highest scale, and culminating in pure red, ultramarine, &c., and all presenting the most perfect harmony, because founded and carried through on well understood and immutable laws. Then look at the composition: mark the arrangement of the two principal figures; how easily and naturally they are placed, and how carefully both attitude and action have been studied to preserve a right balance, as well as to support the subject. The extended hand of the silk-merchant, for example, was a necessity to fill up a space which would otherwise have been vacant; it serves as a counterpoise to the uplifted hands of the lady, and, it marks the impressiveness with which the shopkeeper commends his goods. And, lastly, notice the beauty of the fair purchaser's face—the future Mrs. Primrose—and with what earnestness she examines the piece of rich stuff; the kindly solicitude of her affianced husband, the worthy doctor; and the persuasiveness of the bland and smiling mercer. In the background is his wife attending to a customer; the artist has bestowed no less pains on the good dame than on the other and more prominent persons in the composition. In fact, whether we look for colour, form, expression, or design, we see each and all exhibited in the most attractive, powerful, and recondite manner."

Beyond all this the student will see other and more strictly technical beauties, corresponding exactly with those I have pointed out in other examples; the prominence of the principal figure; the opposition of the highest light with the chief dark in the centre of the composition; the balance afforded by the mass of rich stuff on the stool and the dog—even the ring on the floor is not without its artistic value—the opposition and contrast given to the curved and undulating lines by the straight lines of the piece of stuff in the lady's hand, and in other places; and, lastly, the repetition of the main incident in the background.

The illustration is a reduced phototype, by Mr. Fruwirth, of a wood-cut in the *Art Journal*, whose valuable illustrated articles on "British Artists" afford examples admirably adapted to the use of the student in composition and chiaroscuro.

#### FOR REMOVING THE VARNISH AND COLLODION FILM FROM OLD NEGATIVES.

BY O. O. MASON.

STAND the plates on edge (faces not in contact), in a kettle or boiler of any convenient shape and size, taking care that the plates do not come in contact with the metal of the boiler (this is prevented by placing a cloth on the bottom and sides, or by a light wooden form or rack, suitable for the size of plate under treatment). The boiler is then filled with cold water, and placed over the fire, the temperature being gradually raised to the boiling point, at which it is maintained about thirty minutes (often less); the films will then drop off, or may be easily removed by a little friction with the hand or a piece of cloth. After removing the boiler from the fire, the plates should be allowed to cool gradually before removing from the water, or they may become brittle.

In no case should cold water be used to cool the contents of the boiler, as the plates would be most certainly broken in so doing. I have used this plan for several years, and find it better than any other method of removing films which I have tried.

## Short Essays on Photography and Art.

### No. 5.—ON ART TEACHING AND ART STUDY.

BY "RESPICE FINEM."

DURING the last few years the attention of photographers has been called in a very especial manner to the importance of art study. The technicalities belonging to the science and to the practice of photography have been gradually mastered. Lenses and processes have reached a high degree of comparative perfection. I do not wish to suggest that in regard to these we can speak of finality, or say that nothing remains to be desired, nothing to be achieved: I simply state, in relation to material appliances—chemicals, processes, and lenses—that facilities exist sufficient to enable the moderately intelligent practitioner to devote his chief attention to the development of the plastic power of his art, and the testing of its capacity as a means of securing pictorial effect. And, as was natural, this technical advancement achieved, attention has been directed to higher ends.

Exponents of the art capacity of photography have never been entirely wanting, even in the days when it was asked, in high quarters, "What photographers wanted with pictures?" Some of the earliest calotypists were accomplished artists. In the early days of collodion, men like Grundy and Lake Price, and, at a little later date, men like Rejlander and Robinson, in subject pictures; and men like Bedford, Mudd, and others, in landscape work, have grandly illustrated the fact, that lenses and chemicals were obedient agents in artistic hands. These and others have been silent but efficient art teachers. Some years ago arose another class of art teachers, louder, but less efficient, yet not without their uses. Their business, it seemed, was to denounce what was wrong, rather than to illustrate by practice what was right. Such a mission, although not a lofty one, had its uses. Jonah, when sent to denounce the sins of the Ninevites, was by no means an exemplar of righteousness; but his mission had its specific usefulness. And they who have unhesitatingly, or even captiously, pointed out the artistic shortcomings of photographers, and the soulless emptiness of the mass of photographs—whether they have spoken from without, or as claiming a position within the photographic circle—have performed some service in advancing the art. The fatal fault of these quasi-teachers, who deal in denunciation on the one hand, and in nebulous vagaries on the "awe inspiring mysteries" of art on the other, is, that they confound more frequently than they enlighten; and if they convince the youthful aspirant after art excellence that if he cannot sympathise with these vague inborn yearnings after indescribable mysteries which are supposed to characterise the true artist, his work is naught, he is apt to throw up the effort in sheer disgust or despair. And this is, I need hardly say, the worst frame of mind in which a man can indulge. That there is such a thing as natural capacity, inborn fitness for artistic culture, cannot be doubted, and this is doubtless a necessary qualification for the highest success. But I think that ability to appreciate pictorial excellence, and the desire to acquire the power to realize it, are *prima facie* evidence of some fitness for the work, and I would earnestly impress the idea that with these pre-requisites, and capacity for careful study and honest labour, a fair mead of success is attainable by all students. I have always grieved, therefore, over the denunciatory style of art teaching which at one time prevailed, as little calculated to raise the status of photographers. There is great force in the lines in Bailey's "Festus":—

"Men might be better if we better deemed  
Of them. The worst way to improve the world  
Is to condemn it. Men may overget  
Delusion—not despair."

In speaking of art teachers, it would be impossible to overlook the recent series of lessons in your pages by Mr. Robinson, so admirably clear, simple, full, terse, and practical; but it would be superfluous, as well as inadmissible, I presume,

for me to enter into either comment or eulogy thereon. I may remark, however, that they go far to negative a common apothegm, that very little of art can be taught. But there is another form of art teaching of which we have too little, and another class of art teachers of whom we have too few. I refer to those most valuable of all teachers who strive to produce by photography the highest results of which it is capable in pictorial art, not simply as a matter of business, not as a means of bread-winning, but from a love of the art, from a profound belief in its capabilities, and a resolve, at much cost and much labour, to demonstrate its fitness for rendering pictorial effect. For this, the highest reward they as a rule desire is, the appreciation and honour of their fellows; and this reward they do in the main receive. Such appreciation, I doubt not, in their estimation far outweighs the gibes of the envious and incapable which they must also receive. But putting this latter small class of small detractors aside, it has often struck me that there is too little active and demonstrative appreciation amongst photographers of this highest class of art teachers. I believe that the works they produce are rarely published or offered for sale; but where they have been so published, have photographers generally purchased them, and shown, by their eagerness to secure them, that they appreciated the work? Many of the photographs of the late Mr. Grundy were gems of real art, and, so far as monochrome can go, might have rivalled the works of Gerard Dow or Teniers. And yet I question if one photographer in a hundred ever saw a copy. If I wanted to purchase a copy now I should not know where to procure it, and the negatives are, I believe, scattered about and lost. When Rejlander exhibited his first great picture, the "Two Ways of Life," it was received with coldness by some, with condemnation by others, and with the enthusiastic admiration it deserved by scarcely any. Of the hundreds of photographic triumphs in the field of art, full of fine lessons, which he has since issued, how few have found their way into the portfolios of photographers! When the pictures of Adam-Salomon were introduced to attention—pictures which have unquestionably shown to photographers a new and higher phase of photographic portraiture than they had before dreamed of—many photographers vied with each other in striving to ascertain how little merit they possessed, and how much of the qualities which they could not deny was due to trick or adventitious aid. Robinson, it is true, has been more fortunate; such of his art studies as he has published have, I believe, sold largely, and honours have attended his works wherever they have been exhibited, at home and abroad; not less than a score of medals, if I am rightly informed, having been awarded to them within half as many years.

The form of art study I should especially like to recommend to photographers would extend this class of art teachers. I should like to see more photographers enter the list to produce purely pictorial photography, and demonstrate the capacity for art purposes of camera and chemicals. Lessons in art are now not wanting; so much of art—especially in its relation to photography—as can be taught is now accessible in your pages; but this will be of little value without frequent effort to apply it; and this effort can only be imperfectly attempted in the regular course of the business of portraiture. It is only in the attempt to produce subject pictures, with time at their disposal, with sitters or models under some control, and with discretion as to choice of draperies, accessories, backgrounds, &c., that the photographic art student can hope to develop his powers, and only by such exercise that he can fit himself for securing the highest excellence in the ordinary practice of his profession as a portraitist.

The imperfect appreciation of such work already alluded to may, it is true, be cited as affording but little encouragement to effort in this direction. This is an objection of little weight, and that for many reasons. The reward will be found in the effort itself, and in the skill, facility, and command over ordinary professional duties the portraitist will

acquire by indulging in such studies. The power and confidence gained will be worth much, even if the pictorial studies fall short of the highest art excellence. The art would undoubtedly be elevated by such effort, and many worthy pictures would doubtless be produced, illustrating in various ways the plasticity of photography. Dryden tells us, in one of his pregnant lines, that—

"They had crowns who but endeavoured well."

I fear that in photography the mere aim or intention to succeed would win no crown amongst photographers, because, as a rule, the endeavour could only be made manifest by its success; but of this I am satisfied, that if all photographers who love their art, and are interested in its advancement, would make effort now and then to illustrate its pictorial power in other modes than by the production of "pot-boilers," not only would they gain in skill as individuals, but the standard level of excellence in photographic portraiture would rapidly rise, and with that must come a simultaneous elevation of the general status of photography and photographers.

I should have liked to say more on some phases of art study; but in undertaking to write one of the "short" essays on photography and art, I find space only for a few desultory thoughts is available. Possibly on another occasion I may offer a few further suggestions on the subject.

#### ON THE EMPLOYMENT OF COLLODIONIZED PAPER.

BY LUDWIG SCHRANK.\*

##### *The Industrial Employment of Collodionized Paper.*

WE should feel some embarrassment were anybody to ask us if we could guarantee the successful introduction of collodionized paper, and we therefore propose to place the reader in such a position that he may be able to form his own opinion on the subject. In the first place, the price of the prepared paper is notably higher than that of albuminized paper, for in the fabrication of the former it is necessary to take into calculation the amount of loss incurred by the evaporation of the ether, alcohol, &c. But at the same time it must be remembered that in sensitizing a quire of albuminized paper as much as two or three ounces of nitrate of silver is expended, and this, added to cost of superintendence and the amount to be allowed for waste and spoiled materials, forms an important item, which is seldom sufficiently considered by photographers. The collodion-chloride paper is almost half as sensitive again as albuminized paper, and is always ready for employment, whereas the other must be freshly prepared from time to time. Then the prints produced are much sharper than those on albuminized paper, or, as we heard a Berlin referee express himself, they possess "fabulous sharpness." Lastly, even if the price charged is somewhat high, in these days of competition, it would be well worth while securing superior advantages, even at a notably increased outlay.

The facility with which the collodion film may be removed from the paper renders the material remarkably suitable for making transfers, and in this capacity it is of so great a value to the photographer that no studio should be without it, more especially the studio of the enameller. The latter generally employs collodion positives, produced in the camera by means of an ordinary negative, for the powdering of the porcelain colours; but if these negatives have been designed for making positives on paper, they are too vigorous for the enamel process, and produce, therefore, very hard results; moreover, the half tones sometimes suffer from the great heat to which they are subjected in the burning process. We have now before us several positive pictures produced by means of collodionized paper, in which softness and vigour are blended to such a degree that no better result could possibly be wished for. That the collodionized paper is in every way well suited, not only to the production of

\* Continued from p. 478.

enamel pictures, but also for stereoscopic slides upon glass, and for multiplying negatives, is very obvious.

With regard to multiplying negatives, Professor Freund communicates the following:—

"The negatives which I send you herewith have been produced by means of a glass positive.

"The methods I adopt for reproducing negatives by means of the transfer paper is as follows: A print must be obtained of sufficient depth and vigour upon the collodio-chloride paper, an operation taking some time when conducted in the shade; this is then washed and fixed in the ordinary way. Toning is in my opinion a superfluous operation, and the examples I send you were produced from untinted prints. For making the transfer I employ a varnish made from equal parts of gum elemi and Venetian turpentine, and of spirits of wine ten parts. A glass plate is first warmed, and then coated with the varnish in the same manner as a plate is covered with collodion, and the fixed and washed paper picture (negative) having been pressed between blotting-paper, and likewise faced with varnish by means of a brush, is then placed face downwards upon the plate, and pressed down by means of the hand. Warm water is afterwards poured over the print, and the paper is thus removed, while the collodion film remains attached to the glass. Instead of glass, the so-called *caoutchouc vitrifié* might no doubt be used with good advantage; at the same time, the operation is easily conducted with glass, and the few bubbles formed exert no prejudicial influence, and may be obviated altogether with a little skill."

It has been the custom to multiply negatives by means of tannin plates by first producing a positive, and from this a second negative; by this method it is, however, difficult to guess the exact amount of exposure required, and the defects of the development in the original are exaggerated in the first copy, and again in the second, so that the new negative is in a very great degree inferior to the original. All these unpleasantnesses are completely avoided by the employment of collodio-chloride paper, and the production of reverse pictures therewith; the printing may be carefully watched and controlled, and the gradation of tone improved by judicious covering up of the copying frame; and, moreover, what is of the last importance in producing negatives of old paintings, the retouching may be carried on, not only upon the negative for the purpose of correcting the shadows, but likewise upon the positive to bring about a modification of the lights.

A positive upon transfer paper is free from all inconveniences which might happen from the breaking or injuring of a glass negative, and by its means any number of negatives may at any time be produced.

For the above reasons we would recommend the adoption of collodio-chloride paper at any rate in those studios where valuable negatives are preserved. As manufacturers of the material, we may mention MM. Obernetter, of Munich; August Freund, of Tarnopol, Galicia; and Adolf Ost, of Vienna; and there is no doubt that the time is not far distant when all dealers in photographic materials will find it necessary to direct their attention to a product of so much importance.

## A NEW METHOD OF ETCHING PHOTOGRAPHS UPON GLASS.

BY DR. LIESEGANG.\*

A FEW months ago, one of my pupils, M. E. Siegwart, of Neuchatel, communicated to me a few suggestions relative to the process of etching photographs. With the method he suggested I have made several experiments, and these having convinced me that it is of some practical value, I now publish the details of the same.

Etching upon glass may be employed either for the purpose of producing a dull picture upon a transparent ground,

or a transparent picture upon a dull ground, the mode of manipulating most in vogue being to cover the glass surface with a coating of wax, and to etch the picture upon the same, or to paint the image upon the glass with a wax colour or varnish, and then to treat the naked glass with fluoric acid. The fluoric acid changes the silicate bases of the glass into soluble salts of fluorine wherever it comes into direct contact, but where the surface is protected with wax the acid has no effect; the latter is applied sometimes in the form of gas, and sometimes in a liquid state, but generally a mixture of fluor spar and dilute sulphuric acid is employed.

M. Siegwart proposes the following mode of proceeding:—

A solution of gelatine is prepared similar to that used in the Joubert or Obernetter dusting processes, and made sensitive to light by admixture with bichromate of potash; the surface of the glass upon which the picture is to be produced is then coated with this liquid, and exposed to the sun, either under a positive or a negative, according to whether the image, or the ground, is required to be dull. After exposure, the latent picture is sprinkled over with very finely powdered fluor spar, or, better still, with cryolite powder ( $3 \text{ Na Fl, Al}^3 \text{ Fl}^3$ ), and then varnished with thin normal collodion, when it is ready for treatment with dilute sulphuric acid. The fluor spar attaches itself to those portions of the surface which have not been acted upon by the light, and, on the application of the acid, the process of etching extends likewise to these particles. As the half-tones received less light than the shadows, a proportionately less quantity of the powdered fluor spar adheres to these parts than is attached to the lights, and therefore the half-tones are less deeply acted upon by the etching fluid.

Another method of operating is to employ a gum resin of some kind; as, for instance, benzoin, copal, shellac, dammar, Botany Bay gum, asphalt (all of which melt at  $100^\circ \text{ Cent.}$ ), these being of course very finely powdered and sifted. The fine particles of gum are dusted over the glass surface, and the picture is then transferred thereto; the glass is now warmed to the degree required to melt the resin, so that the picture becomes secured to the glass, the coating of resin serving as a ground for the subsequent etching with fluoric acid. By this means half-tones may easily be obtained.

If, instead of a gum resin, a glass flux easily melted, or borate of lead, is used, and the glass with the picture is placed in a suitable furnace or oven, a cementation of the whole takes place, and by subsequent treatment with a strong acid an image of the most brilliant description may be obtained. Instead of dusting the finely powdered borate of lead upon the glass, it may be added to the gelatine mixture in the same manner as in the carbon process.

Very beautiful effects may be produced by this process, if, instead of using ordinary glass, a white glass is employed covered with tinted glass, so that a coloured picture may be produced upon a white ground. Or images of two colours even may be obtained by taking a compound glass (say, for instance, yellow glass covered with blue); the etching will then produce a yellow image upon a green ground. Many variations of this kind would naturally suggest themselves to the mind of the glass manufacturer.

## Correspondence.

### DISTORTION AND PERSPECTIVE.

SIR,—The subject of distortion and perspective, as brought forward and illustrated by Mr. Cherrill, is of so much interest, and promises, if worked out, to be of so much use to the photographic art in determining the relative value of long and short focussed lenses, that if you will allow me I will go a little more into the matter, trusting, at the same time, that it will be duly taken up by others.

To begin with, then. Like Mr. Cherrill's artist friend, I believe that all photographs are, and must be, if we speak strictly, wrong in perspective (I put aside distortion from curvature, &c.),

\* *Photographisches Archiv.*

but that one may, by artifice, reduce the exaggerations within narrow limits, and so produce pleasing results. I use the term exaggerations, for I think it can be proved to be such, having its advantages and disadvantages, and being a friend or an enemy according to the way we treat it. Let us look at some of the phenomena. Take Mr. Cherrill's mirror test, and here I think a little consideration will show that gentleman that he is reasoning on a fallacy in believing that in your reflection in the mirror you are looking on a true perspective, or such as you would see in a real object. Thus, if you stand at a distance of twelve feet in front of a mirror, you see yourself as a spectator would see you who was twenty-four feet from you, or just as much behind the mirror as you are in front of it; if now you stretch your hand horizontally towards the mirror (call it three feet in advance of you), your hand will look to you enlarged, and well it may do so, for though it ought to appear as it would to a spectator at a distance of twenty-one feet, it will really look to you as if you had pushed it forward a distance of six feet; in fact, as if it was seen with the perspective enlargement of an object which was eighteen feet off the supposed spectator. In other words, taking the absolute plane in which you stand, everything which advances or recedes from that plane will, either in mirror or lens, have its perspective length or shortening doubled; that is, the size of the object represented will not be double, but the perspective increase or diminution of size will be doubled. If you yourself step forward three feet, your image also seems to step forward three feet, and your perspective size has increased by definite laws, not the three feet you actually advanced, but six feet. So if you remain stationary and advance your hand the three feet, you have really multiplied the perspective of your hand and arm by two, so that while the reflected size of the body remains as before, you see your arm and hand as a photograph would show it, and the hand would appear such as belonging to an arm six feet long.

There is a very easy way of measuring this exaggeration of perspective for all distances; viz., taking the oval of the human head and face at about ten inches; on a slip of glass gum some bars of paper at two inches apart; stand in front of a mirror (say at twenty feet off it), place the glass with the bars in the plane of your face, and the face and head will appear to fill five of the spaces between the bars; hold the glass two feet in front of you, and as you look through it at the reflection in the mirror you will find that your oval of head and face will only fill four of the spaces. Now, if you go forwards to a distance of four feet from the mirror, and you place the barred glass in the plane of your face, you will find the oval fill the five spaces as before; and if you advance the barred glass two feet, as you did in the former experiment, you will find, as you did before, that face and head will fill only the four spaces, so that the exaggeration of the perspective would seem to be equal for all distances, and, *ergo*, it would seem that, as lenses obey the laws governing the reflection in the mirror, that, long or short focussed, they would act alike. This would be an error, for a new element comes into operation in this way: At twenty feet off the mirror the exaggeration of the perspective would be only one-tenth of the apparent distance of the object reflected, whereas, at a distance of four feet from the mirror, it is evident that it would be one-fourth of the apparent distance. Therefore, in lens or mirror, although the absolute perspective exaggerations would be the same for all distances, its effect upon the spectator would vary in proportion to the distance; and to illustrate this I have to go to some of the laws of perspective itself.

The artist, or the perspective draughtsman, uses an artifice: he draws objects which really are on a horizontal plane and at various distances from him on a fixed vertical plane, in such a way as to appear to the spectator as if the real objects were still on a horizontal plane, at their proper distances, and seen through the transparent vertical plane which he calls his "picture." The laws by which he is guided are very definite and well determined, so that any marked deviation from them gives rise to a very uncomfortable sensation, although the precise cause may not be at once apparent. I am not going to inflict a treatise on perspective, although to prove my point I must allude to one or two of its laws. To begin with, then, the artist has a point on his horizon (visible or concealed) to which he is supposed to have his eye constantly directed; this is called the "point of sight," and on plane perspective he has also two points, one on each side his point of sight, which he calls his "points of distance"; these points he can fix on himself according to the nature of the subject he is engaged upon;

but his points of distance usually are about as far from the point of sight as the spectator is supposed to be from the vertical plane upon which the artist sketches. What would be the effects respectively if this "point of distance" were taken as too far removed or too near the point of sight? Why these: If too far off, the objects represented would appear flat and poor, and have no effect of depth or roundness; if too near, then the objects would be exaggerated in their depth, they would "stand out too much," and those in the foreground would appear especially out of proportion. So it is laid down as a rule that the point of distance must not only be outside the picture, but that it ought to be some distance outside it; how far is, as I said, left to the discretion of the artist. His lines to the "point of sight" must be intersected by those to the "point of distance" indicating the perspective "depth" of a solid object; so, of course, he arranges in such a way as to produce as much roundness or effect of relief as possible, without rendering his object pseudoscopic.

Now I think it will be seen what I am aiming at. I take it that the approaching very near an object with a short focus lens, in order to get a particular object represented of a certain size, is identical with the attempt of the artist to get his "distance point" all but into his picture. The use of a lens of inordinately long focus, I take it, would be equivalent to the artist placing his "point of distance" so far away as practically to induce a flat, poor effect. Mind, I am assuming all this time what I really believe to be true, viz., that in all cases the lens just doubles the real perspective of objects in different planes; and with that proviso, let us see what all this teaches us as to the comparative advantages and disadvantages of long and short focussed lenses.

In a long focus lens we know there is less spherical aberration over a given area, and a greater number of planes in the composition will come into correct focus; but to put against this you have the fact that objects will have a tendency to look flat and tame, and will detach themselves with difficulty from the background. The fact is, I suppose, that the lens looks at objects as a man would who had only one eye; and if it were not for the artifice of the exaggerated perspective, objects would not seem to stand out as well as they do. Another reason why the lens should exaggerate in moderation: photographers know well that the human head is always in movement, and this gives rise to parallax; that is, objects in different planes behind each other seem to move, and so give the impression of reality. Thus the excess of perspective seems here to be really required to render the effect of roundness to objects which distant monocular vision would seem to render tame. The short focus lens of course exaggerates this relief or roundness, and so gives the impression of vigour and solidity; and it has also this advantage, that there is less thickness of fog or dust-laden atmosphere to work through; but it would seem to have this disadvantage, that you are practically getting your point of distance all but into your picture, and that, as your composition must necessarily be restricted to one plane, your "art of concealing art" will be more limited in its application. Therefore I believe that, on the whole, moderately long focussed lenses are much to be preferred, and, indeed, I believe they are more generally in use where really artistic effects are aimed at.

Mr. Cherrill will see that I quite agree with the latter part of his thoughtful and practical letter, and that I look upon the choosing of a long or a short focussed lens for particular work as similar to the consideration of the artist when about to take a picture, as to when to place his point of distance.

I hope I have not seemed to dogmatise in all this. I shall be glad to be set right in any point on which I may have been in error; and I conclude by the expression of a hope that the subject will receive full discussion, feeling that there never could be one more fitting for the pages of a journal devoted to the photographic art.

JOHN ANTHONY, M.D., Cantab.

Washwood, October 5, 1868.

#### WET PHOTOGRAPHY IN THE FIELD.

DEAR SIR,—Just after the commencement of the publication of the PHOTOGRAPHIC NEWS, in about No. 11, I recommended the use of syrup made with 1 part sugar and 2 parts water, boiled and filtered, to pour over wet collodion plates when working in the field. I have used the above in open-air work ever since, till last summer, when, finding it a sticky, troublesome mess to work in a tent, I adopted another plan. I now merely wash the plates, after development, in a tray with a few ounces

of water, and when working by the sea-side use the 6 ounces of water over and over again, and then transfer the wet plates to a perfectly water-tight plate-box, with a felt lining inside of the lid. After the day's work is done, and the twelve plates boxed, I look out for some clear stream of water, and fill the box to the brim, gently tilt it up and down, and pour it out. The plates keep in excellent order for cleaning and intensifying till my return home, and, if too late in the evening, the plates are put into trays of clean water till the following morning. If water is plentiful on the spot, I partly fill the box, and put the plates to wash without using the tray. This method I have found far more pleasant than using the syrup, and it answers perfectly, even in the hottest weather.—Yours truly,

THOMAS GULLIVER.

#### PANORAMIC CAMERA.

DEAR SIR,—Some time since I promised to inform you if I succeeded in the then (to me) serious defect in the dark or light line where the two halves of the pictures join. I have succeeded in the following manner: The partition is made movable by a small pin in the centre working in a brass socket, and another pin in the top part passes through the top of the camera; to this is riveted a small piece of watch-spring; across the spindle is a short, flat piece of brass. Now, when exposing the plate, it is only necessary to give the cross-piece a slight touch, and then the partition board in the centre of the camera vibrates with a tremulous motion to and fro during the exposure of the plate. This, in a manner, vignettes the one-half of the view into the other, and softens off that unsightly line that has hitherto annoyed me.—Yours truly,

THOMAS GULLIVER.

18, Union Street, Swansea, October 4, 1868.

#### SOUTH LIGHT.

SIR,—I think Mr. Cherrill, in his article on North and South Light, was (to say the least) very one-sided, and I think little good, and much evil, may arise from it.

Mr. Cherrill asks (after doing his utmost to prove that it is impossible to take good pictures in a studio lighted from the south), "Why are not all studios lighted on the north side?" forgetting, I presume, how many photographers have to make their studios as circumstances allow. Mr. Cherrill says not a word about dull days, which, in this country (if we except this year), are more numerous than sunny ones; and I think even Mr. Cherrill will admit that a south light is equal, if not superior, to a north one on dull days.

I should very much like to know who is the enthusiastic south-light gentleman who says, "I close all the windows with dark curtains," as I think such a person exists not except in Mr. Cherrill's imagination, having been drawn specially for comparison with his very scientific pill-box. Mr. Cherrill knows, or ought to know, that there are other ways of checking the sun's rays than by dark curtains (white tissue paper, for instance); and that, by its judicious use, not only some effects—or, as he would have it, sun effects—but any effect that may be desired, can be got.

That studios lighted from the north are the least troublesome I admit; but I could not let the value of south light be so much depreciated without a word in its favour. To assure you I do not write without experience, I may say that I have the sun on my windows almost whenever it shines, and that at no time am I troubled with its presence inside the room; yet I use no dark curtains.—Respectfully yours,

S. BEVERLEY.

Oldham, October 1st, 1868.

#### WET COLLODION WITHOUT WATER.

SIR,—In your Journal of October 2nd I particularly noticed Mr. Robinson's article respecting Wet Collodion without Water, in which he states that he omitted to mention the alcohol to be mixed with the golden syrup. I may mention that since I have taken up landscape photography, which has been for the last ten years, I have never used alcohol in my developer or bath, or in any way at all. Instead of alcohol I use more acetic acid, which I have always found to work well; but for experiment I put—

Alcohol ...	...	...	...	...	½ ounce
Iron ...	...	...	...	...	120 grains
Ammonia ...	...	...	...	...	1 to 2 drops
Water ...	...	...	...	...	8 ounces

for my developer. Having no alcohol with the syrup, I found, on pouring it over the plate, stains and smears were caused; but, on the contrary, when the alcohol was put with the syrup and water, I found it to flow evenly, and to leave the negative clear and transparent; showing to all those who are not experienced hands at manipulating that they had better use alcohol if they want to succeed. But as I never use only syrup and water without alcohol in any way, with proper management I have never had one out of a dozen stained plates from that cause. I have this week forwarded you a whole-plate picture, printed from a negative taken eight days old, and should like to have your opinion on it. It was taken with one of Ross's whole-plate doublets. After exposure, I proceed to my laboratory or dark room, and pour over a sufficient quantity of iron solution to cover the plate. This is important where no alcohol is used. As soon as the picture is sufficiently out in detail, I pour the developer very slowly off, at the same time pouring the syrup and water on at the opposite corner to that where the developer is going off. As soon as the syrup covers the plate I place it in a swing-rack while I am preparing another plate. I then take it down, place it in the negative box, the bottom of which is always kept wet. As I am often away a week without touching the plate after the syrup has been poured over, I may remark that when I take the negative from the box I pour over the plate a weak solution of alcohol and water, and, after sufficiently soaked, I well wash, and intensify if necessary. Next week I will forward an enlargement from plates treated in this way. After trying all the solutions of common salt and alcohol to chloride of calcium and other solutions, I find none are so good and produce such good results as that of Mr. Robinson, to whom I, as well as a good many more, will be greatly indebted.—Remaining, Mr. Editor, yours obediently,  
Lyham, near Buxton and Ealing. JAMES BLANE.

PS.—It is worthy of mentioning that the print represents the residence of Mr. W. E. Jenkins, of Forest Hill, so well known for his kindness to the poor of that neighbourhood.

[The print enclosed is clean and satisfactory, illustrating that the negative did not suffer from the long delay in finishing it.—ED.]

#### Talk in the Studio.

A PHOTOGRAPHER'S RELIEF FUND.—A correspondent says:—"Much has been said and written in regard to this most necessary and much-needed organisation, making it very evident that it only wants a little pressure and general working together to get the wheel into the groove, and send it securely and successfully onward. In all that has been hitherto advanced on the subject, one point appears to have been completely overlooked and unmentioned, and that is the comparatively few men or women who follow photography alone as a profession, trade, or calling, compared with the great number who join photography to some other businesses carried on by themselves, their wives, or families. Now as these persons are for the most part stationers, chemists, watchmakers, tobacco and cigar dealers, fancy toy sellers, lodging-house keepers, or persons of some calling quite distinct from photography, they will be found in general to be members of some club or society mixed up with their original business; so that, having made themselves secure for a rainy day, they take little or no interest in the establishment of a purely photographic fund; but there are, no doubt, many kind and good-hearted individuals among the trades I have mentioned who would gladly contribute if the thing was only fairly lunched and set going. Her Majesty and the royal family are great admirers and patrons of the art, and would most probably be donors and contributors to the fund. The same may be said of the greater part of the nobility, gentry, and clergy, many of whom would gladly assist in furthering so desirable and much-needed an object.—[We fancy our correspondent overrates the number of photographers who follow some other trade as well as photographic portraiture. There is a sufficiently large number of operators, printers, &c., to render the question of an organisation important. We should prefer to see it take the form of a provident or benefit society, but there could be no harm in having a benevolent fund associated with it.—ED.]

BLACK TONES.—A correspondent, Mr. Edward L. Bridge, writing from Deal, says:—"I notice in the PHOTOGRAPHIC

News, July 10th, 1868, No. 514, a formula for toning and fixing in one bath, similar to one long known to me. It stands thus:—

Nitrate of lead	...	...	30 grains
Common salt	...	...	40 "
Hyposulphite	...	...	4 drachms.
Gold at will.			

This bath will give rich blacks. They are mellow and beautifully refined, even in the high lights. The bath, when for immediate use, must be mixed in warm water, and must be used fresh each time, or the print will go yellow. The prints must not be washed before toning."

**WEDDING CARDS.**—It is stated that in France, instead of sending to friends the ordinary engraved name card of the bride and bridegroom on marriage occasions, the custom is beginning to obtain of sending photographic portraits—either two card pictures, entwined with the symbolical silver cord, or a single card containing the portraits of the happy pair prettily grouped. The idea is an excellent one, and, if carried out, will afford opportunity for the production of cards with suitable designs to enhance the fitness for the purpose.

**HELP WANTED.**—An announcement in our advertising columns calls attention to the distress and need of help of a photographer's widow, for whom Mr. Beattie, of Clifton, will gladly receive contributions. How long will photographers subject the indigent and destitute among their ranks to the precarious chances of casual charity, instead of establishing a provident fund?

**POLITICAL PORTRAITURE.**—A new form of candidate's address, &c., lately suggested by a City firm, deserves attention. "It consists," says the circular, "of a photographic portrait of the candidate, with four pages of letterpress for the address, or a short memoir, done up in a coloured wrapper, similar in style to those we have printed for Dr. —, of which a specimen is herewith forwarded. In this form we feel confident the address could not fail to command the attention even of those wholly indifferent to politics; and by the photograph being frequently shown would thus secure, indirectly, a publicity impossible to attain by other means." After giving the names of two photographers who will be glad to make an appointment for the necessary sitting, the terms are stated thus:—

"Photographic portraits, mounted on India-tinted plate paper, with four pages letterpress, stitched in a neat, coloured wrapper, 500 copies, £21; 1,000, £32 10s.; carte-de-visite, with six or eight lines of letterpress on back, 350 copies, £6 6s.; 500, £10; 1,000, £18." Here is certainly a chance for gentlemen who consider their faces important items in their political fortunes. —*The Stationer.*

## To Correspondents.

**WILLIAM STURGEON.**—The use of iodide of potassium is, as a rule, inadmissible in collodion, where a large proportion of bromide is to be added as well, because of the tendency in the bromide to leave its base and form bromide of potassium, and bromide of potassium is very sparingly soluble in collodion. The undissolved powder in your collodion is doubtless bromide of potassium, which has been formed by double decomposition of the bromide of ammonium and iodide of potassium. The bromide of ammonium would have dissolved as before, and no precipitate would have been formed, if you had used iodide of ammonium as previously. The best plan now is to decant the collodion carefully from the sediment for use. Although the total quantity of the bromide added has not dissolved, still you may find that sufficient has been dissolved to enable you to get good results.

**C. C. C.**—For a travelling studio a van would, we think, be more convenient than such a tent as you propose; but, of course, it would be dearer. 2. The glass in the diagram you send is in the right place. 3. We fear that it will be insufficient for satisfactory working. We should prefer not less than 8 feet side and roof; on the north side would be preferable.

**A. G. H.**—The multitude of minute yellow spots, which do not appear until six months or more after the prints are mounted, we can assign no reason for. We will keep the matter before us for further investigation, and will let you know if we arrive at any useful conclusion. In the meantime we should discontinue the use of gum water for mounting.

**ANXIOUS.**—Of the lenses you name, No. 4 seems most likely to answer your purpose, and is the most rapid. Either of the triples you name will include, with good definition, an angle of about

60°, or more with a small stop. We cannot with accuracy give you the relative exposures of the lenses you name, beyond stating that No. 3 is, we believe, more rapid than either of the preceding, and that No. 4 is, *ceteribus paribus*, most rapid of all of them. The American lens you name is, we believe, pretty good, but the angle stated is an exaggeration; we have no reason to believe that it is equal to the lenses of either of the English makers you name.

**A. DONS.**—We know nothing further of the "automatic syphon" than was stated in the letter we published. 2. We cannot tell you precisely what alteration Mr. Cherrill would suggest in making a distinction between vignette and solidly printed pictures; but we may remark that a very little reflection will satisfy you that for vignettes you require a lighter and more delicate image altogether than would be effective in a picture fully printed out. In the latter you can afford to have massive depth and richness, whilst in the vignette you must have tender shadows and a sketchy lightness throughout.

**X. N.**—So far as we can judge by the appearance of the print you enclose, we should conceive the colour to be due to acetate toning. In any case, the acetate bath will produce very similar results. Take 1 grain of chloride of gold, 30 grains of acetate of soda, and 5 ounces of water, and mix. Use 48 hours after mixing.

**COLLODION.**—We will make some enquiry, to ascertain, if possible, a remedy for your difficulty. The plan of washing with repeated changes of alcohol would doubtless remove the water completely, and permit varnishing to be effected; but it would, in the first place, be a somewhat expensive operation; and, in the next place, the varnish, applied whilst the film was still soft and permeable, would probably penetrate very much, and tend to reduce the density. Have you tried applying gum water after fixing? We cannot help thinking that either the collodion you employ is not suitable, or that, from a little under-exposure, prolonged development is necessary, a condition which tends to rot the film. 2. The rapid lens you mention is as suitable for landscapes as the triple.

**VENATOR.**—The illustrations in a book such as you describe generally possess the same period of copyright as the book itself. The copyright in a book continues during the author's lifetime and for seven years after his death; or for forty-two years, if these periods put together do not extend to that number of years.

**NONE ET SEMPER.**—The common material used for powdering the skin or hair is "violet powder"; common wheaten flour or starch may be used. Perhaps nothing will answer better than wheaten flour. There is no danger in its adhering in so thick a coating as to render the white tint too obvious, unless it be very clumsily applied.

**W. J. A. G.**—A good tone can only be obtained from a good negative; but the experience you detail, which would tend to show that only one class of tone can be obtained from one negative, is very curious. Perhaps the most that can fairly be deduced from it is the conclusion that a given class of negative most readily and easily gives a certain kind of tone. We have ourselves produced almost all kinds of tones from the same negative, and from a good negative almost any kind of tone can easily be produced. Difference in tone is due to two things: first, the quantity of metal reduced; and, second, the size of the molecules in which it is reduced; and whilst, with a good negative, very similar tints can be obtained with many different toning baths, yet, on close observation, it will be found that the substances associated with the gold modify the size and condition of the molecules thrown, and hence each bath has a tendency to the production of specific colours in toning.

**A. TAYLOR.**—So far as we can judge, the mirror is produced by a deposition of silver, either by Liebig's or Cimeg's process, most likely the latter, of which you will find full details on page 398 of our Sixth Volume. The silver is deposited on glass from a solution of ammonia-nitrate of silver to which Rochelle salts have been added. It would require too much space to describe the method fully here.

**B. L. P.**—The prints are very fine, but the tone is too cold for our taste. If it had been warmer, the effect would have been much richer. The deepest impression is best. It is necessary to register before selling any copies, in order to make your copyright safe.

**M. R.**—The erapiness you describe is most probably due to the use of solvents containing too much water, and is therefore a defect very difficult to remedy. You may render its effect less marked by allowing the film to set well before immersing in the nitrate bath; or it may be added to another sample of collodion made with anhydrous solvents. 2. As a rule, we should not use more than about one grain per ounce of a bromide in collodion for portraiture.

**OXONIENSIS.**—There is no work devoted to the subject of double printing, &c. 2. You will find on page 471 of our Eighth Volume the best description of the method of double printing. There is also a similar article in our Year-Book for 1864. Should you not have access to these, we shall have pleasure in giving a few details in this column.

RECEIVED: "A Treatise on Optics," by E. Nugent. Several Correspondents in our next.

### TO WHOM DOES A PORTRAIT NEGATIVE BELONG?

A CURIOUS question has been brought under our attention recently, one which has been raised before, but never, so far as we know, authoritatively answered. To whom does the negative belong which a photographic portraitist takes in the regular exercise of his profession? A thousand voices will, we doubt not, be ready to answer at once, "To the photographer, of course." Very naturally answered, and, as we believe, very truly; but clearly not so as to secure universal acquiescence. Let us illustrate at once by laying before the reader a letter we have received from Mr. Rejlander:—

"DEAR SIR,—I have had a novel application made to me by a gentleman in Scotland, viz., to obtain from me three large negatives representing his daughter in various well-invented attitudes. When I say novel, I mean it in this sense: it was not asked for as a favour, or by purchase, but as a right, assuming that he was the rightful owner, and claimed them as his. I must say he was prompted to obtain them by knowing I was going to remove to Victoria Street,\* and, fearing I would not take sufficient care of my negatives during removal, they would run less risk in being sent to the North.

"I can well understand his anxiety, but not his expression that 'the negatives are mine,' nor that of his counsel, who 'is of the same opinion.'

"I should be in a pretty pickle if I were made responsible for negatives I do not care to keep. If claimable properly, I might be held liable for damage, and the harder I worked the poorer I would be.

"Has there not been a question like this before some judge? I fancy I remember something about it, and that it was left unsettled; but the sooner it were settled the better, and that we may claim hire for the safe keeping of the glass, as some say it is 'only a bit of glass.'—Yours very truly,

O. G. REJLANDER."

To clear the question of any extraneous considerations, it should be distinctly understood that these are negatives taken in the exercise of his profession as a portraitist, not pictorial studios, such as Mr. Rejlander often produces. If they had been the latter, perhaps still less doubt on the question might have existed; but we mention this fact to clear the ground, in order that it may be distinctly understood that the question arises in relation to portrait negatives taken in the regular course of business. When the demand was first made, Mr. Rejlander naturally demurred

to surrender that which he regarded as undoubtedly his own property; whereupon the claimant sought legal advice, by which he stated he was fully supported in his claim and assertion that the negatives were his property.

The question, it cannot be doubted, is one of the most vital importance to photographers, and might be made to involve most startling issues. If the claimant and his legal adviser are right, and the claim they make were made and sustained by the general public, not only would the value of every photographic business in existence be woefully depreciated, but the majority of photographers might be ruined, not simply by their losses of property in the stock of negatives which they have regarded as their own, and which has afforded a steady income of greater or less amount, but by actions for compensation in regard to the thousands of negatives they have destroyed, never dreaming that they were not their own property. When a photographic business has been sold, the extent of the stock of negatives from which constant orders were printed has usually formed one of the chief elements in the estimate of the value of the business; and the transfer of such a stock of negatives has been regarded not simply as the sale of such property of specific value, but as the efficient means of transferring the goodwill of the business. We have known of the sales of several such businesses involving in the aggregate many thousands of pounds of purchase money; but if actions for compensation in relation to the negatives in such cases could be sustained, we imagine that considerably increased duties for Her Majesty's Commissioners in Bankruptcy would follow.

To return to the question, however, To whom does a portrait negative belong? We should answer, unhesitatingly, that it belongs to the photographer; and were it not for the proverbial uncertainty of the law, we should never have a moment's misgiving as to any legal decision on the subject. An absolute decision in any case of disputed property can only be given in a court of law or equity; but as, in matters where no statutes exist, the decision is generally based upon precedent and custom, it may be interesting to consider the bearing which custom and analogy have on such a question.

We believe that no legal decision exists which could form a precise precedent in regard to the ownership of negatives, and we should not, in any case, enter into legal technicalities in relation thereto; but we may briefly suggest the considerations in regard to custom upon which common law is often based. Theoretically, the law is the perfection of reason; and practically, errors excepted, probably justice is in the main secured by it. In the case *Mason v. Heath*, in which the plaintiff brought an action against the defendant for refusing to supply him with a portrait negative at a reasonable price, the whole of the proceedings were based on the assumption that the negative was the property of the photographer who took it. The actual question of ownership in the negative, as between the photographer and the

\* Our readers will be glad to learn that Mr. Rejlander is shortly about to remove to a magnificent West End studio, now in course of erection, where, we believe, there is every prospect of his rare abilities as an art photographer being fully engaged, and meeting with the high appreciation they so unquestionably deserve.—ED. PHOTOGRAPHIC NEWS.

sitter, although it has been frequently raised, and always maintained satisfactorily, we believe, by the photographer, has not, so far as we remember, come before any court. We remember one instance in which one of our ablest photographers, having taken several portraits of a certain high personage, did give up, in accordance with the request made, the negative as well as the prints ordered. This was by no means, however, intended as a surrender of the rights of ownership, for when the account was sent in, each negative was duly charged at a price distinct from that of the prints ordered. The business representative to the high personage in question took exception to this account, and sent it back with each charge for a negative struck out, and remonstrated against the excessive charge for what he styled "a piece of glass—a piece of glass!" The photographer, with quiet self-respect, pointed out that a negative was not in any sense merely a piece of glass, but the *cliche* from which thousands of valuable pictures could be produced; he therefore maintained his right to the charge he had made, and received it.

The custom of the profession, recognized and acquiesced in by the public, could of course be proved by a thousand instances. We were told, by an English gentleman, that on visiting the studio of M. Adam-Salomon last year, he asked the young lady in attendance if he could have his negative, and on what terms? "Not for a thousand pounds; M. Adam-Salomon in no case parts with a negative," was the response. "And, pray, why not?" was asked. "Because he has a reputation to maintain, and this must be done by the mode in which proofs are printed, and the care taken to make them permanent. Bad prints in circulation from negatives known to be his might seriously injure him." M. Silvy, on retiring from business, for months advertised that persons who had sat to him could have their negatives on a certain payment. In fact, the whole practice of the profession proves that it is the custom for the photographer to affirm his ownership, and the public to acquiesce.

The customs of all other trades by analogy support the same position. When the manufacturer of a steam-engine, or any similar piece of machinery, receives an order for a specific engine, a number of designers and draughtsmen are at once set to work to produce the scheme of the engine on paper. Next, a number of pattern makers are employed to make various patterns in wood, from which to produce moulds for all the castings. The person for whom the engine is built might with equal propriety demand the moulds, patterns, drawings, and calculations which had been prepared as necessary adjuncts in the construction of the engine, as the sitter demand the negative necessarily taken as a means of supplying the portraits; the painter might be required to give up the studies and sketches taken as aids in the production of any picture; the type-founder might be required to give up the matrixes in which a fount of type, produced to order, was cast; the printer might be required to give up the forme of type he sets to produce a circular or poster; the frame-maker might be required to give up his patterns and moulds; the tailor to give up his patterns and measures; and so on in many other instances. We here refer, not to general trade tools, but to cases in which something is specially prepared as a means to the fulfilment of an order, just as a negative is a necessary step in the production of a portrait, for a negative is no more a portrait than a matrix is a type or a mould a casting.

The only analogy of trade we remember, which might seem to point in an opposite direction, does not do so in reality. We have heard it urged that when a person orders an address card to be engraved, and a number of cards printed, the plate is always delivered with the cards, and regarded as the property of the customer. This is so, we believe, generally; but that it is an exception to general practice is emphasised by the fact that it is the custom of the trade to make the special announcement, "A card-plate and 100 cards for so much." If the plates were

delivered with the cards as a matter of course, no special mention of it would have been necessary; but the circumstance that it is so specially mentioned in the trade announcements of engravers points to the fact that it is an exceptional and not a common practice in trade to give up a mould or a *cliche*.

The nature of a photographer's contract with his customer is simple enough: he engages to produce a given number of portraits at a given price. His contract is fulfilled when he has delivered these portraits and received the price; no question of the ownership in the negative necessary to the production of these portraits should arise beyond this: the sitter possesses a clear right to forbid the production of further prints from it without his consent. This is a tacit understanding between the photographer and his sitter, and it is rarely violated.

Possibly the law of copyright may throw a little light on the legal question, for where no provision to the contrary exists, the ownership of the negative would generally follow the ownership of the copyright. The clause in the statute, stating the conditions of ownership in the copyright of a photograph, provides that if a photographer take a negative for his own purposes, and not as a commission, the copyright belongs to him; but if it be produced as a commission—as a portrait usually is—then it is necessary that an agreement in writing be entered into at the time of the production, in order to secure the copyright either to the photographer or to the person giving him the commission. But if no such agreement be entered into, the copyright belongs to neither, and is, in fact, lost. If we follow the analogy of the case, it would result that where, as in the ordinary transaction of business, no copyright is acquired, no property in the negative—that is, in the image—could be acquired; the glass upon which it rests clearly belongs to the photographer, the image upon it constituting the negative; he can, therefore, clean it off if he choose, or he can, as a matter of convenience, keep it in existence for the future accommodation of the sitter; but it is clear that the latter could not, according to the analogy afforded by the Copyright Act, acquire any property in the negative.

The loss, risks, and inconvenience which would be involved if the sitter became owner of the negative can scarcely be estimated. Besides the immediate and contingent money loss, the possible loss of reputation, such as that suggested in M. Salomon's answer, would be serious. Again, prints from a photographer's negatives being sent out from various establishments, possibly with other names attached, loss of legitimate reputation might follow from that cause, and one strong stimulus to excellence would be destroyed. It is not necessary, however, to enter into detail on the evils which would follow such a decision. They are numerous and patent enough. But should the law ever decide that the sitter was owner of the negative from which his portrait was taken, the photographer would be simply placed under the necessity of defining his contract, by publicly announcing in his reception-room and studio that the property in the negative was always retained, and, in any form of receipt, distinctly stating that the payment is for a given number of portraits, not including the negative.

#### PHOTOGRAPHY OR BRANDING?

ATTENTION has recently been called in a daily contemporary to the degrading and brutalizing effect of the practice in the army, which still occasionally obtains, it appears, of branding an offender with some indelible mark, so that he shall bear the stigmata for life of the crime, and the disgrace attending it. All punishment is, of course, degrading as well as painful, as it should be; but the degradation is rarely, and should never be, of a character which clings for life, no matter how deep the repentance, no matter how full the expiation, or how complete the amendment. But the brand B. C.—bad character—burnt on a man's skin

is too often burnt into his soul, and he becomes permanently the thing he is permanently labelled.

But a means of absolute identification is necessary when a man has been "drummed out" of his regiment, in order to prevent his re-enlistment, and again entering under another name Her Majesty's service. The branding serves this purpose. But the question arises, can its aid not be superseded by something quite as efficient, and much more consonant with the civilization of the age? To meet the difficulty on the score of identification photography has been proposed. The photograph of a criminal has been found in gaols an efficient means of identifying him when he comes within the clutches of the law a second time, and has often been made the means of capturing him when flying from justice.

An army surgeon, writing to our contemporary, points out that the brand-sear is not always efficient as an aid to identification, and thinks that, properly managed, photographing men will be found a much better system of detecting old criminals than the plan of branding them. He says:—

The plan of identification by means of photography has, therefore, the merit of expediency as well as humanity; but I fear the resemblance to a likeness taken under far different conditions is too nice a point for the decision of a serjeant. Be it remembered, also, that it is manifestly contrary to his own interest to raise any point which, like this, may readily escape the notice of his superiors. I would therefore venture to suggest that the portraits might be deposited with the magistrate before whom the recruit is sworn in, and thus the requirements of those regiments be met who have no inspecting officer.

The use of photography as an aid to the detection of criminals is one of the sterner missions of a very beautiful art. If, in the exercise of these missions, it can be made to supersede and abolish a brutalizing and degrading remnant of a much darker day, it will afford some gratification to all those of its votaries interested in the "eternal fitness of things."

#### DECISION AS TO A PHOTOGRAPHER'S PERSONAL LUGGAGE.

The decision in the case to which we recently adverted, in which the question was raised as to what constituted a photographer's "personal luggage," has been given, and will, we fear, scarcely prove satisfactory to photographers. It will be remembered that Mr. Owen Angell, of Exeter, travelling on the South Devon Railway with his photographic apparatus, for the purpose of fulfilling a professional engagement, his luggage was removed at Teignmouth instead of being carried on to Bovey Tracey, whither he himself was going. Having been delayed in the exercise of his profession by the absence of his apparatus, Mr. Angell brought an action for compensation against the Company in the County Court at Exeter. The demand for compensation was resisted by the Company on the ground that photographic apparatus was not personal luggage, and that they were therefore not liable. The decision, which was postponed on the first hearing of the case, was given on Friday last.

Mr. Sergeant Petersdorff, in giving judgment, said that as the case was one of considerable importance, he had deferred his decision, in order that he might refer to the most distinct and trustworthy authorities on the point in question. He had therefore referred to Marshall's valuable work, "The Liability of Railway Companies as Carriers." Here it was stated that "the obligations to carry the luggage of a passenger and the responsibility for its safety as common carriers does not apply to goods unconnected with the *personal use, comfort, or convenience* of the passenger." His Honour then remarked that before he endeavoured to test the question at issue, he should refer to some cases that had already been decided. One—that of *Phillips v. The London and North Western Railway Company*—was in principle strongly analogous to the case before him. It was there decided that a solicitor's documents in an action

in which he was professionally engaged could not be considered "personal luggage." The Chief Justice who tried the case had said: "These were not for the plaintiff's personal use, or usually required, but were taken by him in his capacity as attorney for the use of another." There was also a case against the Midland Railway Company, argued in the Court of Exchequer, which appeared to be completely decisive on the identical case upon which they were now engaged. It was there held that an artist's pencil sketches were not his personal luggage. It was therefore difficult to find any distinction between the mechanical contrivance of taking photographic pictures and the pencil sketches of an artist. After alluding to some other cases, His Honour said that the real test must be the question whether the articles were such as would be essential for the personal use and convenience of an individual travelling. If they did not come within that meaning, then the owner was not entitled to seek compensation from a railway company. He would mention one or two strong illustrations. The professional wardrobes and dresses of actors and actresses, which often were of enormous value, were not held to be personal luggage. The same would apply to the robes of judges and barristers, also to bishops and others. He must therefore decide unequivocally that a mechanical apparatus used for photographic purposes could not fall within the description of "personal luggage." The plaintiff photographer would therefore be non-suited.

The decision, as we have said, will, we fear, prove an unsatisfactory one to photographers, and appears to us based upon a technical quibble rather than common sense. The companies engage to carry a passenger and a given weight of luggage for a given price, and so long as that luggage does not require unusual care, and does not contain substances likely to injure the property of other travellers, we cannot conceive how the question of the nature of the luggage can concern the railway company, except as a technical means of evading responsibility in case of carelessness or neglect on their part. The statement made by the judge, that the robes of actors and judges, barristers and bishops, would, on the principle upon which he decided, be disallowed as personal luggage, seems to give extraordinary point to the unreasonableness of the principle governing the decision.

That photographers should not place amongst passengers' luggage imperfectly packed chemicals, which, by fracture or leakage, might injure other goods, is tolerably clear, and should scarcely need enforcing; but no question of that kind has arisen here. A wise caution would suggest that a box containing the chemicals, in as compact a form as possible, should be taken by the photographer into the carriage with him. Indeed, we commend this course to photographers, in reference to as much of their equipment as convenient. In case of the use of dry plates and small apparatus this will not be difficult, although scarcely available to the wet worker in a large tent. We can only offer this consolation to photographers, that their right to carry apparatus as personal luggage is not likely to be questioned until they raise some claim for compensation, as it is chiefly under such circumstances that railway companies avail themselves of technicalities to justify the unfair treatment of passengers.

#### STUDIOS AND PROCESSES IN AMERICA.

An interesting article in our excellent contemporary, the *Philadelphia Photographer*—of the last number of which advance sheets are before us—describes the mode of lighting and the processes used by two of the most successful portraitists in New York—Mr. Napoleon Sarony and Mr. Fredericks. The writer, who is an amateur photographer who has had opportunity of forming the acquaintance and visiting the studios of many of the ablest professional photographers in the States, premises his remarks by observing that he has invariably found that the best men had no secret dodges upon which they relied for success, their

readiness to communicate generally being in the exact ratio of their ability and the excellence of their work. He says:—"For many years an amateur, and having travelled and photographed over a very large portion of our country, I have, during such trips, made the acquaintance of very many of our best photographers, and, as yet, have never met one who made good work who had any secrets, or who hesitated one instant about comparing his method of working with mine; but have, in several instances, been repulsed by bunglers, of whom I had asked questions solely with the view of correcting errors in their work, which I saw plainly the cause of."

He finds one general principle pervading the operations of the best men, from which he deduces the conclusions embodied in the following advice:—"First. As to the sky-light. No matter which way it faces—north, south, east, or west (good work can be made under either)—let the light be directed upon the sitter, not towards the camera, as is too often the case. Shield the camera from the sunlight, or strong diffused light, either by placing upon the roof some contrivance which will effect the purpose, or cover the tube by a hood. The more diffused light there is about the room the duller, flatter, will be your picture. The stronger your light the less iodides and bromides you should use in your collodion, and the weaker your developer. To obtain the much desired middle tint or detail in the shadows, give plenty of time, and use a quite weak, slow-working developer, avoiding the extreme of intensity."

The first of the visits he now undertakes to describe, was to Mr. Sarony's studio in the Broadway. Mr. Napoleon Sarony was, by original profession, a lithographic draughtsman, and an exceedingly skilful artist. He is the younger brother of Mr. Sarony, of Scarborough, of whom, as a photographer, he was a pupil. He was for some time engaged in Birmingham, and his work, as well as that of Mr. Oliver, had a high reputation in this country. The account of his New York studio will be read with interest. In our contemporary it is described as follows:—

"His reception room—about twenty by sixty feet—is a model of artistic elegance, the walls and tables being covered with specimens of his finest productions, which, to those who know them, is all I need say; while to those who know them not, I propose to them to visit and inspect. They will be politely welcomed by Mr. Sarony, or his partner, Mr. Campbell.

"Upon the floor above, within a room of same size as the one just mentioned, are the skylights, operating rooms—not closets, but good-sized, well-ventilated 'dens.' The building stands nearly east and west, and the lights are both facing the north—one at each end of the room—and so nearly alike in size that a description of one will answer for both. By having the two lights he is not only able to do double the work he would with one, but is able to obtain almost any effect of light and shade that will best produce the desired end, to choose the best side to light up each subject, and operate accordingly, which could not be done with one light. Along the eaves of the building each light extends thirteen feet, which I shall call the length; thence back and upward (at an angle of thirty degrees) thirteen feet; and from the upper or back slopes down, tightly boxed in, at an angle of about forty-five degrees, to the roof, giving a square top-light. The side-light joins the top-light, and is of same length (thirteen feet), and three feet down, or wide, ending in a point five feet above the floor. The ordinary window glass is used, neither ground nor coloured. As the same style of shades are used by both parties, I will describe them hereafter.

"The collodion in use is iodized as follows:—

Iodide of ammonium	...	...	4 grains
Iodide of cadmium	...	...	1 grain
Bromide of cadmium	...	...	2 grains.

Develop with weak ordinary iron developer, and, if necessary, strengthen with pyrogallie acid and silver, of which every one knows.

"The printing is, of course, done upon his own paper, which is floated about one minute upon a plain 60-grain nitrate of silver solution, which is kept clear by shaking up with kaolin, and filtering.

"Any good toning bath will answer. I, however, give the one he always uses.

#### SARONY'S TONING BATH.

Chloride of gold	...	...	15 grains
Water	...	...	2 ounces
Whiting	...	...	a teaspoonful

Shake well, then pour on boiling water until the yellow disappears. Filter, and add three drops of a saturated solution of chloride of lime.

"This bath is easy to work, certain in its results, and can be used several times; in fact, the tone of the prints is superior after using the solution some days. When the day's prints are toned, pour the solution through a filter into a bottle.

"Before using again, add 5 grains of chloride of gold and 3 drops of a saturated solution of chloride of lime.

#### TO FIX.

Hyposulphite of soda	...	...	4 ounces
Water	...	...	30 "

Immerse for five minutes, and wash in the usual manner. Is there any mystery here?"

Mr. Fredericks is one of the oldest established and most successful photographers in New York, holding high position and doing a very extensive business. One peculiarity of his studio, it will be noted, is the fact that all his light enters through ground glass, the aim being somewhat contrary to common, and what is considered orthodox, practice, to obtain a large volume of soft light rather than a more brilliant light through a more circumscribed space.

"Mr. Fredericks works two lights, both essentially different. Either, in unskilful hands, would prove useless, but directed by Mr. Hugh O'Neil (partner in the business), who specially superintends the chemical department, and Mr. John De Bains, whose skill under the light cannot be excelled, work is produced, unsurpassed in all respects.

"The upper light (on fourth floor) is a skylight only. It faces north-west, is of ground glass, fourteen feet square, at an angle of thirty-five degrees, and slopes away and down to the roof, solidly boarded up at an angle of forty-five degrees. At the lowest point, or base of light, it is nine feet above the floor.

"The lower light (on third floor) is a side and top-light combined.

"The top-light extends in length along the eaves of the (rear) building, thirteen feet, thence up, and back (at an angle of twenty degrees) fifteen feet. The side-light joins the other, and is of same length (thirteen feet), extending towards the floor nine feet, and to within eighteen inches of the floor. All the lights are glazed with the whitest and best ground glass. The light on the third floor (one last described) has sliding inside sashes of blue ground glass, which are drawn or pushed over alongside of the other or outer light. This is found necessary in this one, which faces south-west, from the fact that it is nearly always directly in the sun's rays. It is fitted with the ordinary style of curtains or shades, hung in narrow strips, by which any part can be drawn up or down, giving the light any direction towards the sitter that may be desired.

"The upper, or fourth-floor light of Mr. Fredericks, and the top or skylight portion of Mr. Sarony's lights, are provided with a very excellent style of screen, by which the light cannot only be reduced in quantity, but its direction can be changed as well. For example, if we take one of the lights thirteen feet long, dividing this by six it will be found that there are six sections, each twenty-six inches. Now, if the light be also thirteen feet wide (up and down way), the sections are twenty-six inches wide by thirteen feet long. Now make six frames of this size, and cover with blue tissue paper, which put up by means of hinges, or otherwise

attached to the under-side of the top-light, and you have just the thing. It is self-evident that by turning these swinging screens up or down, by aid of cords and pulleys, the effect spoken of can be produced."

It will be noticed that these blinds are analogous to what are known in this country as the McLachlan blinds.

"The formulæ used by Mr. O'Neil are as follows:—

"Collodion, when the light is very strong, like that upon the third floor, he uses—

Iodide of ammonium	...	...	4½ grains
Bromide of potassium	..	...	2 "

For weaker light—

Iodide of ammonium	...	...	5 grains
Bromide of potassium	...	...	2½ "

"Developer: plain iron; strongest under weak light; strengthen with pyro and silver.

"The printing is done upon the papers prepared by Mr. Anthony, and toned in a simple bath of chloride of gold, made alkaline with sal soda (common washing soda), and fixed in hypo.

"Is there any mystery here? None! The great art consists in knowing how to place your sitter properly under the light; when to weaken, when to strengthen, your collodion and developer; and when to stop its action. These come of experience, intelligence, and common sense. They are not told in books or in journals; are only to be had by study and effort on the part of each photographer."

#### PROGRESS OF CARBON PRINTING.

CARBON printing appears to attract considerable attention in America; how far its commercial application progresses we do not learn. There are already three or four manuals of instruction for working Swan's process in existence in the States: the "American Carbon Manual" of our friend E. L. Wilson, based upon our own, with full acknowledgment; an exact reprint of our own; and another which we have not seen. In the *Philadelphia Photographer* we find some records and suggestions which will be read with interest by photographers in this country. Mr. W. J. Land, who some time ago suggested the use of alcohol in the bichromate solution, to aid in the more speedy drying of the tissue, sends the following additional remarks:—

"Since writing to you I have made further experiments in this, and find the use of alcohol very beneficial in hastening the drying of the developed image. After developing and washing, I make use of a small quantity of (95 per cent.) alcohol, in which I dip or soak for a few moments the picture—by osmosis the greater quantity of water is very rapidly drawn from the print—and complete desiccation takes place in less than an hour. I have dried them in twenty minutes, or commenced the final transfer within half an hour after developing.

"With regard to the use of alcohol in the bichromate bath, I think it prevents the tissue from keeping longer than one day: such has been my experience at the present temperature (98°) of our atmosphere. I send you herewith a couple of prints, made a few days since, using alcohol in both cases."

The editor remarks:—"One of the prints inclosed by Mr. Land is silver, and the other carbon. The latter is all we could desire in a carbon print copied from a large photograph, and there is a brilliancy about it which is very pleasing.

"The drying of the tissue, and the caoutchouc paper, are the only real troubles in the process—varying so much with the weather. Moreover, immersing the tissue in the bichromate solution is not as agreeable as floating albumen paper upon a silver solution. The first trouble seems likely to be easily removed by Mr. Land's plan, and the latter is overcome by a very simple and ingenious arrangement, the invention (not patented) of Mr. Quick, of Cincinnati, and a model of which

has been kindly furnished us by our friend Mr. Waldack, of the same place. Both of these gentlemen have the carbon process in successful operation, and have gone into it with a determination to make it successful and popular."

Mr. Waldack, whose name is familiar to our readers as an occasional contributor of interesting matter to the *Photographic News*, writes:—"I am getting ready to make all my large views in carbon. I can get a higher price for them. Mr. Quick has made some very beautiful carbon prints."

Our contemporary gives a diagram of a contrivance, by Mr. Quick, of the improved method of sensitizing the tissue.

"Mr. Quick's contrivance for sensitizing the tissue," he observes, "will be readily understood by the above diagram. Instead of a dish he uses the light frame AA, which is rabbeted inside, about half-way down, the rabbet fitting an ordinary-sized sheet of tissue. The tissue is laid in the rabbet, face up, and forms the bottom of a shallow tray, as it were, in combination with a second frame B, fitted over the sheet into the rabbet. The inside of the frame B is bevelled (c) outwards all around from the top to the lower edge, in order to hold the solution; and it is also supplied with a lip at one corner, by means of which the solution may be poured off. This frame B not only serves to form a tray to hold the solution, but fitting, as it does, the rabbet in the frame AA, presses down upon and holds in place the sheet of tissue, stretching it out straight and even.

"These frames may be made of walnut or other hard wood, and should be varnished with shellac varnish or paraffine. Mr. Waldack writes us:—'Those I use I dipped in hot paraffine, and left them in about a minute, so as to allow the paraffine to penetrate well into the wood.' When in use, the dish is held in an inclined position, the bichromate solution poured in at the lower part, and, by tilting, it is made to flow over the whole sheet of tissue. The great advantages of this method are obvious. It prevents the irregular drying of the solution on the back of the paper, and, leaving the ends quite dry, allows it to be hung up by means of clips, or pins, without sticking to them or the fingers.

"A similar frame is used to coat the sheets of white paper with the caoutchouc solution, or hydrocarbon varnish, as it is called in commerce. This frame, however, need not be coated with paraffine.

"We are certainly greatly indebted to Mr. Quick for this contrivance. It works like a charm, and is eminently preferable to the old plan.

"There is another point mentioned by Mr. Waldack, which is important to those who prefer to make their own hydrocarbon varnish; i.e., that the only benzine suitable to dissolve rubber is that made from coal tar. The petroleum benzine cannot be used. The rubber should be fresh—the white inside of the gum, as it is imported, being best before it is much exposed to the air. The difficulty of obtaining good benzine and good rubber makes it more advantageous to buy your varnish of your stock-dealer."

#### PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN

COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXXVIII.

THE supposed difficulties of photographing children have prevented many photographers from obtaining some of the most beautiful subjects that could come before a camera

Many, even now, when sitters are scarcer than they were, have a great objection to seeing children enter their studios, and resign themselves to their fate in a grumbling humour, as if they were very ill-used in having to deal with such troublesome subjects, which is not the best frame of mind to be in when you are about to deal with children; while others will have nothing to do with anything under six years of age. During the carte mania, it was difficult to get a child's portrait taken at all, except by those whose pictures were so bad that they had little to do, or those who took a delight in the work. I must confess that I am one of the latter, and nothing gives me greater pleasure than to have three or four beautiful children in the studio, with a *carte blanche* as to what I shall produce, and with plenty of time at their disposal. I take a pride in never letting a child go away unaccounted for photographically, however

young or lively. By far the most beautiful photographic portraits that have been done have been those of children; their attitudes are more free and unconstrained than those of older persons, while their expression is generally more natural. The wet process is now so perfect that the exposure, when necessary, may be reduced to a very short portion of time, and all that is necessary to success, apart from artistic knowledge, is sufficient tact in managing the young sitters, who are very clever and quick in finding out whether they are in the hands of a novice or an adept.

One of the most charming groups of children's portraits that have ever been painted is that given in the present illustration by F. Goodall, a class of subject of which the artist was *facile princeps*, before he altered his style and went to Egypt for inspiration. It is called "The Swing," and represents a group of beautiful children enjoying them-

selves under the trees a short distance from the mansion, whose terraced walks appear in the background. Of course it would be very difficult in photography to represent a similar subject, although it is quite possible; but I introduce it here, not only for the purpose of saying a word in favour of children as subjects for the photographer, but also in order to show, as I have endeavoured to do throughout these chapters, that the same artistic laws apply to all subjects, however different they may be in character, and however diverse in effect. For instance, I pointed out in Chapter 34, in which a meeting of Quakers was represented, how the black shoes of the two sitting figures served to join the groups; in the present illustration we have the picture divided into two principal groups, the children seated and standing under the tree looking on, and the little lady in the swing, and the two beautiful boys on each

side of her; these groups are connected together by the light spot formed by the hat in the foreground, which, at the same time, is the supporting base point of each pyramid; place the finger over this spot of white, and the arrangement of lines will appear weak, and without purpose.

Artists should take the greatest care this support is never wanting in their pictures. It may be formed by a light or dark object, by a contrasting line, or by any device that experience or imagination may suggest, but it must always be there. Nothing looks so awkward as a group or figure that cannot support itself. It is for this and similar reasons that the student should well ground himself in the laws of art rather than blindly copy the designs of others who have probably not known what was necessary to the perfectness of a composition or the requirements of an artistic group.

Modern costume is often condemned; but what could be more picturesque, and yet without any exaggeration, than the dresses of the figures represented in this picture?

## ON THE RELATION BETWEEN INTENSITY AND TONE.

BY NELSON K. CHERRILL.\*

In reading a paper before the opening meeting of the present session of your Society, I feel that I have to contend with somewhat serious difficulties. Never having myself resided in the metropolis, and having but seldom visited the locality in which we are now assembled, I have had but small opportunity of making the acquaintance of the gentlemen whom I now see before me. Notwithstanding, however, the disadvantage under which I am situated, I am anxious to bring before you a subject which is worthy the consideration of this, the first meeting of the session, a subject which I do not hesitate to call the most important one at the present time; one, the ultimate and definite settlement of which would do more to elevate the art of photographic portraiture than almost any other; one which is far from being understood, and still farther from being an active principle in the manipulation of every photographic portrait; and one which I believe to be the very foundation and basis of that peculiar excellence which, in the portraits of M. Adam-Salomon, took the world by surprise at the Paris Exhibition in 1867.

I do not at all pretend to say that in the present paper I am going, by any means, to do justice to the subject on hand; it is, I consider, a most difficult one, but it is, at the same time, one which requires much more attention than it receives; and it is one which, I hope, once started, will not be—as far too many subjects are—let drop, with scarcely any further expression of opinion on the matter than that of the author of the paper or article.

Let me now proceed with the matter on hand: the relation between intensity and tone. This, to a photographer of the present day, will doubtless mean the relation between the intensity of the negative and the tone of the resulting print. This is just the relation that I wish to speak of ultimately; but, before I do so, I wish to point out several things: I wish to show what seems to me a very beautiful series of facts, which lead up to the consideration of the present state of photography.

Intensity and tone are two very old words, although I apprehend that among photographers they mean generally two rather new things. We shall best understand my meaning if we consider at some length an example studied from nature. A calm summer sea, the gentle breeze only just stirring the waveless surface into ripples, the sun not setting, but yet so low as to be included in the picture, a few white sails glimmering in the far distance. Can you imagine any subject with much less contrast, with much less real intensity than this, one uniform glare of light, broken only by the greater glare of the sun's "path" on the water, and perhaps relieved only by the darker sides of the tiny ripples? Such a subject, if photographed, would probably not have to be made very intense in the negative, because there would be no gradation of colour to be obtained in the prints; white paper would not be bright enough to represent truly even the middle tint of such a picture; how much less the extreme light? From a picture of such a scene we could hardly gain any true idea of the brightness of sunlight, or of the real effect of light upon the ocean; the picture could have no intensity, and therefore it could have no real tone.

Now let us change the scene slightly. As the sun declines, the wind rises and scatters dark clouds along the horizon. See how at once the face of nature is changed! Now the horizon of the sea becomes dark like the clouds, and now,

too, the sun—before bright enough—becomes yet more brilliant by the contrast of dark clouds which rise towards it. See, too, how, in like manner, the sun's path upon the water is rendered more brilliant and marked by the darkening of the sea all round it, and how each tiny wave becomes darker on the side turned away from the light. Here would be more scope for the photographer or painter. Here would be more room to give some idea of the intensity of sunlight. The light would not be any more brilliant in itself, probably—indeed, it would be less so—but now we have some dark to contrast with the otherwise overpowering light, and contrast is the key-note and measure of intensity. Now we could get a somewhat more definite tone into our picture, which before we could not have done; and the reason why we can get tone in the present picture, and not in the first, is, that now we have a relation between the lights and darks of the picture, one which we can understand and appreciate, and can therefore represent.

Now let us again slightly change the scene we are considering. The tide has been falling, and now appears a line of dark, half-rotten timbers, once the main supports of some old breakwater; these, left bare by the falling tide, give us at once the true key-note to the whole composition. We know at once, from former experience, that the rotten wood of an old breakwater, with (perhaps) lots of seaweed growing on it, must be black, almost, if not quite; and so we have a guide by which to judge really *how* intense the sun's reflection in the water is, and *how* much darker the clouds are than the blue sky of the first picture. In the representation of this subject, either in a photograph or painting, we have the greatest range of contrast to be obtained in nature, viz., perfect black,\* and the sun's disc, which is infinitely more than perfect white, in the same picture. We therefore have to use the greatest *intensity*, either in our colour or our monochrome, to produce the effect required. And what is the result in respect of the tone of the picture? The tone must now be from pure black to the purest white we can get.

There is a curious point to notice here, namely, that now we have an absolute key-note to the picture, we *must* have everything else in proper tone, or else it would be obviously wrong. Not so in the second picture which we considered; in that, by exaggerating the dark parts of the clouds, much more intensity might have been given; but now we have the black of the old breakwater piers to attend to, we are bound not to make the sky too dark, or else it would be out of proportion in colour to the rest.

Now, from what we have already advanced, I wish to gather these points: first, that the intensity of a picture is greater, just in proportion as its contrast between light and shade is greater; secondly, that the tone of a picture must always be governed by some one known and definite key-note, as the extreme black of the breakwater; and I think it will be seen, upon a little reflection, that the relation of every tone in the picture to white will change just in proportion to the intensity of black in the darkest part. When we did not know anything about the black of the breakwater piers, we should have thought the clouds were very much darker than they really were; but as soon as we saw how tremendously dark real black was, the clouds became quite light again, and all the picture seemed in harmony.

(To be continued.)

## SOME REMARKS ON STEREOSCOPES.

BY VALENTINE BLANCHARD.†

I must claim your indulgence this evening whilst I offer some remarks on a subject which, I fear, many of you will regard as done to death and completely out of date. I hope, however, that the time will not be entirely wasted; that

\* By perfect black, here, I do not mean the black of black pigment, but that which results from the simple absence of light.

† Read before the South London Photographic Society, Oct. 8th, 1868.

\* Read before the North London Photographic Association, Oct. 7th, 1868.

something, at least, will arise out of the discussion to make you feel that the evening has not been entirely spent in vain.

I have brought for your examination this evening a very ingenious stereoscope of American manufacture, and I think you will feel with me, when you look at it, that we have in the old-fashioned model only another instance of our peculiar conservatism. The stereoscope is an instrument which is specially suited to while away a leisure hour in the evening, when the gas is lighted; therefore we have gone on, year after year, improving and beautifying our original box model, forgetting or overlooking the fact that, to begin with, it was altogether wrong in principle, excepting for transparencies, which, by the way, could be seen equally well in the model before you. It is true that in the commonest form of stereoscope sold in England you have the light admitted all round; but in consequence of the absence of the divisional bar and the arrangement—only to be met with in the most expensive instruments—for the protection of the eyes from the light, a limited amount of pleasure only can be got from it.

It ought not to surprise us that we have gone on so long with the original box model, when we remember that it is so natural for us to hold fast to old impressions. For instance, in the first experiments on the application of steam to locomotion on land, some old coach bodies were fastened together on a truck, only to be afterwards slavishly copied in our old railway carriages, and to be seen much too frequently on our railway lines at the present moment. Again, I have no doubt that as it was necessary to protect the gas flame from strong currents of air, a common stable lantern served as a model for all our street lamps, for in no other way can I account for their offensive ugliness. I might go on repeating instances, all tending to show how fond we are of a well worn road, and that we do not mind a few cart ruts by the way, but it would lead me out of the right path, so I will return to the subject in hand.

When we remember that only a very few years ago the whole civilized world was taken by storm when the wonders of the stereoscope were revealed to them, it certainly is a matter for much surprise when we notice how comparatively indifferent the mass of even educated folks are to the claims of this really beautiful instrument. If you put a stereoscopic picture into the hands of many of your friends, and offer them at the same time the instrument, in order that they may enjoy it the more, you will find, only too frequently, that it will be declined with thanks. There must be some cause for all this, and I think it will be found in the fact that in the mass of instruments a considerable amount of fatigue to the eyes is experienced after a few minutes' examination of a number of stereoscopic slides by different makers. The distance from centre to centre varies so much in the slides that the eye is constantly strained; hence the number of people who never properly see a picture with true stereoscopic relief.

It will be found that in the ordinary common stereoscope, of (say) 6 inches focus, a picture should not have the objects in the two pictures more than  $2\frac{1}{4}$  inches apart; and yet you will find that so great is the demand for large pictures on the part of the dealers and the public, that a great number of the slides now offered for sale will measure  $3\frac{1}{2}$  inches at least. Now, in the ordinary instrument, such subjects cannot be seen without much fatigue to the eyes; but with an adjusting stereoscope the lengthening of the focus will at once make these pictures combine with comfort. Mr. England and others have complied with this demand for size, without sacrificing the beauty of the picture, by taking away a portion of subject where the pictures come together, and giving it to the extremities, so that whilst the pictures well fill the stereoscopic mount, the centres are not more than  $2\frac{1}{2}$  apart, and not often so much.

The instrument before you combines so completely all the excellencies of all the most expensive instruments, and is, withal, so ingenious and inexpensive, that I felt it only

needed to be more thoroughly known to give a new impetus to a department of photography which has declined much during late years. I felt, therefore, I could not do better than bring it before a Society where its advantages would be at once seen, and its merits thoroughly discussed. The necessity for such an easily adjustable instrument will be seen when I tell you that a difference of five inches in the position of the slide is needed to make it perfectly seen by two of my friends. One of them, a gentleman in this room, requires the slide close up to the partition; whilst the other needs the slide to be placed at the very extremity of the bar. This will be found to be nearly six inches. Another friend, who has looked at hundreds of slides, has never seen one perfectly until now. I hope this instrument will be largely made by the dealers, and that, in consequence, the stereoscope will once more be a pet instrument in the hand of every one.

## NOTES ON PHOTOGRAPHIC SUBJECTS.

BY M. CAREY LEA.\*

*Poisoning by External Use of Cyanide of Potassium.*—Although warnings have been so earnestly and so emphatically given as to the danger of the use of cyanide for removing silver stains, it continues to be used by many in preference to substitutes.†

Some time back a contemporary published a note from a correspondent, to the effect that his fingers had become swelled and sore, continuing so for months, and exuding a sticky substance, so that they adhered to his gloves. He mentions that he has made no use of cyanide except for cleaning his fingers, and attributes to that their present bad condition. This is a singular instance, brought into publicity by the sufferer desiring to find a remedy; but doubtless there are many suffering in the same way, who do not report themselves.

There is no recognized treatment for such troubles, nor have I had the opportunity of observing anything of the sort in person. But I would strongly recommend the trial of the following treatment, which I believe would be beneficial, and which, at any rate, could not prove prejudicial.

Take an ounce of oxide of zinc, and an equal quantity of starch, and a drachm of camphor. Pulverize the camphor by dissolving it in alcohol, and precipitating with water. Dry it, and mix it well with the other ingredients. Rub the powder well into the hands two or three times a day, brushing off the excess. I suggest this remedy as one which, judging by analogy, ought to be advantageous, and, as already remarked, it could do no harm.

It is not, by any means, necessary to use cyanide to get rid of silver stains. It is true that the other means hitherto suggested do not work well. Brushing the hands successively with iodine, nitric acid, and hyposulphite of soda is very troublesome and disagreeable, and, besides, very imperfect in its results. Chloride of iron, as recommended by Obernetter, I have not found to answer. But the remedy which I proposed some months since (bichromate of potash, 1 part; hydrochloric acid, 2 parts; water, 20 parts) I find very efficacious, and use it to the exclusion of all other means. At the end of the photographic work, wash the hands thoroughly with this. The stains disappear as rapidly as with cyanide. The solution leaves yellowish marks, and a peculiar smell upon the hands, both of which are got rid of with a little solution of hyposulphite of soda.

If I return to the subject of this treatment, after having already called attention to it, it is from a profound conviction of the necessity of banishing the detestable cyanide, as far as possible, from the photographic laboratory. The

\* *Philadelphia Photographer.*

† A late number of a German journal comments upon a species of soap offered to photographers for the removal of silver stains, and remarks that the assertion in the advertisement that it was free from cyanide was confirmed by analysis, which also showed that the principal agent contained in it for acting upon the stains was powdered pumice-stone. It was said to be efficacious.

scientific chemist goes through a long education in a laboratory, where part of his education consists in being taught to handle poisons; and yet most chemists injure themselves in this way. One of the most celebrated of living chemists is said now to suffer greatly from the effects of exposing himself to injurious agencies, and to be in the habit of warning his pupils to profit by his experience. And I need not mention the names of Hennel, of Gehlen, of Bullacke, of Stevens, and other regularly educated chemists, who have lost their lives from imprudences of this sort. If these results take place with men who have had all the advantages of a special education, and a thorough acquaintance with the properties of the substances with which they have to deal, how much more must it be so with photographers, who often take up the pursuit without any previous instruction at all, or, at best, a brief course with some practical operator!

Is it not, then, reasonable to ask every one who is in the habit of using cyanide, to discontinue it, at least until he has given a fair trial to the above described substitute?

*Negatives Losing Greatly in the Fixing.*—Every one must have remarked that even when using the same chemicals, negatives seem, at some times, to lose a good deal more than at others in fixing. The difference appears to depend upon the following considerations:—

When a collodion film, charged in the usual way with bromides and iodides, is plunged into the negative bath, there is a formation of iodide and bromide of silver. But exactly where this transformation occurs will depend entirely upon circumstances. It is evident that either the nitrate of silver solution may enter the film and form the new silver salts in the film, or the bromides and iodides in the collodion may pass outside the film and meet the silver solution outside the film, in which case the sensitive layer of iodide and bromide of silver will be formed on the film instead of in it. Of course, a superficial deposit of the sensitive film will lead to the production of a superficial picture, and this cannot but suffer much more in the fixing than one firmly embedded in the collodion film. This naturally leads us to inquire under what circumstances the sensitive layer will be formed in the film, and, under what, upon it. The answer is not difficult to find.

The weaker the silver solution, the more rapidly will those portions immediately in contact with the film become exhausted of their silver by the decomposition at its very commencement. Then the production of the iodide and bromide is checked, and time is given for a portion of the iodides and bromides of the film to pass outside of it, and suffer decomposition beyond it. On the other hand, when the bath solution is strong, silver is supplied as fast, or nearly so, as it is exhausted, the sensitive layer is well imprisoned in the collodion film, and there results a negative that bears fixing with very moderate loss of strength.

It is evident from this, that inattention to keeping up the negative bath to its proper strength may lead to a consequence that might be mistaken for the result of something very different.

In a late number of the *Berlin Archiv*, Haugk mentions a case where this weakening of the negative to excess, in the fixing, took place with an entirely new bath. Although it seemed at first as if this could not be attributable to weakness of the bath, it proved to be so; the nitrate of silver had been largely adulterated with nitrate of potash, so that its strength was greatly inferior to what it had been supposed to be. The same bath, after having been much reduced by evaporation, gave negatives which behaved satisfactorily in the fixing bath.

## Proceedings of Societies.

### NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The first meeting of the winter session of this Society was held in Myddelton Hall on the evening of Wednesday, October 7th, Mr. G. WHARTON SIMPSON in the chair.

The minutes of the previous meeting having been read and confirmed, the following gentlemen were duly elected members of the Society:—Messrs. W. Wool, J. Crasweller, J. H. Shanks, J. Howden, G. Fuller, R. Chappell, Jun., F. Campion, S. Lowry, N. K. Cherrill.

The CHAIRMAN then called the attention of members to the presentation prints for the year, examples of which were on the table, which far exceeded in value the amount of the year's subscription. As the members were aware, on this occasion competition for the supply of the presentation prints was invited, and a large number of pictures were sent for selection. Of these, two had been chosen from the works of very able men, and were now ready for distribution. They consisted of a fine 12 by 10 print by Mr. Lake Price, entitled the "Falconer," which was very admirable as an example of art photography; of a 10 by 12 landscape by Mr. Nelson K. Cherrill, the subject of which was "Rusthall Common," near Tunbridge Wells. This landscape contained some of the finest cloud effects ever produced by photography, and the Chairman had pleasure in informing members that the selection of their committee had in this case met with the endorsement of a jury in Falmouth, as for this print Mr. Cherrill received the first silver medal of the Royal Cornwall Polytechnic Society. In addition to these were two whole-plate pictures, selected from Mr. Rejlander's charming studies, and printed by Mr. Woodbury's process. They were entitled "A Night in Town" and "Six Times for a Halfpenny." He had pleasure in congratulating members on the unusual number and value of the presentation prints the Committee had been able to offer them on this occasion.

Mr. BELTON exhibited a curious little camera and lens, the exact use or purpose of which he could not explain, but it had been placed in his hands as a curiosity, and might have some interest for the Society.

Mr. NELSON K. CHERILL then read his paper on the Relation between Intensity and Tono (see p. 499).

The CHAIRMAN, after proposing a vote of thanks to Mr. Cherrill, remarked that his paper contained so much that none of them would be disposed to gainsay, that he was afraid it would not excite much discussion. Mr. Cherrill had thought out and given definite expression to many things with which they were all familiar by practice, but which few of them had even mentally attempted to reduce to rule. There were, however, some of the practical points raised in the paper which it might be interesting to discuss. For instance, the question might arise: Would the possession of a standard quality of albuminized paper, to which Mr. Cherrill had referred as desirable, be really a good thing? Seeing that with the utmost care and accuracy in operating it would be difficult if not impossible to produce negatives of a standard intensity, might it not be regarded as an absolute boon to photographers that different kinds and qualities of albuminized paper were in the market, by familiarizing himself with which, and intensifying them, the photographer had facility of getting something like uniform results, by compensating want of absolute uniformity in his negatives by the use of papers of varied qualities? This and some other practical points might, he thought, be discussed with advantage.

Mr. HART thought, with the Chairman, that the existence of varieties in quality in paper was often an advantage. Until photographers had agreed amongst themselves as to a standard quality of negative, it would be difficult for albuminizers to satisfy them with a standard or uniform paper.

Mr. CHERILL said it was not uniformity at which he aimed, but that when he purchased paper it should bear some recognized relations to a recognized standard, so that every fresh batch should not require a certain amount of experiment before the photographer knew how to deal with it so as to secure good results.

Mr. HILL said that albuminizers might at least state what proportion of salt was used in preparing the paper, so that an idea might be formed of the strength of silver bath required.

Mr. HART said he feared that this would be of little service to the mass of photographers, as they took little note of the strength of their baths, generally keeping them in use until the albumen being dissolved indicated the need of strengthening.

A conversation on this subject followed, in which several members thought the information as to the salting would be useful.

Mr. HART said, from his experience, he did not think that the majority of photographers would pay any attention to it.

Mr. CHERRILL said that in their operations it would undoubtedly be useful, both as suggestive of the strength of bath necessary, and of the gradual reduction in the strength which would probably take place when a given quantity of paper containing a certain amount of salt had been floated on the bath.

Mr. BLANCHARD held the same view. It would save much waste of time and material if the paper were marked. Every time a new kind was employed, it was necessary to ascertain by experiment the kind of bath it required. He preferred weakly salted papers as a rule. He believed, that in order to get the best results in printing, exposure for sufficient time, independent of mere depth of printing, was an important thing. For instance, a thin negative with a highly salted paper might print deep enough in a very short time; but he did not believe the print would be so good or so permanent as if it had been printed on a paper more weakly salted, which would have rendered necessary longer exposure.

Mr. HART suggested that when photographers were anxious to ascertain the amount of the salt used they could soak the albumen and salt off a quarter of a sheet of paper by means of distilled water, and, by throwing down the silver by means of a standard solution of chloride of sodium, ascertain accurately.

Mr. HILL thought that was like using a steam engine to draw a cork.

Mr. BLANCHARD mentioned the fact that a weak bath would dissolve the albumen off a highly salted paper, but not off a weakly salted paper.

Mr. HART said that the larger the quantity of salt the less readily the albumen coagulated, and hence a strong bath was necessary to coagulate highly salted albumen.

Mr. BELTON agreed with the remarks of Mr. Blanchard as to the advantage of knowing something of the proportion of salt used in the albumen, and scarcely thought that because some photographers would not make good use of the knowledge, that those to whom it would be most useful should be deprived of it.

After some further conversation, in which Messrs. Hart, Blanchard, Belton, Hill, Shave, and Cherrill took part,

The CHAIRMAN said that the opinion seemed general that it would be a boon to photographers if albuminizers would afford them some idea of the proportion of salt used. It would be difficult for many reasons, even if desirable, to secure an absolute standard, and difficult to state accurately the proportion of salt employed. The varieties in the quality and condition of the original papers, a thing beyond the control of the albuminizers, would militate against uniformity. Some papers would absorb salt in greater relation to albumen than others, the degree of concentration of the albumen solution would affect the question, so that if the albuminizer started with a batch of albumen with a given proportion of salt, it would, from evaporation and other causes, have a different proportion before it was used up. Still, if albuminizers would make, say, two kinds of paper, distinguished as weakly and strongly salted, the first containing, say, between 5 to 8 grains to the ounce, and the strongly salted two or three times that amount, he thought photographers would regard this as a great advantage.

After some further conversation the proceedings terminated.

#### SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The first meeting of the session of this Society was held in the City of London College, on the evening of Thursday, October 8, the Rev. F. F. STATHAM in the chair.

The minutes of a preceding meeting having been read and confirmed,

The CHAIRMAN called attention to the remaining presentation print of the year, which was now ready for distribution. It consisted of a magnificent 16 by 12 figure subject, by Mr. H. P. Robinson, entitled "On the Way to Market," printed in carbon by Mr. Swan's process. He considered the picture far exceeded in value the amount of the subscription, and, but for the kind moderation of the artist, they could not supply the members with a second print of such great value.

Mr. WHARTON SIMPSON exhibited some examples of Mr. Burgess's Eburneum process, and briefly explained some details regarding them.

Mr. BLANCHARD then brought before the members an interesting communication on Stereoscopes (see p. 499). He exhibited some examples of the new form of stereoscope, which he described and advocated, and expressed his conviction that the introduction of a cheap and convenient stereoscope would do much to revive the comparatively flagging taste for stereoscopic pictures. Mr. Blanchard also exhibited some charming slides for use in the instruments he passed round.

Mr. BOCKETT also exhibited an old cheap stereoscope, which he had modified so as to resemble the American instrument Mr. Blanchard exhibited.

A desultory but interesting conversation on stereoscopes and binocular vision, the form of instruments, lenses, prisms, &c. followed, after which the proceedings terminated.

#### LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Association was held on Tuesday evening, the 26th ult., the President, the Rev. G. J. BANNER, in the chair.

Mr. FORREST passed round a specimen of his new glass for focussing, and several gentlemen who had used it pronounced it to be the best focussing surface they had seen. Mr. Forrest thought it would be particularly useful in microscopic enlarging.

Mr. HENDERSON reverted to Mr. Hughes's plan, described at a previous meeting, of focussing on white cardboard when enlarging.

A number of pictures, taken on the occasion of the last excursion to the "Old Hunt," were passed round. Amongst them a 12 by 10 print, by Mr. Hubbuck, from a dry plate twelve months' old.

Mr. WILSON produced a picture taken at a previous outdoor meeting, upon a plate two years' old.

The PRESIDENT complained of the bad results he had obtained lately with a new sample of paper, and asked if other members had tried it with a like result.

Mr. GREEN found fault with it for lack of brilliance.

Mr. HENDERSON said he had found that the time of year had considerable effect upon the quality of prints, and that from certain negatives he could not now produce as good prints as he had obtained during the spring and summer.

Mr. GREEN said the same remarks were applicable to fine and dull weather, and, also, that a greater degree of overprinting was necessary in a weak light than a strong. He accounted for it by supposing that with a strong light the image sinks deeper into the paper than with a weak.

A number of pictures by M. Constant-Delessort, of Lausanne, were examined with great interest. They consisted of pictures by the collodio-bromide process with various preservatives. Amongst the number was one of Lausanne Cathedral, which had received the same exposure as the wet process.

A communication was read from Mr. Sayce, thanking the Society and Mr. Green for the picture presented to him.

Mr. WILSON took exception to a remark that no progress had been made in the collodio-bromide process since its first publication. Mr. Wilson called attention to a new source of failure in dry plates. Having been troubled with patches of insensitiveness in the centre of some of his plates, he at last discovered that it arose from his having marked upon the backing of the plate with a wet rag after exposure a distinguishing number, and that when returned to the plate-box the close proximity of the moist back to the front of the next plate had set up an injurious action, resulting in local insensitiveness.

Amongst the objects exhibited were a new panoramic stereoscope and slides by Warner, kindly lent by Mr. Guyton, and a pocket camera and stand by Mr. Hubbuck.

The meeting was adjourned until the 27th inst., when a series of papers will be commenced upon the collodio-bromide process. Several gentlemen have promised to take up the different branches of the subject.

#### Correspondence.

##### PUBLISHING PRINTS FROM PURCHASED NEGATIVES.

DEAR SIR,—Have you room for the following question in the form of a warning?

If one sell a business with all pecuniary advantages desirable from the negatives, &c., does that confer the right to publish from such negatives as if they had been made by the purchaser himself?

My reason for asking is, that my successor is now publishing portraits of many eminent persons, all from negatives taken by me, with his name in full as the artist. I know such cannot be morally done; if it can do done legally, it is well the profession should know it, as in such cases they will know how to act in the sale.—I am, sir, yours truly, JOHN BEATTIE.

13, Buckingham Vale, Clifton, October 12th, 1868.

[The legal question could only be definitely settled in a court of law or equity, most probably the latter. We believe, however, that the practice commonly obtains to which you refer, and is not always as the result of dishonest intention, but because the photographer conceives that in purchasing the goodwill of a business he has a claim to all reputation, &c., attaching to it; and he further mounts the prints from the negatives he has purchased on cards with his own name and address as a matter of course. Perhaps the point you raise ought to be made matter of specific agreement at the time of transfer.—ED.]

## Talk in the Studio.

**PRIZE PORTRAITS AT THE ROYAL CORNWALL POLYTECHNIC EXHIBITION.**—We have been favoured by Mr. Netterville Briggs, of Leamington, with a copy of the portrait for which he received a silver medal at the exhibition now open in Falmouth. The photograph is in size 12 inches by 10 inches, and may be described, in general terms, as similar in treatment to the portraits by M. Adam-Salomon, and is a noble example of a grand and effective style. It is a portrait of a gentleman, easy and graceful in pose, rich and deep in the shadows, pure and delicate in the lights, with admirable half-tone and modelling. In the interesting report of our Falmouth correspondent allusion was made to a roll of paper in the hand as slightly disturbing the repose. In the copy before us the roll in question, being low in tone, rather serves to spread and repeat the lights, and gives value to the picture. The definition throughout is sufficient without being too sharp, the texture of the flesh being very fine. The composition and chiaroscuro are satisfactory, and the whole picture effective. We are glad to see Mr. Robinson's successor at Leamington so worthily taking a position amongst first-class portraitists.

**INTENSIFYING VARNISHED NEGATIVES.**—Some years ago we described to our readers our method of intensifying varnished negatives by means of an alcoholic solution of iodine. Mr. Kjellander informs us that he has recently been treating some of his old negatives, which were a little wanting in vigour, by this method with the most satisfactory results, the prints obtained from such negatives being much superior to any they had yielded before. Photographers who have not tried this method should experiment with worthless negatives, in order to familiarise themselves with the manipulations, as much of success depends in stopping the operation at the right point.

**PHOTOGRAPHS ON GRAVESTONES.**—The custom of placing photographic portraits of deceased persons on their gravestones is gradually becoming customary in some parts of the country. They require, of course, to be placed under glass, and carefully sealed up to preserve them from the influences of weather. We notice, in a provincial paper, that two such portraits have recently been placed in a cemetery in a town in the north. When enamel portraits become a little more accessible and popular they will doubtless be found most suitable for such a purpose.

**PHOTOGRAPHY IN CHURCH.**—We have received from a correspondent a copy of the *Newcastle Daily Chronicle* of last Wednesday, which contains the following letter:—"Photography in the Church.—Sir,—On Saturday last, a wedding (probably a fashionable one) took place at the church of St. Saviour's, Tynemouth. After the ceremony was over, the vicar (the Rev. T. Featherstone) from within the altar rails requested the congregation and the bridal party to remain still for a few minutes. Guess, Mr. Editor, the object! Oh, hor-

rible to relate! it was to enable a photographer to take the portraits of the bridal party and the vicar with his robes on. Has the vicar forgot the robuko given by our Saviour to those who sold and bought in the Temple, when He overthrew the tables and the money changers, and the seats of them that sold doves, and said unto them, 'It is written, My house shall be called the house of prayer, but ye have made it a den of thieves'?—I am, &c., Edwin, Tynemouth." The photographer, we know, is almost ubiquitous, and very pertinacious. He cannot well be blamed for exercising his craft wherever it is possible. It is no part of our duty to enact the ecclesiastical censor, otherwise we should certainly regard the action of the vicar as open to grave rebuke for making the church a studio in which to photograph a bridal party.

**WEAK BATHS.**—Describing the operations in producing the very fine illustration to the October number of the *Philadelphia Photographer*, by Mr. Koeler, of Philadelphia, the *Photographer* says:—"It was printed during the whole summer upon an average solution of eighteen grains. Sometimes I used as low as thirteen grains. My formula is about as follows:—

Silver ... ..	480 grains
Water ... ..	24 ounces
Alcohol ... ..	1 ounce.

Fleet the paper one minute, fume five minutes. This paper kept white through the hot weather; more so than any paper I have used.

### TONING SOLUTION.

Water ... ..	32 ounces
Acetate of soda ... ..	60 grains
Table salt ... ..	60 "

Take one bottle of gold containing fifteen grains, and dissolve in eight ounces of water. Take one ounce of chloride of gold solution and neutralize with bicarbonate of soda, and add to the above, one hour previous to using it. This bath may be used an indefinite number of times by adding the above amount of gold each time."

**PHOTOGRAPHIC IDENTITY.**—In New York it is announced that the directors of the Park Bank, in establishing regulations for their new safe-deposit vaults, have adopted the idea of identifying each lessee of a safe by his own carte-do-visito previously obtained.—*Philadelphia Photographer*.

**EARTHQUAKES AND PHOTOGRAPHY.**—It is stated that in America the price of gun-cotton is about to be advanced, for the reason that the earthquake in South America has cut off the supply of nitrate of potash.

**"SCIENTIFIC OPINION."**—A new series of this journal, the publication of which had been suspended, is announced for issue next month by Messrs. Wyman and Sons. It will contain a general *resumé* of the progress of current science, and, as such, will be interesting to many of our readers.

## To Correspondents.

**TYRO.**—If you have access to the *Edinburgh Philosophical Journal* for 1819, you will find Sir John Herschel's very full account of the hyposulphites, and the first intimation of their value in dissolving salts of silver. Three forms of hyposulphite of silver are there given: First,  $\text{Ag O, S}_2 \text{O}_3$ , a salt very sparingly soluble in water, but soluble in a strong solution of any alkaline hyposulphite. Second,  $\text{Ag O, S}_2 \text{O}_3$ ;  $\text{Na O, S}_2 \text{O}_3 + 2\text{H O}$ , sparingly soluble in water, but soluble in a strong solution of an alkaline hyposulphite. This is the salt commonly formed in cases of imperfect fixation from the use of a weak or exhausted fixing bath or imperfect immersion. Third,  $\text{Ag O, S}_2 \text{O}_3$ ;  $2\text{Na O, S}_2 \text{O}_3 + 2\text{H O}$ . This salt is readily soluble in water, and is the salt which should be formed in the ordinary process of fixation. It is upon the conversion of the chloride of silver, which is insoluble in water, into a hyposulphite of silver, which is soluble in water, that the process of fixing depends: for whilst much of the silver is dissolved out of the print in the hypo bath, if the silver salt which always remains in the print on leaving the bath were not soluble in water, we could have no perfect fixation or approach to permanency. You will find an account of the hyposulphites of silver and their behaviour in Hardwich's Manual, p. 168 of the last edition, or

p. 57 in the sixth edition. It is our practice in writing for non-chemical readers to deal with a subject as popularly as possible, avoiding technical terminology and the use of symbolical formulae. Ignorance is pardonable where it is modest and confessed. It only becomes very contemptible when it is paraded and exulted in.

**OXONIENSIS.**—In double printing there is constant necessity for the exercise of personal judgment and ingenuity, and these will grow with practice. There are often several modes of doing the same thing, but there are also certain recognized methods which are most simple and effective. In a landscape with a soft, tender distance forming the sky-line, it is a good plan to practically vignette the mask which covers the sky into the landscape by means of a little cotton wool. Where a spire, or a series of pinnacles, or similar objects cut sharp against the sky, if it be necessary to mask the sky, there is no better plan than painting on the varnished surface of the negative with lampblack or other suitable water colour, or black varnish, carefully following the outline of the object. An ordinary roughly cut mask is then used, which does not come quite close to the spire, &c., but overlaps the painted portion. 2. Sunning down a sky, so as to produce a graduated tint, may be done in several ways after the print has left the pressure-frame. A piece of board may be used to shade it, gradually uncovering in the degree required; or, the landscape portion being quite covered, a cylindrical roll of paper may be placed upon the sky in such a position that it partially protects the paper, and just allows sufficient light to produce a graduated tint to fall on the white sky. Where a spire or similar object projects into the sky, it may be disregarded in the process of sunning down; in this way the slightly increased depth of the top portion will not be apparent in the finished picture. 3. It is probable that large prints will be injured in a small syphon tub. The principle of such machines is very good, but it should be applied in vessels of suitable size for the prints. The plan of Mr. England's machine is a good one for large prints. We described it a few months ago. There are several good washing machines to be bought; but there is nothing superior to constant change and draining by hand for those who only require a few prints, and take a personal interest in their excellence. 4. Baths often rapidly discolour again after the use of kaolin, because they are often made slightly alkaline by some impurity in the kaolin. There is no serious harm in using a discoloured bath, so long as the tint acquired by the paper is removed by the hypo bath, which it commonly is. We prefer decolorizing the bath by the addition, with agitation, of a few drops of a strong solution of common salt, which, in forming a precipitate of chloride of silver, carries down colour and other contaminations. The use of one-eighth of alcohol in place of water in the nitrate bath often checks discolouration.

**J. CARTER BROWNE, M.A.**—We are glad that you got rid of your troubles by returning to your old process. We fear that there is no developer which will give tones similar to those of Ferrier's transparencies on tannin or tannin and sugar plates. Gallic acid would not help you. The ordinary pyro and citric acid developer generally gives very good tones; but you may possibly get a colour more approaching to black by the use of tartaric acid in place of nitric acid. 2. The soft, somewhat hazily-defined effect of the print to which you refer is not in any way due to the printing process, but entirely to the negative, which was probably purposely taken a little out of focus. 3. As almost any pigment you may choose may be employed in the tissue in Swan's process, there can be no great difficulty in obtaining a suitable green to give the tint of foliage, if you wish it. Such a colour could only be used, of course, in close bits, in which no sky is seen, as nothing would be more hideous than a tint of green in the sky. You might produce the tint by the addition of some of the green pigments sold by artists' colourmen, such as sap green, emerald green, malachite green, &c., or by the mixture of a blue and yellow pigment. 4. We should be glad to have a fuller description, for publication, of your printing-frame for transparencies.

**W. J. A. G.**—Mr. Gordon prefers the iron development for his gum plates, as giving the best results and securing immunity from some troubles. The details of iron development were given by Mr. Gordon in our number for May 15th, p. 230 of the present volume.

**W. S.**—Mr. Solomon, of Red Lion Square, is the agent for the sale of Harnecker's dry collodion in this country.

**QUANDARY.**—The term plain paper is used simply as a distinction from glazed or albuminized paper, and, for transferring collodion prints to any good smooth plain paper, whether photographic paper or not, will serve. The only advantage of using photographic paper is derived from the fact that it is of a more even, perfect texture generally than ordinary writing papers. 2. The glazed or enamelled papers for the purpose are prepared in France, but are, we believe, sold by most London dealers. We do not know the price. If we remember aright, we have seen it for sale at Mr. Hughes's, in Oxford Street. 3. If albuminized paper be employed, it would not be necessary to gelatinize it, probably, but it would be necessary to have it without salt, which commercial samples are not; so you had better abandon the notion of using albuminized

paper. 4. In referring to the dry method of transferring, we said the manipulations were similar to those used in enamelling, because we had often described the process. You will find details in our YEAR-BOOK for 1865, page 82. We may briefly state the plan thus: when the transparent print is toned and dried, coat it with a warm solution of gelatine, 1 ounce in 12 ounces of water. When this is set, moisten the paper for transfer, and bring it into contact with the gelatinized paper. When dry, a knife point is run round the edge, and the whole leaves the glass. We prefer the wet transfer as simpler and requiring less delay, and as also giving a little less gloss, which we prefer. 5. Yes; the gelatinized paper should be moistened with cold water.

**A. CONSTANT READER OF THE NEWS.**—Both the lenses you name are very excellent, but we prefer that you distinguish as A.

**B. L.**—A transparent trick, very common in the quarter you name, which we understood before we received your letter. Thanks.

**YOUNG AMATEUR.**—In Mr. Bartholomew's acetate of morphine process the plate is not washed after treating with the 1-grain morphine solution, but is simply drained and dried. 2. In Mr. Gordon's gum process, the gum and sugar-candy solution is not washed off; the plate is simply drained after its application, and dried. 3. The choice must depend much on circumstances. The first is simplest, but it should only be used for plates to be used within a few days. Plates by the latter will keep for months. 4. All good bromo-iodized collodions answer well. That you mention (Rouch's) will, we believe, be found suitable. 5. A good developer for collodion positives on glass stands as follows: proto-sulphate of iron 15 grains, nitric acid 2 drops, glacial acetic acid 15 drops, water 1 ounce, alcohol *quantum suff.* 6. Dry plates are not well suited for the production of positives, but it is possible to produce tolerable results upon them.

**JAMES KERR.**—You will find an article describing several methods of employing two prints to form one picture on page 544 of the Eighth Volume of the PHOTOGRAPHIC NEWS, the number being that for November 11th, 1861. The process, with slight modifications, has been repeatedly patented, but we do not think that any of the patents are in force.

**ACTINIC (Jersey).**—The design and general proportions of your proposed studio are excellent. The only modification we would suggest is the extension, if convenient, of the side light on the north side to ten feet.

**E. SAWYER.**—We hope you will receive sufficient information to enable us to rectify the matter satisfactorily in our next. We will bear your request in mind.

**GUM GALIC AMATEUR.**—Your communication arrived just as we were going to press, but shall have attention in our next. Although the handwriting and crest make our correspondent known to us, he should have enclosed his card in a letter making such an offer.

**RECEIVED:** A series of Micro-photographs from the Surgeon-General of the United States army; the Quarterly Journal of the Quekett Microscopical Club; and a Portrait from Netterville Briggs. Communications from E. L. Wilson (Philadelphia), Diogenes, Major M. (Rajapur), and several other Correspondents.

\* \* An Article on the Late Eelipse, "Visits to Noteworthy Studios," an Article from Mr. Boyce, some Reviews, and several other Articles in type, are compelled to stand over from the pressure on our pages.

Several Correspondents in our next.

### Photographs Registered.

**MR. C. MURRAY, London.**  
Six Photographs of Robert E. Gay, Esq., M.R.C.S., &c.

**MR. J. STEART, Glasgow.**  
Photograph of David Macrae, Esq.

**MESSRS. BEAUFORD & BRUCE, Nuns Island, Galway.**  
Photograph of the late Father P. Daly.

**MR. J. COLLINGS, Cardiff.**  
Ten Photographs of Ball-room and Cardiff Castle.

**MESSRS. W. & D. DOWNEY, Newcastle.**  
One Photograph of Her Majesty the Queen.  
Three Photographs of H.R.H. the Duke of Edinburgh.  
One Photograph of Prince and Princess of Wales and Family.  
Three Photographs of Right Hon. B. Disraeli.  
One Photograph of Dr. Norman McLeod.

**MR. H. BIRLON, Bradford.**  
Photograph of Mr. Chippendale.

\* \* All photographs forwarded to the Publisher for registration receive attention at once; but the pressure on our space sometimes compels us to defer the acknowledgment in this column. It should be borne in mind, therefore, that non-acknowledgment at once does not necessarily imply non-receipt or non-registration.

### A NEW AID TO HARMONIOUS PRINTING.

The importance of skill, taste, and judgment in printing, especially in portraiture, is, we believe, but imperfectly appreciated amongst many photographers. To print a negative fairly, so as to do full justice to its good qualities, as well as its defects, without suppressing or exaggerating either, is not such a mechanical task as some imagine. To get all in the print which is in the negative is one element of good printing, but it is by no means all that is required, nor all that is possible for the printer of artistic taste and skill to secure. By the exercise of a little judgment contrast may be decreased or increased, defects modified or suppressed, shadows deepened, and spotty lights toned down or removed. In short, by skill on the part of the printer, a good picture may be produced from an indifferent negative.

Mr. Samuel Fry has just communicated to us an important aid to artistic and harmonious printing which he has for some months past employed with very great success. It depends on a system of masking in which he has most ingeniously employed existing means to a most important end. Let us, before proceeding further, explain the circumstances under which this aid becomes of special value.

Every photographer is familiar with a class of negatives in which there is a slight excess of density. All the detail and modelling are there, but from the unexpectedly non-actinic colour of the deposit when dry, or from the temptation, so strong to some operators who love brilliancy, to give just a moment too long to the intensifying, the lights are slightly too opaque. The consequence is, that the shadows are bronzed before the modelling, due to delicate half-lights, is sufficiently impressed on the sensitive paper, and, if the portrait be printed sufficiently deep to do this modelling justice, all detail in the shadows is buried, and blackness and want of transparency is the result. The use, in printing, of paper and bath giving little contrast, sun printing, and shading the deeper parts of the image during the progress of printing, are remedies each of which affords some advantage in such cases; but the expedient we are about to describe is simpler and more efficient in many cases than any of them.

The mask Mr. Fry employs is a transparency from the same negative. It will be seen in a moment how this operates. The transparency or glass positive is in all respects the reverse of the negative. Where the latter is opaque, the former is transparent; where the negative is transparent, the positive is opaque. When the paper print from an over-dense negative is sufficiently printed in the shadows, the lights still remaining chalky and without detail, the transparent positive on glass is brought into use. It is placed outside the printing-frame, of course, because the print could not with advantage be disturbed, and because extreme sharpness in the printing of the mask is not required. It

will be seen now that the deposit forming the shadows of the transparent positive protects the print in those parts which are already sufficiently deeply printed, whilst the whites, being transparent, permit the rays of light to pass freely, and so to continue to print through the dense lights of the negative, and thus to secure in the proof all the delicate detail in the lighter portions of the picture without losing transparency, burying detail in the shadows.

It will be seen that this kind of mask suits itself to the precise degree in which the excess of contrasts exists in the negative, and must, if used with judgment, inevitably tend to produce harmonious prints from dense or hard negatives. Where special effects are required, such a mask may easily be manipulated a little. For instance, it may be necessary to preserve the extreme purity of some few points of light, whilst it is desirable to reduce, or get detail into, many others. In such a case it would be easy to stop out in the transparent positive the points where further printing in the lights is not desired. Modifications of this kind will doubtless suggest themselves to the judicious printer as the occasions arise.

In some instances, instead of taking a glass transparency, a paper print, made transparent by means of varnish or wax, might be employed as the mask; but it would not be so efficient, as the registration of gradation would not be so perfect, and the amount of light obstructed by such a paper mask would make the final harmonizing operation somewhat slow. As every new aid to artistic printing is of great value in securing the progress of portrait photography, photographers are indebted to Mr. Fry for an ingenious and useful method of obtaining harmonious prints from over-intense negatives.

### A PHOTOGRAPHERS' RELIEF FUND.

We have received several letters of late on the subject of a photographers' relief fund, all of which, with some diversity of opinions on points of detail, agree in the general idea that "something ought to be done." Some few think that the time is not quite ripe for such an experiment; and that it would be a pity to try it and fail. This view was forcibly put to us by one of the oldest and ablest of our artistic photographers, who recently called upon us. He suggested that photography, as a profession, is undergoing a weeding process; that many who took it up hastily, because of the promises of profit it seemed to hold out a few years ago, but who did not, in a legitimate sense, belong to photography as a profession, were forsaking it again for their own respective legitimate callings; and that it would be better to get this weeding process completed before establishing any benefit fund, the existence of which might tempt them to remain longer in a profession which, for their own sakes, they had better abandon.

The question as to the proper class of persons to be admitted to the benefits of such an organization, although really a detail for subsequent decision, stands sufficiently in front of the question to merit some consideration at the outset, as it might materially determine the character of the organization. If a benefit society proper, upon an economic basis, be established, the wider and more catholic the qualifications of the members the better, for a benefit society works most perfectly when it consists of large numbers. The averages upon which the distribution of relief must be calculated work out more perfectly over a widespread area than they possibly can within any limited range. If, on the other hand, a benevolent fund be contemplated, it becomes important that relief designed for photographers should be preserved for them, and not poached upon by the quasi-claims of hangers-on of the profession. It is not necessary, at present, to define the qualifications which should entitle the possessor to inclusion in the benefits of any contemplated fund; but it may be worth while to bear in mind certain broad distinctions, such as we have hinted at, in any steps which may be taken in the matter.

In the meantime, as we have said, every one seems to be satisfied that it is desirable that something should be done. Indeed, ever since we first broached the idea, four years ago, this proposition has received general assent. But the important question, Who will undertake the practical initiation of the matter? remains still unanswered. Our immediate purpose in writing now is to place before photographers a very important offer which has been made. We have received a letter from a gentleman, whose handwriting we know—although no name is appended to his letter—as that of an amateur of high standing, offering, if a satisfactory committee be formed within six months, to contribute fifty pounds towards the formation of a fund. We print his letter without further preface, and shall then add one or two observations to correct certain misconceptions it contains:—

“THE PHOTOGRAPHIC PROVIDENT FUND.

“To the Editor of the PHOTOGRAPHIC NEWS.

“DEAR SIR, —I see by the various journals numerous letters respecting the late Goddard Fund, and also that there is an idea to create a new one to assist photographers generally. Some of these letters imply great blame with those who had the management of the former fund. I think it was a great error of the trustees to withhold the money from Mr. Goddard, seeing it was asked for in his name. No doubt they thought it would be for the best to make the money received the commencement of a fund for more general purposes, and so it has gone on until now.

“At the present time much good might be done by starting a Provident Society Fund, to be composed of those who may some day or other require help, and also those who are well off, and able, from their means, to assist those most deserving. The great end of such a fund should be to give assistance only to those who, when in health and earning good wages, had tried to make a saving against accident and misfortune as far as laid in their power, and those who had been overtaken by accident without having had that opportunity. It is very much the fashion for charitable institutions to give to all who ask, or to those who can put the most pressure on the subscribers, instead of making more enquiries as to the cases being deserving or not. These do much more harm than good, and serve as an encouragement to the improvident.

“Supposing these views meet the approval of many who are willing to help, and a fund is started, no doubt the balance remaining of the Goddard Fund would be handed over to the committee, and a start made in the right direction. If some one would act as secretary, to receive the subscriptions, the journals would most likely publish a full account of all done during each year, and every subscriber would know how the money was distributed.

“If these ideas can be carried out in the course of the

next six months, and a committee appointed to my satisfaction, I will commence with a donation of fifty pounds to the fund.—I remain, dear sir, yours truly,

“October 12th, 1868.”

“GUM GALLIC AMATEUR.”

Here is a noble offer, coupled with the simplest and most reasonable conditions. It will surely not be suffered to lapse without some effort to make it available. We may add that we have in our possession various other promises of liberal subscriptions, payable when such a fund shall be formed.

The errors or misunderstanding to which we alluded have reference to the Goddard Fund. It is no part of our duty to anticipate the report of the gentlemen under whose direction the fund has been administered; but as an agent through whom part—the larger part of that, indeed, sent through the journals—of the money was forwarded to the treasurer, and having so acquired a quasi-trusteeship, and, of course, a perfect knowledge of the facts, it would be unfair in us to print the above letter without correcting the misconceptions it contains. There are two points to mention:—

*First.* The fund was raised to relieve Mr. Goddard from a state of extreme indigence bordering on starvation, and the trustees, with a much fuller knowledge of the circumstances than we can here detail, administered the fund as they believe best secured the purpose for which the money was asked; and from the commencement of the subscription to the time of his death Mr. Goddard was provided for, and was in the receipt of relief from the fund averaging three or four times the amount of his previous income, derived from precarious charity. If the committee had agreed to part with the sum raised, instead of resolving to invest it in an annuity, they had reason to believe that, although it would have relieved them of immediate trouble and responsibility, they would have failed in securing the end for which they had appealed to the public. This is simply a question of judgment, in which the trustees, with a more minute knowledge of facts than would be easy to make public here, took the course involving the greater trouble, in order to keep faith with the contributors to the fund.

*Second.* The notion that the trustees have, or ever had, any intention of employing the Goddard Fund as the nucleus of a general fund is altogether an error. We know that statements to the effect that such an intention existed have been industriously circulated; such statements are pure fabrications, without a shadow of foundation in fact. When Mr. Goddard died, the end for which the money had been contributed had been achieved, and the balance of the money, after paying the liabilities and funeral expenses of Mr. Goddard, the trustees at once felt belonged, not to them, to dispose of as they chose, but to the subscribers, by whom it had been entrusted to them for a specific purpose; and they resolved to return the balance to the subscribers, dividing it in the ratio of the contributions. This would have been done at once, but certain claimants arose, alleging that the money had been bequeathed to them by Mr. Goddard. Although the claimants for money supposed to have belonged to Mr. Goddard at his death had left him to indigence in his life, it would have saved the trustees some trouble to have handed over the balance at once; but the view entertained by the trustees of the ownership of the money being confirmed by legal advice, they had no alternative but to restore the balance *pro rata* to the subscribers. As we have said, this would have been effected without delay, but those concerned in Mr. Goddard's will having signified their intention to contest the ownership of the money at law, the trustees were instructed that no steps should be taken to redistribute the money until the lapse of a sufficient period of time. This done, it was necessary to collect as perfect a list as possible of subscribers, with their addresses, a work of no little time and labour, already, so far as we believe, nearly accomplished. Every subscriber to the fund sufficiently interested in the matter to make enquiry, has received full information of the facts, and in every instance has expressed unqualified

approval of the course taken by the committee, upon whom a troublesome and thankless task had fallen.

Under these circumstances the committee have not felt concerned to notice the false reports, raised for mischievous purposes, in sham letters, by unscrupulous men, who avoid the risk of detection and punishment by writing anonymously. That any one so high-minded and straightforward as the correspondent who makes the above munificent offer should for a moment be misled, is a temporary evil very readily rectified. Anonymous slanders cannot in any way injure the gentlemen against whom they are directed; but they may in some degree effect other mischief, by temporarily narrowing or retarding the stream of benevolence, and by rendering able—and therefore generally busy—men indisposed to subject themselves to false statements and offensive innuendoes by undertaking the onerous duty of initiating and managing such an organization.

Our correspondent will see, however, although at first glance it might seem desirable that the balance of a fund raised for a specific benevolent purpose should be applied to a benevolent project of similar aim, but wider scope, despite the injurious suggestions as to motive made by malignant persons, yet those to whom the funds were entrusted have no power to make such application. The money belongs to the subscribers, and is only held in trust until the proper moment arrives for returning it to its rightful owners.

#### THE PROPORTION OF SALT EMPLOYED IN ALBUMINIZING PAPER.

A QUESTION which "crops out" at intervals amongst photographers was raised at the last meeting of the North London Photographic Society, and is again referred to in our pages in the present number. The question is: Is it important that albuminizers should state what proportion of chloride is employed in conjunction with albumen in preparing photographic paper? The question is simple enough, and it might be imagined that no discussion whatever need arise on the subject, but that it would be answered without a moment's hesitation, whether the information were of value or not. But, oddly enough, the question is not answered: a circumstance which has induced some photographers to ask the question put by a correspondent in our columns this week: Is there some occult reason for this reticence? Is it possible that albuminizers work so much by rule of thumb that they are uncertain of the proportion of salt employed?

We do not think that any such reason for reticence exists, or that any reasons exist at all beyond a certain amount of indifference, and an impression that the information is not really required by the public. Mr. Hart stated at the North London meeting that few photographers had any interest in such information, or could make any use of it if they possessed it; and he suggested that those who were anxious to know the proportion of salt could easily dissolve the albumen and salt off a quarter of a sheet of paper, and, by precipitating the chloride by means of a standard solution of nitrate of silver, obtain means for estimating the proportion of salt present. In making this suggestion Mr. Hart overlooks the fact that, apart from the delicacy of the operation to persons non-familiar with chemical manipulations, it is the trouble to which they are put which is the ground of protest on the part of photographers. They complain that with a fresh sample of paper they have no guide to the mode of treatment required without some experiment; and, as a remedy, Mr. Hart suggests an experiment which, to many of them, will be far more troublesome.

We know Mr. Hart to be a skilful, intelligent, and conscientious manipulator, and that all his operations are based on sound chemical knowledge of his subject, and careful consideration of the wants of photographers, neither guesswork or chance governing his operations. We do not imagine for a moment that the operations of any albumin-

izer are conducted so loosely, or so much by rule of thumb, that he could not give a tolerably accurate statement of the proportion of salt used. From a variety of causes we need not dwell on, exact precision in the statement might not be easy, but a very near approximation might be given, quite sufficient for the purposes of photographers. Very few photographers now prepare their own paper: with all the uncertainties of which we occasionally hear complaint, it is found, as a rule, easier and better to buy albuminized paper ready for use than to prepare it at home. At a time, however, when photographers did albuminize for themselves, we remember that it was the custom of some of the most able men to prepare two distinct kinds—a heavily-salted paper for vigorous negatives, and a lightly salted paper for soft negatives. Why should not albuminized paper-makers do the same, and state that the strongly salted paper contains from 10 to 12 grains of (say) chloride of sodium to an ounce of albumen solution, and requires exciting on a 60 or 70-grain bath; and that the other contains 6 or 8 grains of the chloride, and requires a 30 or 40-grain bath? There could be no great difficulty in this; and the information would be acceptable to many, and might be useful to all.

Mr. Hart, plausibly enough, asks, Why photographers do not ask the constitution of the collodion? Two or three answers to the question arise at once. It might be first replied, that they have often done so, and the more intelligent of them would always be very glad to have some idea of what they are using. It might be replied, in the next place, that such information is often, at least in a modified form, supplied. Manufacturers generally willingly state whether a collodion is simply iodized or bromo-iodized, and also whether it contains an extra proportion of bromine. But the most important answer is found in the fact that variations in the proportion of salt in albuminized paper produce greater variations in result, less under the control of the photographer, than the slight variations which exist in commercial samples of collodion. In printing, very much of the quality of the picture as to vigour or weakness depends on the preparation of the paper, and the photographer has not much facility in modifying this, except so far as it can be done by altering the strength of the silver solution. With collodion the case is different; the control possible in the developing and intensifying operations renders the original tendency of the collodion of far less importance.

Mr. Hart said—and, we are satisfied, truly—that photographers could generally obtain the information by asking for it of the manufacturer. Would it not be well that it should always be given in general terms without asking, and that in future a 6-grain or a 10-grain paper be as familiarly spoken of as a *Rive* paper or a *Saxe*?

#### FAILURE OF PHOTOGRAPHING THE ECLIPSE IN INDIA.

It is a matter for deep regret and mortification that the photographic part of the operations of the Expedition sent out from England to India to observe the late solar eclipse was a comparative failure. Some weeks ago the members of the Royal Astronomical Society received copies of a letter sent by Major Tennant to the Astronomer-Royal, recording the results obtained at Guntoor on the 18th of August. The photographic portion of the report was so unsatisfactory, or even humiliating, that we felt little inclination to publish it. An extract secured from a second letter, although recording that the results were better than were at first believed, does not serve to redeem the operations from the stigma of comparative failure. The first letter of Major Tennant opens as follows:—

*Guntoor, August 18, 1868.*

This morning was very promising, and if it had followed the course of its predecessor, we should have had a magnificent clear sky; but it clouded over the east with thin cumulostrati, which, while hardly stopping vision, interfere very much with the photographic energy; and the result was that every negative was under

exposed, and we have little more than very dense marks showing the protuberances. The six plates arranged for were duly exposed, but the heat so concentrated the nitrate of silver solution, that, besides showing but faint traces of any corona, they are all covered with spots. Still we may make something of them, and will try.

Our first impulse, on reading such a statement as this as the result of such an expedition on such an occasion, was to repeat the famous sentence of Ruskin, "This is not failure, but disaster!" Compared with the results obtained by Mr. Warren de la Rue in Spain, in 1860; compared with those secured by the German expedition, and recorded in our pages by Dr. Vogel, such an issue as the above is most humiliating. The plates were under-exposed, and covered with spots, we are told, as though the possibility of guarding against such contingencies was a thing undreamt of. In a subsequent letter to Mr. Warren de la Rue, Major Tennant is more hopeful, and better satisfied with the results obtained. The extract from his letter, published in the *Athenæum*, is as follows:—

I did myself the pleasure of sending Mr. Airy a report, such as I could hurriedly make, upon the 18th, of what we had seen and done. Since then we have been enlarging the photographs, and I am very well satisfied. The clouds reduced the actinism very much and very unequally, but that has shown new things to me. 1st, there is very little corona; 2nd, the cloudy structure of prominences is very marked. But the most remarkable thing is a great horn, which seems to have been 3m. 20s. nearly high. I have, as I told Mr. Airy, clearly seen in its spectrum C D and b, and believe I saw F, but did not identify it. Now this shows, both in Nos. 1 and 3 [photographs], as a ribbon of light, coiled spirally round a semi-transparent centre. It is very beautiful, and marked in 3, which was taken two minutes after the [commencement of] totality, and I am doing my best to keep this feature [to retain this feature] in the copies. No. 1 was taken apparently before the last of the sun went. Phillips [one of his assistants] says it was, and there is a spot of fog such as would be the result. There is a fine line of light seen through all this fog, much brighter than the corona. This, too, I am keeping on enlarging. We have got six enlarged positives, about 2½ inches in diameter, from each negative. Every one of these shows the same remarkable spiral structure in the great horn. I find there are traces in a drawing which Dr. Janssen got made of that prominence [mentioned in the first part of his letters as invisible to the eye] of which I spoke. The positive copies I will enlarge to 9 inches.

The result of the under-exposure, it is here suggested, was less injurious than was at first suspected; but the multitude of spots, from the nitrate of silver becoming "concentrated," of course nothing can remove, and their presence must seriously interfere with the value of the photographic record of the eclipse. A Fellow of the Royal Astronomical Society, writing to us on the subject, has some excellent remarks, from which we make one or two extracts. After calling our attention to "the ignominious failure of the photographic part of the expedition," he adds, that it seems to have occurred "simply because, to the best of my knowledge, there was not an experienced photographer among the expedition who knew how to prevent the nitrate of silver solution becoming so concentrated that it produced a mass of spots. It is true, a certain number of the party had been taught the operations of photography at Crauford Observatory (*i.e.*, W. De la Rue's) shortly before starting; but was that sufficient to insure success? Why not have procured the services of an experienced photographer, such as accompanied the expedition to Spain, in the person of Mr. Downs (of the firm of Cundal and Downs) an 'old hand' at all the ins and outs of photography? Or, perhaps, better still, the expedition might have procured the services of an Indian photographer who knew how to arrest the rapid concentration of nitrate of silver!

"The German Expedition, as per your insertion of Dr. Vogel's letter, have secured three perfect negatives without spots. And why? Because the party composing that expedition numbered at least three thoroughly experienced photographers among them, clearly showing that they, at least, knew what was wanted to insure success as regards the photographic part of the expedition.

'What excuse has the Royal Society for this signal

failure? for every practical photographer who has read Dr. Vogel's letter, and who now reads Major Tennant's, cannot fail to divine the cause of non-success of the English Expedition."

This expedition was sent out by the Royal Society, aided by Government, and we fear very much that it is to the aid of the latter much of the failure may be attributed. It is probable, in fact, that it is due to red tape. A staff of men provided by Government might or might not be fitted in all respects for the work; but if the men "told off" for the duty knew nothing of photography, it would be against all precedent to import a photographer from another department. If the men were selected from the Engineers, and they were not familiar with photographic operations, it would be quite inadmissible to introduce amongst them men from (say) the Artillery, who were skilled photographers. It is probable, from what we can learn, that to a cause of this kind the failure in result was due. Be this as it may, however, it appears tolerably clear that no experienced photographer formed part of the expedition staff, or we should not have heard of such puerile difficulties as spots from concentration of the silver solution.

The photographic operations of the German expedition, so well described in our columns, were admirable in their systematic prevision. Possible forms of failure were anticipated and carefully provided against. The condition of the various chemicals was carefully tested, and the relative working conditions of various collodions ascertained under the precise circumstances in which they would be required. Preliminary exposures were tried on the spot. In short, everything was so well rehearsed, and every one so carefully told off to his duty, that failure from preventable causes was scarcely possible. If this expedition were distinguished by anything of military routine, it was in the efficient drill by which they prepared themselves for actual operations; whilst the one military element which was missing in the expedition in India was this effective drill.

We have in this country several photographers of high repute and great practical skill who have had experience in Eastern photography, and who have succeeded amid the gravest difficulties. We refer to such men as Bedford, and Frith, and Goode. Surely it would have been possible to have secured the services of some of these or other experienced photographers, to whom the purely photographic operations should have been confided, and who would have certainly secured immunity from the disasters attending concentrated silver solutions, and probably, also, from the risk of under-exposure.

We add here the remaining paragraphs of Major Tennant's letter to the Astronomer-Royal:—

Capt. Branfill reports the protuberances unpolarized, and the corona strongly polarized everywhere in a plane passing through the centre of the sun.

Complementarily, I have to report a continuous spectrum from the corona, and one of bright lines from the prominence I examined. I am, I believe, safe in saying that three of the lines in the spectrum of the protuberances correspond to C, D, and b. I saw a line in the green near F, but I had lost so much time in finding the protuberance (owing to the finder having changed its adjustment since last night) that I lost it in the sunlight before measuring it, and I believe I saw traces of a line in the blue near G, but to see them clearly involves a very large change in the focus of the telescope, which was out of the question then.

I conclude that my result is, that the atmosphere of the sun is mainly of non-luminous (or faintly luminous) gas at a short distance from the limb of the sun. It may have had faintly luminous lines, but I had to open the jaws a good deal to get what I could see at first, and, consequently, the lines would be diffused somewhat; still, I think I should have seen them. The prominence I examined was a very high narrow one, almost to my eye like a bit of the sun through a clink in brightness and colour (I could see no tinge of colour), and somewhat zigzagged, like a flash of lightning. It must have been three minutes high, for it was on the preceding side of the sun near the vertex, and was a marked object, both in the last photo plate just before the sun reappeared, and to the eye.

Captain Branfill saw the prominences coloured, as did two other gentlemen; but one in my observatory (like myself) only saw it

white. I should, however, say that for long I never saw a *Orionis* markedly red, nor *Antares*, and I may not catch red soon, though I cannot conceive this being so.

In conclusion, I may note that the darkness was very slight, and the colour not half so gloomy as in the eclipse of 1857, which was partial at Delhi, where I was then.

The spectroscopic examination of the eclipse by Lieut. Herschel, given in a letter to Mr. Huggins, will be read with interest by many photographers:—

The week preceding the event had quite prepared me for disappointment. There seems to be an annual cloudy and rainy season at Jamkandi, which lasts about a fortnight, and was said to be somewhat later and more marked than usual this year. The morning broke, however, as usual, clear, but the driving monsoon clouds soon showed the kind of sky we were to expect. About a quarter of a minute before totality a thick cloud obscured the sun. I had placed the slit (of the spectroscope) so as to cross the crescent at about the vanishing point of the limb, and was watching the narrow solar spectrum grow rapidly narrower. You may conceive the state of nervous tension at this moment. Whatever the corona was competent to show must in a few seconds have been revealed—unless, indeed, it should so happen that a prominence should be situated at that precise spot, in which case the double spectrum would be presented. But the solar spectrum faded out while it had still appreciable width, and I knew a cloud was the cause. I went to the finder, removed the dark glass, and waited—in that fever of philosophical impatience which recognizes the futility of irritation, even while it chafes under the knowledge of fleeting seconds—how long I cannot say, perhaps half a minute. I can well recall the kind of frenzied temptation to turn screws and look somewhere else, checked by the calm ticking of the clock, telling of a firm hold of the right place, cloud or no cloud. Soon the cloud hurried over, following the moon's direction, and therefore revealing first the upper limb, with its radiating, and, as I fancied, scintillating corona, and then the lower limb. Instantly I marked a prominence near the needle point in the finder. A rapid turn of the tangent screw covered it with the point of the needle. Those few seconds of unveiling were practically all that I saw of the eclipse as a spectator. With the exception of a hurried glance into the finder at a later period, to watch for another break, I was the whole time engaged at the spectroscope. I have not the remotest idea, from actual experience, of the external phenomena which were present to the thousands of upturned faces whose voices I heard outside. I might easily have lifted the curtain and looked out while the clouds were obstructing. That I did not do so is only to be explained by the absence of mind, as regarded all else, produced by the concentration of attention on the problem before me. To return: the instant the prominence was under the needle point, I returned to the spectroscope. A single glance solved the problem in great measure. Three vivid lines—red, orange, blue! No others, no trace of a continuous spectrum. I think I was a little excited about this time, for I shouted, quite unnecessarily, to my recorder, "Red, green, yellow!" quite conscious of the fact that I meant orange and blue. I lost no time in applying myself to measurement. And here I hesitate; I have no idea how those five minutes passed so quickly. Clouds were evidently passing continually, for the lines were only visible occasionally. The red must have been less vivid than the orange, for after a short attempt to measure it I passed on to secure the orange, and, succeeding to my satisfaction, tried for the blue line. Here I was less successful. The glimpses of light were rarer and feebler, the line itself growing shorter and further from the cross. I did, however, place the cross very near the true position, and got a reading just as the re-illumination of the field of view informed me that the sun had reappeared on the other limb. I consider there can be no question that the orange line was identical with D (sodium), so far, at least, as the instrument is competent to establish an identity. I also consider that the identity of the blue line with F (hydrogen) is not established; on the contrary, I believe that the former is less refracted than F, but not much. With respect to the red line, I hesitate much in assigning an approximate place. It might have been near C (hydrogen). I doubt its being so far as B, but there would be its limits. The corona may have projected a spectrum of some kind, but I saw none. I therefore conclude it was a faint solar spectrum, a conclusion in accordance with other characteristics of the phenomenon, but especially with the (flickering?) radiating appearance, and with the satisfactory determination by Lieutenant W. M. Campbell, R.E., of the conditions of polarization obtaining in the corona. At present it is sufficient to state that these observations leave no doubt that the light of the corona is polarized in places passing through the sun's centre. I have had no communication with any other observers since the event. I am curious to learn how far our results will corroborate each other.

## UNEVEN DRYING OF SENSITIZED ALBUMINIZED PAPER.

A DIFFICULTY, the cause of which is not well understood, but which is productive of most annoying results, is sometimes troublesome to photographers. We refer to the uneven drying of the excited albuminized paper. Instead of the solution draining and evaporating evenly, a portion of it remains standing in drops, at greater or less intervals, all over the surface of the sheet. These drops dry, of course, very slowly, and in the finished print their places are marked out by grey spots of less vigour than the remainder of the image.

Various causes have been assigned for this irregular drying, and various remedies suggested, but considerable uncertainty as to the actual cause or cure remains. One reason for its occurrence, suggested by a manufacturer of albuminized paper, is the use of a nitrate bath much stronger than is required by his paper, which, being lightly salted, does not require a strong bath. No reason was stated for the unsatisfactory action of a strong bath; it was simply said that experience had shown that the trouble in question followed the use of a strong bath, and disappeared when a weak one—or, rather, one of the proper strength—was used. The probable explanation of that fact is, that very rapid and very complete coagulation was produced by the strong bath, and the very horny surface had a somewhat repellent action on the solution, causing it to run into drops instead of draining and drying evenly. Another manufacturer of albuminized paper, Herr Schering, of Berlin, sent an interesting communication to our columns, stating that the defect in question was often the result of the paper having been kept in a very dry place before sensitizing, and that the defect would disappear if the paper were placed in a cellar or damp place for a few hours before it was floated on the silver solution. The only time we met with the trouble ourselves we found this plan proved a remedy; but we have repeatedly had cases brought under our attention in which neither remedy proved efficient. One simple and certain cure remained, but it was troublesome, and sometimes introduced another evil. If, instead of allowing the excited sheet to dry in the ordinary way, it was blotted off with clean bibulous paper, there was, of course, no risk of uneven drying. Adopting this course has generally proved quite satisfactory, but in some instances it has been alleged that the prints on such paper possessed less vigour, owing to the removal of the free nitrate by the blotting-paper.

A correspondent in India has recently sent us another remedy, which he finds to give eminently satisfactory results in every way. We may mention, by the way, that our receipt of this suggestion affords an interesting illustration of the wide-spread community of feeling which the devotion to a pursuit of mutual interest engenders. Three months ago, a correspondent, simply signing the initials "J. S.," in our columns, mentions his difficulty. Another photographer, a major of cavalry in the Punjab, reading his *News*, and seeing this difficulty mentioned, writes a letter to "J. S." to give him a remedy which he has found to be a perfect cure. The letter is forwarded to us for "J. S.," with a suggestion that we should make the recipe public, if we think it worthy. "J. S." and his address are alike unknown to us: a great many of our correspondents in difficulties give us no clue to their identity; nor is it necessary that they should. In case of letters for publication it is, as a rule, necessary that we should receive the name and address of the writers; but we are well content that applicants for advice should preserve their incognito. "J. S." will, however, doubtless see in our columns the letter intended for him, which we now subjoin.

"Rajapore, Punjab, India, 29th August, 1868.

"MY DEAR SIR,—I have just received my PHOTOGRAPHIC NEWS of the 24th ult., and have noticed that you are in just the same fix as I was, until a short time ago, when a friend helped me out of my difficulty by recommending a dodger

whereby to put an effectual stopper to the *uneven drying of the sensitizing solution on albuminized paper*. With the hope that you may find it as effective as I have, I send it to you; viz. —

"Beat up the white of an egg *well* in 4 ounces of distilled water; add to this 4 ounces of the ordinary silver printing solution; allow this to settle, and, rejecting the sediment, add a portion of the solution to the paper sensitizing bath. If the *blisters* still continue to appear, add more of the solution till the evil is eradicated.

"Isolated, as I am here, on the borders of a desert, you can readily imagine the many and great difficulties I, as an amateur in photography, have to contend with, and can, therefore, the more readily imagine my delight and surprise to find the above recipe the *very thing* I wanted. The strength of my sensitizing bath is now only 50 grains to the ounce, and I secure as rich and vigorous prints as if I were using a 90-grain solution.

"I shall be glad to learn that the remedy has proved as successful with you as it has done with me. My toning bath is the old acetate of soda one:—

Acetate of soda	...	...	30 grains
Chloride of gold	...	...	1 grain
Distilled water	...	...	8 ounces.

Mix the soda and gold in an ounce of the water, and let stand for half-an-hour; add the rest of the water, and tone."

#### ON THE APPLICATION OF THE CAMERA-OBSCURA TO HARBOUR DEFENCE.

For some time past the subject of defending harbours and rivers by means of submarine mines or torpedoes has received much attention in military circles. In this country a committee, entitled the "Floating Obstruction Committee," has been for some years past engaged in considering the best and most efficient method of employing explosive machines in warfare of this description, and in studying the most certain and readiest manner of planting and igniting the same. In Austria, also, during the late German war, the subject excited much interest, and, under the superintendence of Baron von Ebner, a distinguished officer of Engineers, the lagoons of Venice were strongly fortified with torpedoes, consisting of stout metal cases containing charges of from one to five hundred pounds of gun-cotton. Some of these machines were, we believe, automatic, or self-igniting, on their coming into contact with an enemy's vessel, but the majority were connected by means of insulated wires with the shore, whence they could be exploded at the will of an operator placed so as to command a view of the whole expanse of water.

During the past month experiments have been made by the Belgian Engineers at Antwerp, with a view to effect a perfect system of fortification on the Scheldt, by means of submarine explosive mines. The method adopted was very similar to that pursued at Venice, and appears to have given great satisfaction to the Belgian authorities. The mode of proceeding was as follows:—

At a convenient and sheltered spot near the expanse of water to be planted with torpedoes was constructed a camera-obscura of the ordinary description, the lens of which was so fitted as to be perfectly rigid and immovable, the picture being reflected upon a white convex surface sufficiently large to include a reproduction of the space to be defended. A vessel proceeds to lay the torpedoes in any line or position that may have been determined upon, and whenever the vessel stops to sink a charge, an operator, who is watching the ships' movements upon the table of the camera-obscura, proceeds to mark the exact spot upon the board, attaching to each mark a consecutive number. Insulated wires are led from each torpedo to the interior of the camera, and placed in the same order, or marked with the same numbers, as those upon the table, which refers to their respective whereabouts. By this means the operator

is enabled to watch the approach of an enemy's vessel over the apparently unobstructed water, and to explode any specific torpedo over which the unlucky ship may chance to pass.

This seems a very simple method of operating, and although it has never been tested in actual warfare, inasmuch as Venice was never attacked by sea during the late war, there is every prospect of the plan working efficiently. The Belgian Engineer officers were so delighted with the efficacy of the method that they have at once recommended the institution a further and more extended trial; the only weakness observed in the system was, that it is perfectly useless by night, a fault, however, which is inherent with every method of optical observation. At night, when the landscape is so dark that no picture is reflected upon the camera table, the observation of the surface of the water by means of a telescope would be equally without result; and it could only be when the torpedoes themselves were insulated and connected with a galvanometer on shore, so that the fact of any body touching the machine would be recorded by the completion of the circuit and a movement of the galvanometer, that the approach of any vessel could be made known. A combination of the camera-obscura and self-recording systems of torpedo defence would, we believe, constitute a perfectly trustworthy method of carrying on this description of warfare.

#### MODES OF LIGHTING THE SITTER.

BY JOHN BEATTIE.

Will you allow me space for a few remarks in addition to the quantity of sense and nonsense that has been written upon the almost all-important subject to a photographer, his best method of using light?

I give them not dogmatically, nor as food for discussion, but simply as my experience. I have made use of a due-south light for eleven years; my glass house was 30 feet by 12 feet, and fifteen degrees from due south and north; side walls 11 feet high, a very sharp angle "A" roof, 8 feet of glass in the roof, and perpendicular towards the east; the sitter was placed at the north end. The windows were fitted carefully with valves, coloured pure white on one side and black upon the other; and the *whole* of the inside of the building painted a dead-slate black. On the right side of the sitter I had a canvas, neatly stretched upon a frame, and painted pure white; upon this worked a black curtain, and by this means I got my inner half-shades. The time of my sittings was from two to eight seconds. Such was my plan of working a south light, which, if got free from reflected impure light coming from immediate surroundings, I would prefer to any other for use in this country.

What so many overlook is, the fact that every object in the glass room is throwing back its colour in the face of the sitter, and that is done with an intensity in proportion to the amount of diffuse light in the room; and to the same proportion lengthening the sitting and flattening the picture produced.

I will give two instances out of many I could quote. When travelling this last summer, I called upon one who was much troubled with weak pictures with dirty shadows; he had tried all collodions and developers ever used or thought of. His light was well placed, but far too much of it. The inside of his glass house was light grey. His sittings were twenty-five seconds. He closed out six feet of glass, painted all the surfaces black, got his reflector for half-tone; his sittings were reduced to five seconds, with finely-marked pictures as the result. Another had a very large room, with enough of glass in it for a crystal palace—immense surfaces of glass in front of his sitter; he was large in his knowledge, and pugnacious when reasoned with; but I observed he sat, with a good lens and moderate light, forty seconds.

Now what is really wanted? A pure light, unaffected by reflections from houses or any other surfaces, passing through

as small a space as may be deemed judicious, well directed upon the sitter. There must be no influence, either above or around, to the least oppress the countenance or render the pupil of the eye small; all must give a sense of comfort.

With above conditions, and a keen sense of beauty and grace on the part of the artist, fine results will follow; amongst those results (presupposing moral conditions present) will be plenty of employment at remunerative prices.

Lastly, I believe if artists would look for genteel situations, though private, where fine light could be obtained, instead of public places, with too often bad light as the result (after all, it is the work that is got out into society that makes the success, and not the samples placed at the entrance), they would be more sure of gaining a position.

13, Buckingham Gate, Clifton, October 19th, 1868.

## PHOTOGRAPHIC PRINTING IN SILVER, THEORETICAL AND PRACTICAL.

BY W. T. ROVEY.

### CONCLUDING REMARKS ON TONING, ETC.

A short time since a correspondent, writing to the Editor of the News, was especially severe in his remarks on account of my having recommended the use of a minute quantity of free nitrate in the toning bath. I trust that ere this the gentleman alluded to has studied my comments on toning matters with sufficient attention to glean therefrom the fact that, however he might conceive it necessary to eradicate every particle of free nitrate from prints intended to be toned by the methods advised by his accepted authorities, the adoption of my formula renders it imperative that the prints undergo a brief wash only, prior to their entering the toning solution, for the following reason, the quantity of chlorine is so limited that it is too feeble to attack silver reduced by light; and were it not for the more readily reduced free nitrate, toning would proceed very slowly indeed, and, not unfrequently, the bath would be entirely inert. The conditions differ when the carbonate of soda bath is employed, for except the carbonate of soda has been added in excessive quantity, the chlorine freely attacks and reduces the silver of which the print is composed, and toning action is set up and continues until the requisite amount of free chlorine is exhausted. That free nitrate of silver is capable of setting up toning action was amply proved under circumstances I now proceed to describe.

A sample of paper was sent me by a friend who was desirous that I should try my hand on an unusually obstinate article. The surface of the paper was horny and extremely brilliant, as if the coating consisted of the thickest of albumen, and the drying effected at a high temperature. On floating the sheets on the silver bath the albumen proved impervious to the action of the fluid, for when lifted off the bath the liquid collected in globules on the surface of the paper; and printing under such adverse conditions was, of course, an impossibility. To remedy the evil I reduced the strength of the silver bath, and thus conquered difficulty number one. But why reduce the density and strength of the bath? Simply because I deemed it requisite to allow the water to remain for use a portion of its solvent powers, which acted on the albumen, and so gave admission to a uniform supply of silver. The printing on the sheets thus sensitized proceeded satisfactorily, and all went well until the prints were immersed in the toning solution, when I found myself once more at fault, for toning action there was none. This set me once more cogitating, and, on reviewing the conduct of the prints in the washing water, it occurred to me that the water extracted only a very minute quantity of free silver. Reason why: the comparatively impervious condition of the albumen caused the film of silver to be of an extremely superficial kind, and as the chlorides had failed to unite with silver throughout the whole thickness of the albumen, the pictures were formed on the outer surface only, and no interstices were present in which free silver could

obtain a seat. I might have found an effective remedy by further diluting the silver bath, but I did not wish to lose the prints that were in the toning solution; besides, as the pictures were remarkably delicate and brilliant, I was desirous of retaining those good qualities; so, to effect my object, I added a few drops of a weak silver solution to the toning bath, when, to my gratification, I found my anticipations realized, and the prints passed through the ordeal triumphantly. Had I been using the ordinary gold bath, as generally adopted, toning action would have proceeded immediately the prints were exposed to its influence, the reduced silver surface would have been attacked, and that attack would have resulted in a ruined batch of prints—a rich yield of the vilest form of mealiness, as the slightest reduction of the prints must have destroyed all their claims to the beautiful. The gold bath, which was prepared by the simple formula I have provided, could not act on the reduced silver, and as long as the feeble chlorine found nothing it could act upon, toning action was in abeyance; but directly the free silver was provided, the chlorine found work suiting its capabilities, and all ended satisfactorily. I subsequently used up a ream of the same kind of paper, and suffered no further difficulty. But it strikes me that I have said enough about toning baths, and may now dismiss the subject by removing the prints from the toning fluid to another dish that contains the washing water.

(To be continued.)

## PRINT-WASHING AIDED BY OSMOTIC ACTION.

BY W. J. LAND.\*

THE perfect removal of hyposulphites from photographic prints in the shortest space of time possible is a desideratum worthy of study by every lover of photography. Having made a few experiments to test the value of osmotic action as an aid in washing prints, and believing that hyposulphite can be removed in a shorter time by this method than any other known—excepting, probably, the treatment with peroxide of hydrogen or chlorine, both of which agents are apt to injure the finer half-tones—I offer the following, hoping that it may be of interest to the practical photographer.

When a print is removed from its hypo fixing bath, and thrown into a vessel of warm water, a strong osmotic action takes place, the albumen film acting as an excellent *septum* to the thousands of hypo-vesicles just beneath. At a temperature of 130° Fahrenheit the paper rapidly gives up its hyposulphite, and this strange action soon becomes much weakened, and unable to give up the remnant of the pernicious salt, unless agitation or other mechanical means is brought to its assistance. If, however, after a few minutes, the print, which has now lost the greater portion of its hypo, be transferred to a ten per cent. solution of (tribasic) phosphate of soda, a stronger and more rapid osmosis is again set up, and much of the remaining hyposulphite is soon diffused in the solution of phosphate of soda. If, further, at the end of eight minutes, the print is transferred from this solution to a new portion of warm water, the (reverse) action is continued, and, by a dozen such alternations (using fresh portions of the liquids at each transfer), the print may be freed from its destructive enemy within one hundred minutes, if the temperature of the liquids is kept up as high as 140° Fahrenheit, and eight minutes be allowed for action in each liquid. Lastly, the apparently harmless phosphate may be sufficiently removed by short treatment with successive portions of hot water.

The apparatus which I use for the convenient working of the process consists of a couple of two-gallon tin cans, with faucets soldered near the bottoms; these may be placed on an iron stand, and the temperature of the solution and water maintained at 140° by a Bunsen burner, which may be shifted from one vessel to the other as occasion requires. The deep porcelain trays in the market

\* Philadelphia Photographer.

serve admirably as washing vessels in small operations. The cheapness of ordinary phosphate of soda makes the process an economical one: moreover, the quantity of solution required is just sufficient to cover the prints well, and allow of gentle agitation, that they may be kept separated, to allow of uniform action. Phosphate of soda was adopted on account of its great osmotic power. Chloride of sodium was tried, but found too weak and slow in its action. It is well known that all septa, allowing rapid osmosis, are more or less injured by chemical action; but in this case the albumen suffers so slightly as to withstand all but microscopical scrutiny. This process, if not practised as here described, can be used as a subsequent treatment (making but two or three alternations), thus economizing to a greater extent.

## ON THE RELATION BETWEEN INTENSITY AND TONE.

BY NELSON K. CHERRILL.\*

LET us now turn from out of doors to the studio. Let us suppose a child to be taken: very fair, very light hair, light blue eyes, white dress, and (if any) light blue ribbon round the neck. This seems to me very like our first view of the sea, all white—no intensity, no tone, no contrast. Does it matter how much you intensify the negative? I think not; an intense negative will print more slowly, and, perhaps, give a better colour in the print, but a very weak one will give all the tone there is in the picture. Now let us imagine a change: the child has grown, her hair has darkened, they have given her brown ribbon for her neck, and she now wears a coloured dress. Is it now a matter of indifference as to the intensity of the negative? I think not. There is more tone in the picture, there is more intensity of contrast in nature, and, therefore, more need of hitting the relative tone of various parts in the picture when finished. But let us take a third case. The girl has grown to woman's estate; she comes decked in gorgeous apparel; she wears black velvet for her dress, and pearls for her head-dress; her eyes are dark and lustrous, and her complexion fair and delicate. Now is it any matter of indifference as to the intensity of the negative? *Certainly not.* We are certain that the blacks of black velvet are black, and that the high lights of a fair face are white, and that the spots of light upon a tiara of pearls are bright, like stars, and, therefore, any negative which will give less than the whole range of tone from white to black will not do justice to our sitter. This, I believe, and this alone, to be the great secret of M. Adam-Salomon's brilliant effects of lighting: that he gets subjects which will give a full range of tone from white to black, and he so manages the intensity of his negatives that his prints give the nearest approach possible to the scale of gradation in nature.

From what I have now advanced, it will be thought that the greater the range of tone in the picture required, so much the greater intensity is needed in the negative; and this is to a certain extent true, but not altogether. The greatest or deepest black we can represent in a negative is absolutely clear glass; we cannot go farther than this; we cannot have less than nothing for the darks of our picture; but the quality of black which clear glass in the negative will give in the print is dependent upon the intensity of the lights, and so clear glass in the darkest part must, to give its full value, be supported by enough intensity in the high light to give pure white. But, at the same time, it is quite useless to have more than enough intensity in the lights, because the black can only be black, and if we have too much intensity in the lights we shall lose some of the darker tints, as they will be all buried in black together. So, then, while I partly agree with those who say that a negative should be quite opaque in its highest lights, I am not prepared to admit the absolute truth of the proposition. The proper intensity for the very highest light of all in the picture is

just that which will screen the paper under it from the action of the light till the blackest black is printed as deep as the process will admit; less intense it should not be, as then either the blacks must suffer in not being deep enough, or else the lights will be too much printed; more intense it must not be, as then either some colours not quite black will be lost, or else the lights will be too white. Perfect tone, or harmony of tone, it will thus be seen, depends more upon the intensity of a negative being exactly right than on anything else. The intensity of the negative is much dependent upon the form of the studio in which it is taken; an ill-constructed studio will give either too much contrast of light and shade, or too little; but whichever it gives, if, by dodging the development, you can get the intensity right, the pictures will be right in tone and gradation. The difficulty is, as I say, to get the intensity right when the studio is badly constructed. If, for instance, there be too much side light, the difficulty is not so much to get detail on the shade side of the face, as to avoid getting too much intensity on the side nearest to the light, and thus the pictures produced will have a harsh, black-and-white tone, instead of the beautiful gradation seen in nature.

I have hitherto been speaking only of particular instances of this relation between tone and intensity; but before concluding the present paper I wish to make one or two more general considerations. I think that if what I have advanced about the three stages of the portrait we had under consideration just now is true, we may make the following general propositions:—That the greater the number of gradations in a picture, the greater the need to pay especial attention to the exact intensity of the negative. And this leads me to a consideration of the greatest moment. What is to be considered a normal intensity for the high light of a picture? At present I am afraid I must say I do not know. It is a fact, and one much to be regretted, that paper (albuminized paper) is so various in its quality that the greatest uncertainty prevails as to what the intensity should be to give a certain result. It would conduce greatly to aid the photographer in the production of perfect work if the makers of albuminized paper would agree among themselves as to some standard by which, and up to which, they would work. At present no two papers in the market are alike: one gives, as the maker will say, "fine rich, warm tones," and another, tones with two or three other adjectives, varying according to the idiosyncrasy of the maker, or, possibly, with the probable credulity of the buyer.

In doing small portraits, such as cartes-de-visite, the exact range of tone is of much less consequence than in larger sizes; hence the greater technical difficulty in the larger pictures. It is by no means difficult to get a paper that will give good proofs from carte-de-visite negatives, but it is a very difficult thing to find one that will print a 10 by 8 portrait à la Salomon; and when you have found the paper, the negatives must be made of just the right intensity to suit that paper. Until paper makers will make us a uniform article, I am afraid we have no choice but to vary our negatives to suit the paper. For those who would succeed with portraits in the style of M. Adam-Salomon, it is imperatively necessary to get a paper which will give very considerable depth of tone in the blacks. One of the greatest faults with paper now-a-days is, that it is suited to such thin, weak negatives; it will not bear any depth in the shadows without bronzing all over.

I have all along been speaking of negatives in which the gradation of colour begins with clear glass, because any fog on the shadows is to my mind most detrimental to good work; indeed, I do not think any amount of intensity in the high lights can compensate for want of clear glass in the extreme blacks. Fog in the shadows was quite an understood thing in the days of waxed paper negatives, when the shadows were veiled with the substance of the paper, but now that good collodion can be bought at any photographic shop, and that all photographers know how to manage the baths and other chemicals, fog ought to be

\* Continued from p. 499.

quite an unknown evil. The great reason why I so much object to fog on the negative is, that not only it involves an enormous expenditure of time in printing, but the result is by no means so fine when obtained. A perfect negative will, with good paper, give grey high lights and rich warm blacks in the same picture, but if there be any fog on the shadow, just in proportion to its amount will be the lack of that beautiful and peculiar property. The reason of this greyness of a picture in the light, when made under favourable circumstances, I take to be twofold: firstly, some peculiar substance used in the preparation of the paper, which gives the result in M. Adam-Salomon's works in a slightly more marked degree than I have seen it elsewhere; and, secondly, the well-known tendency of the print to tone greyer when the light is feeble than when it is strong, the light which reaches the print through the high lights of a picture being much more feeble than that which passes through the shadows unimpeded.

I cannot conclude this paper without adverting for a moment to that grand field of labour and enquiry which has recently formed part of a series of papers by Mr. H. P. Robinson, in the *PHOTOGRAPHIC NEWS*; I refer to the chiaroscuro of photography. It is in the study of this most interesting of topics that the true and grand relations of light to shade, and of tone to intensity, develop themselves. It is only when photography is studied as an art that these relations can be seen and appreciated, and it is only then that they can be really useful in guiding the everyday practice of photographers. I have endeavoured to treat the subject without any reference to these papers, and to consider it in a more mechanical light, from a feeling that such was first needed before the high branch of chiaroscuro came under consideration; but for those who wish to carry the subject further than I have been able in my present imperfect attempt, I would certainly suggest a careful perusal of Mr. Robinson's papers on the subject. For those who would succeed with portraits in M. Adam-Salomon's style, I would suggest particular attention to the intensity of the negative, as being mechanically one of the most important means to secure the full range of tone to be found in his pictures. And to all who would succeed more than they have done hitherto, I would suggest still more attention to the intensity of the negative, as a good negative will not only save time and material in printing, but will also render it easier to satisfy that most discerning of critics—the public.

## TO SWING, TO TILT, OR TO LEVEL?

THAT IS THE QUESTION.

BY PROF. JOHN TOWLER, M.D.\*

AN important question, forsooth, when it has reference to the camera, and one that is worthy of discussion.

Some cameras are supplied with what are termed swing-backs. The swing-back derives its name from the swinging of the plate-holder and the ground glass upon a horizontal axis, which allows either the top or bottom of the same to approach to or recede from the front of the camera. In addition to this motion, some plate-holders and ground glasses have a swinging motion upon a vertical axis, which allows the sides to approach to or recede from the front of the camera supporting the lens.

To tilt and to level the camera need no explanation.

It is our purpose to examine the theory and practice of the swing and the tilt, and then to march a step or two on level ground. We cannot well dispense with a figure to illustrate this important subject, and we select the square tower or steeple of a church for the object to be photographed. Let A B represent this steeple, L the lens, and *a b* the ground glass, which, in the first instance, is parallel with the steeple. It is evident that the distance A L is greater than the dis-

tance B L. Now, we know from the relative bearing of *m* and *n* in the equation for conjugate foci—

$$\left(\frac{1}{f} = \frac{1}{m} + \frac{1}{n}\right)$$

that, as *m* increases, *n* decreases, and *vice versa*; therefore,

if B L increases and becomes A L, L *b* must decrease until it becomes L *a*. From this we learn that if *b a* is to be an accurate picture on the ground glass of A B, L *a* must be less than L *b*; but in the figure the reverse is the case; consequently, *a b* cannot be an accurate picture of the object. Now, in order that *a b* may be an accurate picture of the steeple, the two triangles must be similar—that is, the triangle A L B and *a l b*—and, since conjugate distances are inversely as real distances, the long sides must be both either above or below; that is, in the example, the sides A L and L *b* respectively must be greater than B L and L *a*. This being the case, the angle at *b* must be equal to the angle at A, and the angle at *a* equal to the angle at B. In the figure this is not the case, and in order to make these angles in accordance with the enunciation, the line L *b* must be made longer than L *a*. Let L *c* be this line, and the angle *c* equal to the angle A, then *c a* will be the picture of A B. In order, therefore, to make these two triangles equal, the ground glass *b a* must swing back upon the point *a* as a centre, until it gain the position *c a*. This is the theory of the case. Now for the practice.

Fix the camera level or horizontal upon its tripod, at a proper distance from the steeple, and focus the top of the steeple quite sharp at the bottom of the ground glass. You will find the bottom of the steeple far from being sharp on the ground glass, but by drawing back the top of the ground glass from its parallelism with the front of the camera, towards *c*, the picture of this point will come more and more into focus until you arrive at *c*. Practice and theory, therefore, coincide, as they always must; otherwise, the theory is false. Now, although the top and bottom are in focus, this is no reason why the whole length of the steeple should be in focus; this would be the case if the point B, on the line A B, were the nearest point to the lens; D is a point as high from the ground as the lens, and is, consequently, the shortest distance from the steeple to the lens; and, since D L is less than B L, the picture or focus of D must be further off from L than L *c*; and the picture of all the parts of the steeple from B to E (E D is twice the distance E B) will be found behind the ground glass *c a*, whilst the distance E A will be represented on the ground glass. If, therefore, you focus upon the top of the steeple, and swing the ground glass back until the bottom is in focus, the part E B will be slightly out of focus; whereas, if the back be swung until D is in focus, then the part A D will be sharp, and D B alone will be out of focus.

There is, consequently, an apparent advantage in the swing-back. Now the same result can be obtained by tilting the camera on a horizontal axis supposed to pass through the lens, until the ground-glass in this case is parallel with the position of the ground-glass when in the previous case swung back, and then, by focussing the point D of the steeple, the top of the steeple and all the intermediate parts from D to A will also be in focus.

To tilt the camera and to swing the back, therefore, produce equivalent results as regards sharpness of focus, but there is a slight difference between these results in favour

of the swing-back, for, in tilting the camera, you will observe, in practice, that the ground-glass, through its whole extent, has to be drawn back a distance equal to the distance at the top which was swung. This causes the conjugate focal length to be slightly greater when the camera is tilted than when the camera is kept level and the ground-glass is swung back; and this little difference produces a disadvantage for the tilting.

When the camera is horizontal, the picture is not accurately in focus, but an approximation to sharpness may be obtained by what is called equalization of focus; that is, by focussing more upon the middle or above the middle parts of the steeple, when both the top and bottom will be nearly in focus.

Now let us examine the results of sharp focussing in the two cases of swinging and tilting.

In optics it is a well-known fact that the size of the picture of an object varies inversely as its distances from a lens; that is, the greater the distance of the object from the lens, the less the picture. Let this principle be examined in reference to the space on the steeple situated between two parallel lines; since the top of the steeple is more remote from the lens than the point D, the picture of this top space will be narrower than that of the space at D; that is, the parallel lines must converge towards the top. Hence, in both cases (of tilting and swinging) all parallel lines of objects higher than the lens converge upwards; and, if the objects are lower than the lens, downwards. But the convergence is slightly greater by tilting than by swinging the back, owing to the slight difference in the absolute conjugate focal length in the former above alluded to. The consequence of this convergence is that the steeple will appear to be the frustum of a pyramid; and if you focus on the point D, the parallel lines of the steeple will converge in the picture from *d* to *c*, and from *d* to *a* in both directions, up and down. This will cause the lines of the picture to be barrel-shaped, or, still better, like the sides of a lamp-chimney. This conversion of parallel lines into convergent lines can be avoided, to a great extent, by levelling the camera, both in the gallery and in the field, and by equalizing the focus.

You now know the facts of the three cases; draw your own conclusions, and work accordingly. In this exposition there is no condemnation; I sometimes avail myself of each case, but I prefer the horizontal when it is feasible.

## Correspondence.

### CLEANING OLD PLATES.

SIR,—Many suggestions have appeared in that part of the PHOTOGRAPHIC NEWS devoted to correspondence, respecting the cleaning of plates, and in removing the varnish and collodion film from all negatives. I have read carefully all that has been said at various times by your contributors on this subject, and have tried many experiments tending to solve this difficulty. If the method I adopt and here explain is not a complete solution, it is, at all events, superior to any that has hitherto crossed my observation, for its simplicity, inexpensiveness, and effect.

I use Gray's solution—or, what is commonly called by painters, liquid wash—adding clean water in equal proportion. Let the plates remain immersed in this for twenty-four hours or more. In taking the plates out, be careful to use a flat stick, or the finger-nails will be marked as though nitre of silver had been used. Have clean water at hand, or flow from a tap, to clear the plates from all superfluous wash; be prepared with a pad of cotton or wool to rub both sides of the plate, particularly the edges; half-a-dozen changes of clean water, slightly rubbing each time, will complete the process. Plates that have been considered useless through the presence of paint, varnish, grease, &c., I have thoroughly restored by the above simple method. I would also add that the liquid wash alone will remove varnish films in three or four hours.

During two days of the past week I have cleaned upwards of two hundred plates, varying in size from quarter-plates to 10 by 8's, in order to thoroughly test this process, which I now present to your readers.

P.S.—Many thanks to Mr. Bovey for his valuable recommendation of "sugar in the printing bath for the preservation of sensitive paper." Enclosed are four specimens of the paper, a week and a fortnight old. No. 1 was in the bath forty-eight hours; 2, 3, and 4 were upwards of twenty-four hours each. To Mr. Nelson K. Cherrill I am also indebted for his information on fixing and toning at once. The specimens enclosed are sent as evidence of the complete success of the above-named gentleman's communication. Remarks as to tone and the white will oblige,—Yours obediently, S. GARSIDE.

Church Street, Ambleside.

[The prints enclosed are excellent.—Ed.]

### AMOUNT OF SALT USED IN ALBUMINIZING PAPER.

SIR,—At the North London Association I made a suggestion which, with your permission, I will give in the words as delivered, viz.: "I do not think that any manufacturer of albuminized paper—when asked—ever objects to give an approximate idea as to the amount of salt in his paper; but when photographers are so very anxious to ascertain the amount of salt in the paper, they can soak the albumen and salt from a quarter sheet, and precipitate with a standard solution of nitrate of silver." By a standard solution I mean (in speaking to a photographic public) any known strength—say the floating strengths of 40, 50, 60, 70, or 80 grains per ounce, as the case may be. Then, with a minim measure, how easy it will be to find the number of grains of nitrate it will take to satisfy a sheet, and so calculate the quantity required for the daily consumption, where proper instruments are not employed for the purpose!

This I take to be the aim of the few who now and then bring up the subject. If they desire further information, pray let me suggest that they commence at the first of their processes, and ask the collodion manufacturers the particular amounts of iodides, bromides, &c., with their respective bases, and particularly the preparation of the cotton and solvents. Possibly this would aid those who produce indifferent negatives about as much as the salting of the paper would those who get but indifferent prints, while others, using the same materials, produce the finest results without any trouble.

In the report of the meeting in your last I am made to suggest testing the paper with a standard solution of chloride of sodium. This is clearly a slip of the pen, but ought to be corrected. Had I accidentally made such a *lapsus lingue*, it would, doubtless, have been at once corrected in the meeting. Yours, &c., F. W. HART.

8, Kingsland Green.

[The misprint is better corrected, although no one would dream of attempting to precipitate common salt with common salt. We have a few words on the general subject in another column.—Ed.]

SIR,—I notice that at the last North London meeting Mr. Hart recommended photographers who were anxious to know the proportion of salt in albuminized paper to dissolve the salt and albumen off a quarter of a sheet, and precipitate it with a standard solution of nitrate of silver, I presume, although chloride of sodium, evidently by some error, appears in the report.

I wish to ask Mr. Hart how many photographers he thinks are prepared with apparatus for such an operation? How many could conduct it with sufficient delicacy and care to be of any service? And, finally, if it is not a little unfair to ask two photographers to take this trouble to ascertain a fact which the albuminizer should be able and willing to give him without any trouble at all? I cannot understand why it is that albuminizers seem to place themselves in antagonism to photographers on this point. The request that manufacturers should give some idea of the proportion of salt their paper contains has often been made, but has never brought any systematic compliance with the request. It has, on the other hand, so often evoked a querulous protest against the necessity, that one is tempted to believe some occult reason exists for the habitua

suppression of information about which there should not be a moment's dispute. Is it true that salt is used by the hand, rather than by the ounce? I have heard such wild statements made, but have not hitherto believed them.—Yours sincerely,  
X.

### DISTORTIONS AND PERSPECTIVE.

DEAR SIR,—Your correspondent, "John Anthony, M.D.," in his letter on the above subject in your issue of last week but one, falls into error.

He says:—"If you stand at a distance of twelve feet in front of a mirror, you see yourself as a spectator would see you who was twenty-four feet from you, or just as much behind the mirror as you are in front of it; if now you stretch your hand horizontally towards the mirror (call it three feet in advance of you), your hand will look to you enlarged; and well it may do so, for though it ought to appear as it would to a spectator at a distance of twenty-one feet, it will really look to you as if you had pushed it forward a distance of six feet; in fact, as if it was seen with the perspective enlargement of an object which was eighteen feet off the supposed spectator."

This is a mistake; it would look as it ought to do; viz., as if it were twenty-one feet from your eye, because your eye is situated, not at the tip of your finger, but in your head, which is three feet behind said tip, and therefore eighteen *plus* three feet from reflected image of hand.—Yours truly,

D. WINSTANLY.

### Talk in the Studio.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.—Our readers should not forget that the winter session of the Photographic Society will open with an exhibition, as it did last year, to which all photographers, members and non-members, are invited to contribute. It will, as before, be held in the Architectural Gallery, 9, Conduit Street, opening on the evening of the 10th of next month. Members, their friends, and exhibitors will be invited to a social reunion, similar to that held last year, which proved so pleasant. The exhibition will remain open for a week. We shall have something more to say on the subject in our next.

POLYTECHNIC EXHIBITION.—Amongst several very attractive novelties recently introduced at the Polytechnic Institution in Regent Street, is an interesting and capitally illustrated lecture by Professor Pepper, on the late total eclipse of the sun, to which we especially commend the attention of our readers. An old German story is made the vehicle for introducing some of the startling optical effects which have during the past two or three years made the Polytechnic famous. A musical and scenic history of the Maid of Orleans gives occasion for the introduction of some of the finest lantern effects we have seen, both from photographic and painted slides. The other attractions—all excellent—are more numerous and varied than we can describe here.

CARBOLIC ACID IN THE BATH.—A correspondent says:—"I have tried carbolie acid added to the negative bath as recommended, and find it admirable in its effect, fully answering the purposes of additional rapidity and cleanness. I use, however, more than a trace; in fact, about the same proportion, or more, as I should nitric acid—i.e., about one drop to ten ounces of bath."

PHOTOGRAPHIC ART STUDIES.—Our contributor, "Respieo Finem," recently lamented the small appreciation and limited sale of such art studies as those of Mr. Reilander. We were glad to learn from that gentleman, in a recent conversation, that the sale of his various published pictorial photographs has recently become very brisk; so much so that he had difficulty in keeping up the supply. Our readers will share in our pleasure on learning such a fact. We hope, for their own sakes, that a large proportion of such pictures are bought by photographers.

PHOTOGRAPHY.—We have received from Mr. Fruwirth some specimens of his method of photography which admirably illustrate its capacity for some forms of art reproduction. An enlarged copy of an engraving entitled the "Two Grand-

mothers" is very excellent. The original is a print 9 inches by 8 inches; the phototype is about 13 inches by 10½ inches; and the rendering is clean, delicate, and perfect in a high degree.

PHOTO-LITHOGRAPHY.—We have received from our excellent confrère, Herr Schrank, editor of the Austrian photographic journal, the *Correspondenz*, a very fine and enlarged example of photo-lithography, from which we glean that they have advanced further in Vienna in rendering half-tone perfectly by photo-lithography than we have done in this country. The subject is a reproduction from a painting entitled "Die Lustigen Weiber von Windsor" ("The Merry Wives of Windsor"), rendering the scene in which Sir John Falstaff is being packed into the buck basket. The photo-lithograph is in size 16 by 12, and is well rendered in every gradation by an exceedingly fine grain, which gives the effect of half-tone perfectly. The names of the photo-lithographers appended are Reiffenstein and Rösch.

### To Correspondents.

NORTHERN LIGHT sends us the following:—"Keeping and Dating Brown-iodized Collodion.—Statement for opinion of Editor of the PHOTOGRAPHIC NEWS.—Seeing your two articles on the above subject in the News of June 28 and October 11, last year I at once set to work to try my hand at the collodion iodized as therein set forth, and proceeded as follows:—No. 1. Having some of Keene's plain collodion in stock, I made up the iodizer for 15 ounces:—

Iodide of cadmium	...	...	...	100 grains
Bromide of cadmium	...	...	...	30 "

Dissolved in 5 ounces alcohol, sp. gr. 820, and added to the 15 ounces plain collodion—12th December, 1867. No. 2. To 15 ounces of Rouch's plain collodion I iodized with—

Iodide of cadmium	...	...	...	90 grains
Bromide of cadmium	...	...	...	30 "

Dissolved in 5 ounces alcohol, supplied by Rouch, and added to the plain collodion—25th December, 1867. I kept the lot in a dark and cool pantry, and tried both No. 1 and No. 2 last June, and found foggy negatives, but, otherwise, indications of good negatives; rather dense in the face, hands, and light drapery. Tried both No. 1 and No. 2 last week, and found again foggy negatives. Consulted Hardwich's Photo. Chemistry, and then added alcoholic tincture of iodine to the samples No. 1 and No. 2, and then found clear, clear negatives, but very much thinner and more like glass positives. The collodions, before the adding of tincture of iodine, were both colourless, and after the addition, straw colour. I expect that keeping the collodions for other six months or so might remove the tendency to fog; but as I want a bottle or so for immediate use, I beg to ask you whether you can oblige me with any other mode of treatment than adding the tincture of iodine, which seems to reduce the density of the negative rather too much. I can see from the indication beneath the fog that time will give me a most excellent collodion, only I fear it will be perhaps too dense in the whites and rather inclined to solarise. I am therefore anxious to know whether this tendency would be removed if I was yet to add some more bromide of cadmium, or what other treatment will help it." [There are various modes of dealing with the collodions described. In the first place, the tendency to fog might have been removed and the vigour retained by adding a smaller proportion of tincture of iodine; or, without altering the collodion, the tendency to fog might have been removed by adding a slight trace of acid to the bath; or, without altering either collodion or bath, the tendency might have been removed by adding a little more acid or a trace of gelatine to the developer. The tendency to excess of density in the lights would be best removed by giving a little fuller exposure, and avoiding prolongation of the development. It is probable that a slight modification of the developer and of the manipulation in development would prove the most desirable remedy. It is probable that a little longer keeping will make the collodions perfect.] "Best Means to reflect Light for the Opaque Side of Interior of Studio.—I find great difficulty in getting the shadows on my sitters softened to suit general taste and wish to know whether any other article than a white calico screen has been tried with success. I have heard of screens covered with tinfoil: have such been found good? I may say that it is quite possible. My side-light—northern aspect—does not extend far enough from the sitter, and so the light will come in a sharper angle, and so have the greater tendency to make deep shadows on the face. My total length of side-light is twelve feet, the windows coming close up to background. I have then about three feet of this screened off, just beside the side of the sitter, and leaving about eighteen inches of clear glass next the background, to give the effect of light streaming in at open window side slip,

so that by this arrangement I have only about six or seven feet in length of side-light in advance of the sitter at north side. The south side is quite opaque, but I have a top window in advance of sitter on south side, to try to soften shadows by that plan, and this I can do by leaving it completely uncovered when I have no sun; only being obliged to screen off completely in sunny days. I get the heavy shadows again." [Some operators have found screens covered with tinfoil answer well for reflecting purposes. It is probable that if our correspondent works cross-corner-wise of his room, turning his sitter so that he slightly faces the light, he will get rid of heavy shadows. See diagram recently given in Mr. Robinson's article on Pictorial Effect. If the top-light answer the purpose when there is no sun, it will also answer when the sun shines if the light pass through a thin blind of tracing-cloth or tracing-paper.]

**GEO. SIMMONS.**—The printing in the card sent is not at all bad. Possibly a very slight degree deeper printed and warmer toning would please our taste more. 2. You cannot do better than follow the instructions for printing given by Mr. Bovey in his recent articles, or as briefly given in his article in our last YEAR-BOOK. 3. Gas-light will not injure sensitive paper, unless it be very unnecessarily prolonged in exposure to such light. 4. Good paper for card pictures may be prepared with various chlorides. Chloride of ammonium, or a mixture of that and chloride of barium, will give very good results.

**LITHO.**—There is no difficulty in photo-lithography which may not, by an intelligent photographer, be overcome with care and perseverance. It will require much practice and a careful observation of instructions. The best instructions will be found in an article in our YEAR-BOOK for 1867 by Mr. Butter, a skilful practical photo-lithographer; and in a series of articles which have recently appeared in our pages (commencing June 12th), written by Lieut. Waterhouse, who has carefully worked out the processes he has described. Photo-lithography would be scarcely well suited for reductions so small as that you enclose; any lithographic process will scarcely do justice to such delicate lines.

**UNIQUE.**—Various formulae for toning and fixing in one bath have been published. A recent formula by Dr. Liesegang, which gives very fine results, stands as follows:—

Water ... ..	2 ounces
Sulphocyanide of ammonium ... ..	50 grains
Hyposulphite of soda ... ..	240 "
Acetate of soda ... ..	15 "
Chloride of gold ... ..	1 "

Mix all but the chloride of gold, and, after mixture, dissolve the gold in a little water, and add to the solution. Bear in mind, however, that prints toned and fixed at one operation are more doubtful in their permanency than those fixed at a separate operation. 2. It is impossible to state the proportion of permanganate of potash necessary to oxidize the organic matter in a silver solution because the quantity of organic matter is uncertain. You will find many details on the subject in our numbers for March last (6th, 13th, and 20th). A few drops of a 10-grain solution will generally be found sufficient. The solution will acquire a brown turbidity, which will finally precipitate, or may be filtered out. This precipitate consists of the organic matter and oxide of manganese.

**AN AMATEUR.**—The chief difficulty in rendering the paper perfectly transparent consists in its inequality of texture and in the difficulty of perfectly removing the sizing material employed. There are various modes of manufacturing tracing paper, each manufacturer employing his own method. Canada balsam dissolved in turpentine, with sometimes the admixture of poppy oil, almond oil, &c., are materials commonly used. Try almond oil alone. Remove the size from the paper with hot water; then soak it in the oil for some hours; drain, and hang up to dry.

**C. A. M. W.**—After the golden syrup solution has been applied, the plate is insensitive to light, or nearly so. It may be examined in dull light, but it will be safe not to expose it long, or to a brilliant light. The intensification may be conducted in a dull diffused light; but it is well to remember that as light aids the reduction of silver, too much of it may induce fog.

**THOMAS STOTHARD.**—The difficulty of dealing with blues and yellows in an illuminated window cannot be entirely overcome by photography. The only mode of dealing with the matter that we can suggest will be to manipulate both negative and print a little. Even with fully bromized collodion and full exposure, light through blue glass will act vigorously, and produce density in the negative, and light through orange glass will scarcely act at all, and will be rendered in the print by a dark, instead of a light luminous tint. 2. If we remember rightly, the use of sulphate of zinc in a developer was referred to in one of the letters of "Lux Graphicus." We will search, and, if necessary, repeat the formula. We are glad that you found carbolic acid in the bath useful.

**PHOTO DEALER.**—Have no fear; the new Sale of Poisons Act is not in operation; it does not come into force until the commencement of next year. The print from which you quote is wrong, as usual.

**IGNORAMUS.**—The winter session of the Photographic Society will open with an exhibition, as it did last year. It will be open to the contributions of all photographers. It will open on the 10th of November. Contributions should be sent to 9, Conduit Street, addressed to the Secretary of the Photographic Society, not later than November 9th.

**W. J. A. G.**—A red brick building, partly in shadow and partly in sunlight, is a trying subject for a wet plate, and still more so for a dry one, which, as a rule, is less sensitive to weak radiations than wet collodion. We can only advise you to give full exposure, and be patient in development. One of the greatest sources of failure with novices in dry plate work is impatience in development. Accustomed to the rapid development of wet plates, they are not prepared for the tardy appearance of detail in dry plates, and in attempting to force development they produce fog. We have had no failure with the Liverpool plates, and have usually given them from three to four times the exposure of wet plates upon a properly lighted landscape. Try again; follow instructions carefully, and work patiently.

**STRIKE-A-LIGHT.**—We tried the collodio-bromide process as described by Mr. Sayce soon after its introduction, with success. We used the preparation within a week after it was mixed. We cannot say from experience how long it will keep after mixing. Mr. Bolton, one of the originators of the process, is also a skilful worker of it, his results, which we have seen, being very excellent. As our own experience with the process is less than his, we fear that we cannot give you any better formula; but if you will state wherein your failure consists, we may be able to advise you. 2. There have been no especial results of the discovery at all, so far as we know.

**F.**—The writer who signs "Respiec Finem" is well known to the photographic world; but you must take his opinions on photography and art on their intrinsic merit. If he had made statements affecting the interests of individuals, it would have been necessary to substantiate them with his name: opinions on abstract questions may with propriety be stated anonymously. The writer in question is neither Mr. Robinson nor Mr. V. Blanchard. The "authority" you mention is, as usual, incorrect.

**NEW SUBSCRIBER.**—You do not state the intended dimensions of your studio, a somewhat necessary element in deciding as to the amount of glass. We will assume, however, that the size is about twenty-five feet long and twelve feet wide, and advise for such proportions; you can then modify as may be desirable. The proposed position of the studio is good. It will not be necessary to have any glass on the south side or roof. At the west end let about six feet of side and roof be opaque, and about ten or twelve feet side and roof be glazed, the side lights coming to within eighteen inches of the ground. Avoid having any windows in the east end. Let the walls, backgrounds, accessories, &c., be of a quiet grey tint.

**STEREO.**—You will see that we have alluded to the view you put of the Relief Fund in an article in the present number. We quite agree with you, that to attempt the thing and fail would be disastrous; and we quite agree that the initiatory steps must be taken by men of standing and credit, to afford the slightest chance of success. As to whether the profession is sufficiently numerous, or whether the time is ripe, are questions which require discussion. Let us have your views and arguments fully stated for publication, instead of in a letter for private perusal. The appeal for Mrs. Pearson did not appear in our literary columns because we are, as a rule, unwilling to trench upon the space belonging to our readers with any matter not properly relating to that department. It appeared gratuitously in the advertising columns because we had a better right to trench upon space the granting of which only involved a sacrifice on our own part. We saw the remark: a mean mind judges everything by its own standard.

"Pictorial Effect," "Noteworthy Studios," some Reviews, and other Articles in type, are again compelled to stand over until our next. Several Correspondents in our next.

### THE FORTHCOMING EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

As our readers are aware, the coming session of the London Photographic Society will be opened with an exhibition of photographs, to be held in the usual meeting room of the Society, at the Architectural Gallery, 9, Conduit Street, Regent Street. The exhibition will be opened on the evening of Tuesday, November 10th, at half-past seven o'clock, when members and their friends, and exhibitors, are invited to a similar social reunion to that which passed off so pleasantly last year.

The original intention in regard to last year's exhibition merely comprehended the idea of devoting the opening evening of the session to a display of photographs. The number and excellence of the contributions were, however, so great that it was resolved by the council to keep the exhibition open for a week. The success of last year has suggested a repetition of the experiment with a little more pre-arrangement. On this occasion the exhibition will be opened with a distinct understanding at the outset that it will continue open for a week, during which time it will remain open to the public gratuitously.

Photographers at large are invited to contribute, members of the Society and non-members alike, so as to bring together a fair and creditable representation of the present state of English photography. Members of the Society will doubtless feel themselves in some sort bound to aid by their contributions the success of such a display. But photographers at large have an interest in such an endeavour not less than the members of the Society. The value of exhibitions as furnishing at once landmarks of past progress and aids and incentives to renewed effort scarcely needs enforcing. To amateurs, few things afford more pleasure than the opportunity of examining the various developments of the art, and especially the results obtained by fellow-devotees to some special branch to which they themselves have given attention. To professional photographers, the opportunity of examining a collection of pictures fairly representing the characteristics and degrees of excellence attained by their professional compeers must be a matter of commercial value, as well as personal interest. And as a large section of the public interested in the progress of science and art will visit this exhibition, all concerned in the reputation of photography should aid, by contributing the best examples they can, to produce a worthy exhibition.

Where it is convenient to the photographer, it is of course advisable to send pictures in frames; but for the accommodation of those to whom the trouble and expense of framing a large number of pictures might prove an obstacle, unframed pictures will be received for exhibition; but it will be understood that the mounts in such cases will suffer a

little in the process of pinning to the wall and by exposure for a week without the protection of glass. Collections of prints in portfolios and albums will also form an agreeable addition to the contributions.

Apparatus of various kinds will be admitted to the exhibition, and we shall hope to see a good display of the most recent improvements in the mechanical and optical appliances of photography.

Contributions should be delivered at No. 9, Conduit Street, addressed to the Secretary of the Photographic Society, not later than Monday, November 9th. It is desirable that every frame or separate picture should have the name, and number of contributions, of the exhibitor at the back. On the front of each, the name of the exhibitor, the name of the subject, and the process employed, should be written for the benefit of visitors, because, in the absence of a catalogue, this will be the only mode in which information on the points indicated can be conveyed. Contributors should also send a list of their contributions, with the name of each subject forwarded for exhibition, addressed to the Secretary of the Photographic Society, at the Gallery in Conduit Street.

The meeting will, as on the last occasion, be of the character of a conversation, without the necessary formality of evening dress, the aim being to secure a social and agreeable reunion of all interested in the exhibition. All members, and all contributors who are not members, are invited to attend and to bring their friends with them, ladies being especially invited. No cards of invitation will be issued, the announcement in the last number of the Society's Journal, and the invitation, which we are authorized to repeat, being, it is believed, sufficient to bring together a large number of those interested in such a display of photographs as it is confidently hoped will be exhibited on this occasion.

We see no reason to doubt that the great success of last year will be repeated next month. We should be glad to see it surpassed; and we earnestly invite all our readers, who possibly can, to contribute themselves, and induce their friends to do so as well, so as to bring together such a display as will at once gratify all photographers with the illustrations of present excellence, and stimulate them to greater triumphs.

### ALCOHOL IN DEVELOPING AND INTENSIFYING SOLUTIONS.

An incidental remark in a communication by Mr. Russell Manners Gordon to our YEAR-BOOK of 1866 contained a suggestion the importance of which in practice cannot be over-rated. A recent allusion to this suggestion in one of our own articles has brought several enquiries which induce us to think that simple and self-evident as the idea is, it is

not as familiar to photographers generally as it ought to be, and that it is worth briefly re-stating.

The object of adding alcohol to the developing solution is, as every photographer knows, not to produce any chemical effect or to aid in developing, but to harmonize, as nearly as possible, the physical condition of the developing solution with that of the free nitrate of silver on the plate, so that the former may flow evenly over the film without forming greasy-looking lines, which arise when the two solutions are not in the same condition. The suggestion to which we have referred is simply to carry out the practice, employed with developers, to all the solutions employed in developing or intensifying, a thing which, obvious as it may appear, is by no means commonly done. Whatever quantity of alcohol is added to the ordinary developer should be also added to the intensifying solution, and to the silver solution kept for adding to the intensifying solution. We are here assuming that the intensifying is effected, as it now most commonly is, by means of an iron solution. It will be seen in such case that the application of the developer can be followed by the application of the iron intensifier, or that of the silver solution, without either washing between each application, or running any risk of the production of stains from the repulsion or imperfect mixture of solutions containing different proportions of alcohol. The convenience in operating which arises from being able to apply one solution after another without washing and without risk will be readily appreciated by practical operators who have not hitherto tried such a simple aid to clean and convenient working.

#### NEW METHOD OF MASKING PRINTS.

SOME correspondence which has reached us, on the subject of the method of masking prints employed by Mr. Fry, which we described in our last, suggests that we had not made the precise purpose and scope of the operation so clear as we intended; and it is pointed out that unless used with judgment, the employment of a transparent positive as a mask might be made to produce, instead of improvement, a negation of all gradation and modelling.

This is perfectly true: but we meant it to be used in the right way and with judgment, although it seems we did not point out the limitations of its use with sufficient detail and iteration. Let us glance, therefore, at the matter a little further. One of our correspondents points out, very truly, that the thinnest or most transparent part of the mask proposed will be the points of highest light, and that the lights in a print exposed under such a mask will be the first portions upon which light will act, and that degraded lights instead of increased detail will be the result. As there is something ingeniously erroneous in the argument of "R. F.," it may be worth while, before correcting him, to make his position quite clear by an illustration. He states that the first effect upon a print of using a transparent positive as a mask will be a degradation of the high lights, and then the gradual impress of gradation, but that the gradation will be in the wrong direction, darker towards the lights, and lighter towards the shadows. Thus, if we print an image of a sphere from a negative, assuming it to have been produced in an ordinary glass room, we shall have a spot of light near the top, gradually merging into deeper shade as the surface of the sphere recedes from the light, the under surface being only relieved from absolute blackness by reflected light. If we then take a transparency from the same negative, and print an image on paper from this transparency, we obtain an image exactly the reverse of that printed from the negative. Instead of a light near the top, we have in its place the intensest black, gradually merging into white as the surface of the sphere recedes, producing, instead of the effect of relief, the effect of hollowness or intaglio. Our correspondent then points out that as this is the kind of image which a print from the mask would present, it will produce just such an effect when superposed

on the print, limited only in degree by the time of exposure under such a mask.

As we have said, this assumption is so ingeniously wrong that it was worth while to state it fully before correcting it. All that "R. F." has stated would undoubtedly result if the mask were used as he is assuming it would be; that is, upon the print after it is removed from the pressure-frame. But it is not, under any circumstances, to be so used. Let it be distinctly understood that it is to be used as masks usually are—practically to modify the character of the negative during the progress, or part of the progress, of printing. The negative is assumed to be too hard; to possess too much contrast; to allow some portion to become too deeply printed, so as to bury detail in the shadows before the details in the lights are printed through. This mask will practically reduce the contrast, retarding the printing of the shadows without impeding the printing of the lights, and so bringing about the balance necessary to produce harmony. There is no danger of the lights being degraded, because they are at all times protected by the dense negative; and there is no danger of inversion of gradation, as however the mask may modify the passage of light, that light must always pass through the negative before it reaches the print. As we said in a former article, the mask may be worked upon to any extent the photographer may desire, in order to produce special effects; but in order to correct the effect of an over-dense negative, it merely requires to be a good transparent positive from such negative.

Mr. Rejlander, in a private letter, makes a capital suggestion in connection with this subject, one which would be valuable in dealing with subjects in which the inherent contrast is too great to receive full justice from photography. He suggests that if the collodion film could be safely transferred from the glass, a negative giving fine results might be formed by the superposition of two films: one thin and soft, with abundance of delicate detail and half-tone, and the other with more contrast, doing full justice to the more vigorous lights. As there is really no difficulty in removing the collodion film from the glass, after a very little practice, either by the method described by Mr. Woodbury or others, the suggestion of Mr. Rejlander might easily be put into operation, and some harmonious pictures produced from difficult subjects.

#### Critical Notices.

ON THE RETOUCHING OF PHOTOGRAPHS; A Manual of Instruction in the Perfection of Negative and Positive Photographs, and in Colouring the same with Water, Aniline, and Oil Pigments. By JOHANNES GRASSHOFF. (Berlin: Louis Gerschel).

In a compact little volume of eighty pages, M. Grasshoff gives us very clear and precise directions on the subject of improving and beautifying photographs. The subject is one upon which the author is well qualified to write, and the simple unaffected language in which his ideas are conveyed to the reader render his remarks easily intelligible to the novice, and awaken a spirit of trust and confidence in his teaching. It is essentially a practical book; and, in the preface, M. Grasshoff informs us that he has, as far as possible, eschewed all theoretical dogmas, and confined himself to the description of methods which have stood the test of many years. He pre-supposes nothing further than a slight elementary knowledge on the part of the student, either in regard to manipulation with the camera, or with the brush; but remarks that, as a natural consequence, in order to produce perfect results, some skill is necessary on the part of the operator.

The volume is divided into eight chapters, treating respectively of the following subjects:—Retouching on the original; retouching on the negative; retouching of ordin-

any photographs upon matt paper with black pigments; retouching of albuminized prints with black pigments; colouring of photographs in ordinary water colour; colouring with aniline water colours; varnishing of photographs; and colouring prints in oil. All the directions given bear particular reference to portrait photography.

In regard to the retouching of the original—or, in other words, the treatment of the sitter—the author urgently recommends a judicious employment of powder and puff for removing summer freckles and spots, and for toning down hair and beards of two fiery a colour. The photographer is advised to put forward his utmost powers of persuasion, and use any amount of Ciceronian eloquence he may possess, to effect this method of retouching the original whenever the same is absolutely required, but he is warned not to overstep the bounds of necessity, as, in most cases, a mere thought of starch powder lightly applied by means of a swan's-down puff is amply sufficient to bring about the desired alteration. Any colouring of the cheeks or lips with a red pigment M. Grasshoff holds to be quite unnecessary.

The chapter devoted to retouching the negative is one of the most interesting and instructive in the book, and we therefore trust to be able to place the same before our readers in its entirety at an early opportunity, the subject being one which has of late received considerable attention by the photographic world. The fact that M. Grasshoff has been one of the most successful operators in this branch of photographic manipulation is sufficient guarantee for the practicability and efficiency of the methods he recommends.

With regard to the retouching of photographs upon matt paper with black pigments, the author makes the following cautionary remarks:—

"In the early days of photography very little attention was paid to the quality and durability of the pigments used for retouching, even when the pictures operated upon were to be continually exposed to the effects of air and light, as in the case of exhibition and show prints. Thus, when an elaborately retouched picture covered with a pigment of inferior value began to lose its originally beautiful tone, and to change colour, assuming an ugly bluish-green tint, the cry was at once raised that photographs were of a very perishable nature, and that no confidence could be placed in their permanence. The character of the photograph was thus impugned instead of the genuineness of the colouring matter with which it was covered.

"To prevent a mishap of this kind I employed myself for some time in looking about for pigments, and particularly for a good red, in the permanent character of which confidence might be placed; my selection falling eventually upon Vandyck brown, whose fiery red tint was found to impart the requisite tone and to give excellent results. By adopting this brown I was enabled to dispense altogether with the use of carmine, neutral tint, and similar colours for mixture with the black Indian ink."

The preparation of the composition to be used for retouching in black is thus described: "A cake of Indian ink is rubbed in a small porcelain dish with water until a solution of thick consistence is obtained; the ink should be of first-rate quality, as upon this depends the facility with which it is afterwards manipulated. As the Indian ink possesses a very dark brown tint, a little blue (either Prussian, Paris, or Pinkert) is added; and in order again to correct the bluish tint which the ink may thus acquire, a small quantity of Vandyck brown is put in. The colours should be thoroughly mixed together by means of a brush, further quantities of blue or red being added until the tone of the picture is well imitated, a little of the compound being applied by a brush to white paper and allowed to dry, in order to make the comparison. When a suitable pigment has been thus obtained, three or four lighter tints of the same colour are mixed in several porcelain shells, by taking small quantities of the thick

solution and diluting them with different volumes of water; thus the painter is provided with every gradation of tint necessary for his work."

M. Grasshoff recommends the application of several coatings of a light tint, rather than one of a dark nature, whenever great depth of shadow is required, and states that, inasmuch as the Indian ink always soaks well into the paper, a former application of the pigment is never injured by subsequent elaboration with the brush. It is for this reason that Indian ink is so well adapted to photographic retouching. To give the retouched picture a finished appearance, the author suggests a vigorous brushing of its surface with a clean, dry clothes-brush. If the print has been only slightly worked upon, it may, after brushing, be polished with a compound consisting of equal parts of white wax and good oil of turpentine, or oil of lavender, melted together.

The fourth chapter, devoted to the retouching of albuminized prints with black pigments, contains but little novelty. The pigment to be employed is prepared in a similar manner to that described in the previous chapter; but, inasmuch as more brilliancy is required, a sufficient quantity of a thick solution of gum is added to effect this purpose. Glycerine or sugar mixed with the pigment enables it to be the more easily applied to the albuminized surface, which should also be moistened with saliva, or a dilute solution of white of egg, to facilitate manipulation.

Painting photographs in ordinary water colours forms the subject of the next chapter, which bears especial reference to the manipulation of albuminized prints of small dimensions. As this has always been a subject of great interest, owing to the large number of coloured cartes-de-visites which are sold, we intend on a future occasion to place this chapter likewise before our readers, without curtailing any of M. Grasshoff's valuable remarks upon the subject.

The employment of aniline colours, recently brought into commerce by Dr. Jacobsen, of Berlin, is next discussed. The opinions of those who have used these colours, says M. Grasshoff, are very divided, as by some they have received unqualified praise, while by others their qualities have been greatly decried. The author proclaims himself in their favour, and attributes to ignorance and inexperience any cause of failure. Their manipulation is not different from other water colours, but care must be taken never to overstep the outlines in the picture, as the perfect removal of extraneous paint is extremely difficult, if not altogether impossible. Another drawback to the use of aniline colours is the fact that some of the tints are wanting, and in this case M. Grasshoff suggests their being eked out with ordinary water colours.

In Chapter 7 M. Grasshoff treats of the varnishing of photographs, always recommending a double application of a preserving fluid. A dilute normal collodion containing from two to three per cent. of gun-cotton is poured over the picture and allowed to dry. Defects may now be remedied, or improvements made upon the collodion film, and afterwards a sandrac varnish is applied to the print by means of a large and broad camel's-hair brush. This mode of varnishing is best adapted to prints upon albuminized paper; but matt pictures may also be treated in this manner, provided a thicker and stronger varnish is used. In general, the polishing of pictures of the latter description with white wax is preferable. Photographs painted in aniline colours must not be coated with a spirit varnish, as these pigments are soluble in alcohol.

The last division of this little book treats of the painting of photographs in oil colours. The author goes very fully into this method of colouring, detailing the manner of selecting and treating the print before colouring, and of laying on the various pigments. He also gives directions for the preparation of canvas upon which photographs may be printed, to serve as designs for oil paintings. A list of the different pigments required is quoted, and in-

structions as to their management imparted, as far as it is possible in so small a space; the finishing and varnishing of the pictures is also touched upon.

As M. Grasshoff rightly remarks at the outset, he does not profess to teach anybody to paint solely with the help of his book, but that, in all the manipulations he describes, some amount of skill is necessary on the part of the operator. The author's object in publishing his remarks is to simplify the process as much as possible, so as to enable photographers and amateurs of ordinary ability to produce coloured pictures in the easiest and best manner, and to understand the principles upon which they work. That M. Grasshoff has been successful in doing this there can be little doubt; and we feel sure that many aspirants will be greatly aided in their work by a reference to the volume now before us. We hope the time may not be far distant when the author will again resume his pen to tell us something of photographic backgrounds and accessories, a subject upon which his remarks would be equally valuable with those at present under discussion.

**A TREATISE ON OPTICS;** or, Light and Sight, Theoretically and Practically Treated, with the Application to Fine Art and Industrial Pursuits. By E. NUGENT, C.E. (London: Virtue and Co.)

THIS is a comprehensive and popular treatise on optics, which, in the dearth of such works, will be welcomed by the student. That an elementary work intended for a text-book for schools and colleges should be a compilation from recognized authorities was not unnatural, and accordingly we find that Sir David Brewster's work on optics has furnished the basis of the present work, and that the author has fallen into an error, only too common, of omitting to mention the authorities on whose pages he has drawn. Nevertheless, the work is a very valuable one, containing much information on photographic optics and the apparatus connected therewith, the information on these subjects being brought to a later date, and being therefore fuller, than in any other work on the subject. The work is well printed and copiously illustrated, and it contains that valuable but rare adjunct, a very complete index. Altogether, we can recommend this volume to those of our readers who may desire to know something of the principles which underlie their art. The work is clearly written and carefully arranged, and is at once comprehensive and popular.

**PHOTO-MICROGRAPHS** Executed for the Army Medical Museum, United States.

WE have been favoured by the Surgeon-General of the United States Army with a series of photo-micrographs executed by Brevet-Major Curtis, Assistant-Surgeon of the Army. Several of these photographs have become familiar to English photographers by the examples sent over to this country by Col. Woodward, which have been exhibited at meetings of some of the societies. Criticism on such work is altogether superfluous; it appears to be simply perfect, both in definition and brilliancy. We have examples of amplification varying from 30 diameters to 2,100 diameters with perfectly satisfactory definition. A Podura scale, for instance, taken with Powell and Lealand's 1-50th inch objective, with the latter amount of enlargement, is marvellously well defined. The same test-object, however, taken with a 1-25th inch objective by the same maker, magnified 756 diameters, is, in our estimation, preferable. The following extract from a description of the operations in producing these enlargements, contributed by Col. Woodward to our Philadelphia contemporary, will interest many of our readers:—

The essential parts of the process are, the use of object-glasses corrected so as to bring the chemical rays to a focus, and illumination by violet light. The steps are, briefly, as follows:—

The microscope is used in a dark room, the windows of which face to the south. Outside of one of these windows is a shelf, on which stands a Silbermann's heliostat, so arranged as to reflect the direct rays of the sun upon the mirror of the microscope, which is fixed on an arm outside of the window, and, in its turn, reflects the sunlight through a short tube in the shutter. The microscope is placed at the inner extremity of this tube in a horizontal position, while at the outer end hangs a plate-glass cell, filled with a saturated solution of ammonio-sulphate of copper. Through this solution the sunlight must pass to enter the tube, and in so doing all but the violet ray is absorbed. Two steel rods, attached to the mirror, permit it to be adjusted without opening the window, and a black velvet hood thrown around the stage of the microscope prevents any leakage of light into the room from the space between the condenser and the objective of the instrument. With high powers, an ordinary achromatic condenser is used; or, in some cases, a pair of simple plano-convex lenses, with a large central stop, may be advantageously substituted, to give greater obliquity to the illuminating pencil. Objectives properly corrected for illumination with violet light have been manufactured for the Museum by Mr. W. Wales, of Fort Lee, N. J., who has produced a three-inch, four-tenths, one-fifth, and one-eighth, the quality of which, in my opinion, is all that can be desired. The plate-holder, properly centred, slides on a horizontal walnut frame, by which it is held perpendicular to the axis of the microscope, and can be clamped at any distance not exceeding nine feet from the stage. By the side of this frame is a round rod, on the extremity of which, next to the microscope, is a grooved wheel. The milled head of the fine adjustment of the microscope is also grooved, and a silk cord over the two enables the operator to focus the microscope by means of the rod, no matter how far from the instrument the plate-holder may be.

To arrange the illumination, position of the object, &c., the operator stands by the microscope, puts in an eye-piece, and focusses in the usual way, adjusting the mirror by means of the steel rods. The violet light is readily borne by the eye, even when the whole power of the sun is employed in the illumination. This adjustment completed, the eye-piece is withdrawn, and, going to the plate-holder, the final adjustment is made by turning the rod. In this final focussing, the object is viewed with a focussing glass on a piece of plate-glass held in the plate-holder. The sensitive plate is then exposed in the usual way, the time required being from less than a second to twenty minutes, according to the power employed.

For low powers, the objective alone is relied on to give the necessary size. To obtain the highest powers, however, an achromatic concave is placed at the upper extremity of the microscope body. The one now employed gives a perfectly flat field, and increases the number of diameters between six and seven times. This concave is about half an inch in transverse diameter, and has an angle of aperture of 28°.

Many objects—as, for example, some of the tissues, certain diatoms, &c.—present interference lines when illuminated with a powerful pencil of parallel rays, and in order to prevent this false appearance, it is necessary to interpose a piece of ground glass in the solar pencil to disperse the light: in this case the time of exposure necessary is, of course, much increased.

By these contrivances we have been enabled to produce pictures of the utmost sharpness, and perfectly satisfactory in every other respect, with powers up to 2,500 diameters; and these pictures bear a further enlargement of from six to eight diameters in a copying camera. We have thus obtained excellent pictures with no less than 19,000 diameters.

If the foregoing points are duly attended to, it matters comparatively little which of the very many excellent photographic processes in use for ordinary work is employed. As to collodion, many different samples have been used with good results—among others, for example, one containing two and a half grains each of the iodide of ammonium, the iodide of cadmium, and the bromide of ammonium, to the ounce of collodion. With the highest powers, a collodion containing two grains of bromide and five of the iodide of magnesium to the ounce has been found advantageous, the resulting nitrate of magnesia preventing the plate from drying during the long exposure necessary. The nitrate bath is used of the strength of forty grains to the ounce, and is acidulated with nitric acid. We use the ordinary iron developer, restrained by the gelatine solution, on the plan proposed by Brevet-Major W. Thomson in a recent number of your journal. The picture is fixed with hyposulphite of soda or cyanide of potassium, and afterwards intensified with iodide of mercury dissolved in a solution of iodide of potassium, and, when necessary, still further with Schlippe's salt. Great intensity is especially required in pictures of the diatomacea, and other lined objects. The negative is finally varnished, and prints taken on albumen-paper in the usual way. I send you samples of these prints. It is to be remarked, however, that for the Museum we prefer transparent positives on glass, mounted before a piece of ground-glass. A fac-simile of the field of the microscope is thus obtained. I should take plea-

sure in showing any of your readers who may visit the museum the splendid series of specimens prepared by this method.

It may be remarked that, with the very highest powers—such as, for example, the new Powell and Lealand's one-fiftieth objective, one of which is in the possession of the Museum—the correction of the objective, to suit the index of refraction of the violet ray, is so small as to be practically unimportant. At least, by illuminating this lens with monochromatic light, we have obtained with it excellent photographs, one of which I send you. This remark, however, does not apply to the one-eighth nor to any lower power. I have not yet experimented with the one-twelfth or one-sixteenth, but believe, also, that with these glasses the special correction will be found indispensable to the best results. I may also say that with the one-eighth and the amplifier we have obtained photographs with magnifying powers as great as we have been able to obtain from the one-fiftieth. Comparative pictures taken from the same object give the preference, in some particulars, to the one-fiftieth; in some, to the one-eighth and amplifier.

The process I have above sketched is employed in the Museum in preparing the pathological illustrations for the medical history of the war, and diatoms, &c., have been employed by us simply as test-objects.

### PHOTOGRAPHY IN EGYPT.

As we have before stated, the German photographic expedition despatched to Aden to record the solar eclipse has received instructions to pursue some photographic investigations in Upper Egypt, and obtain records of the various ancient relics and inscriptions which abound there. Our friend, Dr. Vogel, will communicate to these pages notes of matters of interest to photographers occurring during his Egyptian tour. In the meantime we reproduce his first letter, addressed to Dr. Jacobsen, who edits the *Mittheilungen* during Dr. Vogel's absence:—

*On the Nile, North of Minieh.*

In my last letter I communicated to you the fortunate issue of our photographic observations of the eclipse of the sun; since that time scarcely four weeks have gone by, and in the meanwhile I have travelled by the Suez canal from Suez to Port Said, in the Mediterranean, ascended the Pyramids, spent eight days in the deserts of Sahara, and now am sailing on the Nile, towards Upper Egypt, for the purpose of fulfilling a new scientific engagement, which it appears was part of the mission of our expedition after the principal object, photographing the eclipse, should have been completed.

The first intimation of the expedition to Upper Egypt reached us at Aden. In Cairo we found the leader of the expedition, Dr. Dumichen, awaiting us. He had a barque already furnished to take us up the Nile, a splendid supply of chemicals from Berlin, and a stock of provisions purchased; so that after a very short sojourn we were enabled to proceed.

Our new duty was to photograph important historical inscriptions and sculptures on the Egyptian temples and tombs. For this purpose we were provided with a considerable quantity of magnesium and a magnesium lamp, to work in the mausoleums. Further, Dr. Dumichen had brought with him a gigantic tripod, twelve feet high, for our camera, together with the ladders belonging to it, to enable us to photograph correctly the higher friezes and writings. This tripod admits of the camera being placed almost perpendicular, so as to take drawings on the ceilings, &c.

First, we proceeded to Sahara. Here lies the field of the dead and the old town of Memphis, to which also belong the great pyramids. Here, in the sands of the desert, you find thousands and tens of thousands of tombs filled with earth. The ground is covered with potsherds of earthenware, the remains of sarcophagi and bones, the desert wind driving the tattered linen shreds of mummies over the waste and desolate plain.

The director of the Egyptian Museums in Cairo, and principal Inspector of all that is untombed in Egypt, acted as our convoy, and showed us many interesting tombs which he had discovered and laid open to view. Some of them formed noble courts roofed and columned; others simple chambers, with numerous bold reliefs on the walls. The whole of the rooms were half dark, being only lighted through small openings to be found in the ceilings.

The photographing of these reliefs was our first task, and we had to deal not only with the difficulty of defective light, but with that of their exceedingly short distance from us. On this account our first photograph was taken through the employment of the magnesium light, but we were only able to produce a few of the heads of portraits. Naturally, under these circumstances, very little could be done at a time, and in order to produce the picture of a long wall many photographs had to be taken. In the lighter tombs we photographed by daylight, and brought out the dark corners through reflected solar light, which we threw into the dark

parts by means of mirrors. In order to avoid faults in the lighting, we kept the mirrors continually working in rotation. Many of the dark places were photographed by using both the daylight and the magnesium light at the same time.

Besides these difficulties, when working in the desert, we had many other troubles to encounter. The wind perpetually blowing endangered our tent, and threw the fine sand upon our prepared plates. The exceeding dryness of the wind caused defects, and the muddy water of the Nile, for washing and rinsing, rendered any clean work most uncommon with us. We were best off when we could make our preparations in one of the tombs. For instance, we made use of the tomb of a prime minister of one of the Pharaohs, Ti—to judge from his heroic deeds, recounted on the wall, a sort of ancient Egyptian Bismarck. In his lifetime he certainly never could have dreamt that 4,000 years afterwards his tomb would be used as a photographic dark room.

In indifferently lighted rooms the Steinheil applanatic objective proved itself to be the best for photographing large surfaces. We were furnished with a complete supply of the different objectives, but none, with an equally large aperture, gave so even a picture as Steinheil's.

The most interesting part of the field of the dead is the Serapeum. This consists of subterranean catacombs executed in the rocks, in which are the colossal coffins of granite of the sacred bull Apis. M. Mariette had these mighty chambers lighted, so that we could behold at one view their magnificent dimensions. The size of the coffins may be imagined from the fact that we, eight men, found room at one table, not merely sitting, but standing also. The excessively heavy granite covers of these coffins are lifted aside in a body, and their contents removed. Diggers for treasure had rummaged out not only these, but almost every other tomb, long before European Egyptologists came into this country.

We tried at the end of our sojourn in the desert to photograph such an Apis-sarcophagus in its cavern with the aid of magnesium wire and a Dallmeyer portrait lens, and obtained, at the expense of eight metres of magnesium wire, a successful picture.

After encamping for six days in the desert, we got back to our barque. Our photographic implements followed us, partly on camels and partly on the heads of the natives.

On the 12th September we again set sail, and steered for Denderah. The first day we made seventy miles with a strong north wind, and had already begun to entertain hopes of soon reaching our destination, when, all of a sudden, our boat got aground and stuck fast at five o'clock in the morning. Vain were the exertions of the sailors to get her afloat. They called upon Mahommed, his wife, mother, and grandmother, shrieking to escape, but all to no purpose. After two hours' continued efforts, twelve men were fetched in a small boat from the nearest village; these, however, could not manage to float our barque. Now our situation became critical, and nothing remained except for our dragoman to be sent up the river to the nearest town to bring another vessel or a steamboat for our salvage. We thus spent twenty-four uncomfortable hours in the middle of the Nile. Fortunately we had been strongly recommended to the authorities of the country through our Consul. The Mushir of the place to whom our dragoman applied gave immediate orders for a hundred men to be sent off to float our barque, in which they succeeded.

We sailed again with a fresh wind, which continued until the following night. From that time the favourable north wind ceased, and now we are crawling slowly along; sometimes, indeed, not moving at all.

This dependence upon the whim of the wind, together with the danger of getting aground, is not the most agreeable part of a trip up the Nile. No man can with certainty dispose of his own time; and this affects me the more, as my duties for the middle of October call me back to Berlin.

### PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

CHAPTER XXXIX.

Why are photographers so afraid of shadow as their works indicate? It is seldom that a photographic portrait by an English artist is seen with more than sufficient shadow to ensure a certain amount of roundness and modelling in the head; and the effect of a head in shadow, or with the light coming from behind, is never found. On the Continent, photographers have seen the advantage of occasionally varying their effects. In Germany, especially, very beautiful things have been done with the face in shadow, and the

light, coming in from the back, skimming the side of the head. Very delicate and transparent effects, of which the engraving is a sample, are produced by this means. The subject entitled "The Sisters" is from an engraving published by Goupel; our illustration being a reduction, by

Mr. Fruwirth's process, of a wood engraving in an excellent little publication entitled the *Children's Friend*. It is not necessary to have a window in the background end of the studio to admit the light; it will be found quite sufficient and effective if a portion of the roof is used. A clearer

understanding of the method will be obtained from a reference to the diagram of the roof of the studio described in Chap. 30. The white spaces represent glass, covered with

white blinds, numbered 1, 2, 3, and 4. To produce the effect of light coming in from behind, the sitter is placed under No. 2, or rather nearer to the bar which divides 1 and 2. Blind No. 1 is pulled up, leaving clear glass, and blinds 2, 3, and

4 are pulled down; being made of white calico they admit a small amount of light, which allows a very soft shadow on the face. The camera is placed under No. 4, or any distance beyond necessary to the size of the picture required. The exposure necessary will be found to be very little longer than for a portrait lighted in the usual manner. If the negative be not over-intensified—at first it is difficult to believe that the broad mass of the face should be left so thin—the result will be exceedingly fine, luminous, broad, and without heaviness. I have left out of the account the side of the studio which should be blinded in the same proportion as the roof. If photographers could be persuaded to depart occasionally from the usual and monotonous manner of producing portraits which make their photographs so very "photographic" and unlike other works of art, they would soon find other variations in the mode of lighting which would create variety in their productions, and, in all probability, give their patrons a new interest in their works.

One of the evils which has prevailed amongst photographers, and a very natural one, is, that they have studied

too much from photographs. When they have seen a good effect in photography they have admired it and tried to imitate it; an aim laudable enough in itself, especially if very occasionally indulged; but which has, nevertheless, been carried out to such an extent as to produce in the mass of photographic portraits a dreary, common-place monotony, modifications of one or two or three leading styles being perpetuated *ad nauseam*.

I was consulted some years ago as to the wisdom of publishing a little work on posing and arranging, to consist chiefly of lithographic copies of actual photographs by the best masters, and was asked to undertake or superintend its preparation for the press. In the midst of the rapid demand for portraits, which allowed very little time for study or arrangement in the glass-room, such a work, it was deemed, would be eagerly sought after, and, I have no doubt, might have been a successful business speculation. It would, however, in my estimation, have been a mischievous book, and for the sake of photography I at once condemned the idea, and used my influence in preventing its issue. Photographs themselves were plentiful enough, and were too commonly imitated and copied; but to make copies of such things, and distribute for imitation, appeared to me worthy of all condemnation. It is true, there are a few masters of artistic effect in photography whose works might form valuable studies; but sufficient of the photographs themselves of these men are for the most part accessible where they are required for art study; and, as I have just said, photographic portraits are already too much alike, and modelled too much on one style. I have striven in these papers to impress upon the student the importance of avoiding direct imitation as a practice; and for suggestive studies I should recommend him to go outside of photography and examine the wealth of engraved pictures readily accessible. Many of the old mezzotint engravings to be picked up for a few pence each on London book stalls are invaluable. A habit of studying these would much improve the notions of chiaroscuro of most photographers, and teach them the value of shadow and the importance of securing transparency in shadow. The horror which photographers have had of shadow has been chiefly due, I believe, to the fear of blackness and unrelieved heaviness. A good mezzotint will show how much general depth of tone may be secured without blackness; it will show also how the distribution of half lights in the midst of shadow effects this. With the materials arranged to give light and shade in the photograph similar to that seen in a good mezzotint, the photographer will find that good lighting and full exposure will give him results not very far inferior to those in the engraved pictures.

#### PRINTING TRANSPARENCIES ON DRY PLATES WITHOUT CUTTING THE NEGATIVES.

THE production of transparencies is generally a favourite winter occupation with the photographer, and to the dry-plate worker it is an important point to be able to transpose the images without cutting the original negative. This can only be effected by means of a suitably arranged printing-frame requiring some ingenuity to contrive. One or two of these have already been described in our pages, and we now bring another under the notice of our readers, which seems admirable in its simplicity. The name of the Rev. J. Carter Browne, the inventor, will be recognized by many of our readers as that of an experienced and successful dry-plate man. He says:—

"I send you, according to your request in last week's NEWS, an account, with diagrams, of a frame I have extemporised for printing transparencies on glass without cutting the negative. Let me briefly describe it.

"Fig. 1 represents the interior view: *a b c d* is the body of the frame, around which I have run an edging of wood three-eighths of an inch deep; in this the negative lies: *p p p p* is a

hole the exact size of one of the pictures to be printed, which, allowing for a margin of one-eighth of an inch above and below, and three-eighths at each end of the plate, leaves us three inches square: *e f g h k* is a flange of tin, tacked on to the lid,

Fig. 1.

in order to prevent light finding its way between the body and lid of frame when closed; in this flange two slots are cut, to allow the two eyes at *t t* to come near enough to the two hooks to close the frame during printing.

"Fig. 2 represents the reverse of Fig. 1. On the lid *5 5 5 5* is the outline of a stereo plate, *6* denoting the extremity of the central line; this is in order to get the exact middle of the sensitive plate, so that I ensure against any double printing in the middle of my transparency: *1 2 3 4* are two fine pieces of

Fig. 2.

list, to prevent the plate being scratched when resting on the wood for measurement; the middle line is marked at its extremity by the point of a small arrow-head of paper gummed on the non-prepared side of the plate. During the printing this arrow-head is made to coincide at one time with the one, at the other time with the other, of the arrow marks in *a b* of fig. 1: *l m n r* are pads of india-rubber, which press the prepared plate tightly and equably to the negative when the frame is shut.

"I have tried many processes, and find that, next to the plain albumen, no process gives better tones or more delicacy than—

Tannin	...	...	...	...	15 grains
Sugar	...	...	...	...	1 lump
Aqua dest.	...	...	...	...	1 ounce

The exposure (in a northern light) at mid-day at this time of year, with sun shining, is (with a first-class negative—i.e., full of half-tone and not over-dense) six to eight inches; for other negatives in proportion to their class. Ordinary pyro and citric developer. It is by far the most satisfactory work at this time of year; seldom a failure, and always plates to prepare for the next day, and some to develop of the bygone day.

"I hope to have your critique on my transparencies not long hence, when I can get away to London.—I am, sir, yours faithfully,

"J. CARTER BROWNE, M.A.

"Horncastle Grammar School."

#### SENSITIVE DEVELOPMENT PRINTING PROCESS.

HERE STERNBERG communicates to the *Archiv* a highly sensitive development printing process, suitable for obtaining

enlargements with very short exposure. The paper is prepared as follows:—

Rain water	...	...	1 litre
Tapioca...	...	...	20 grammes
Iodide of potassium	...	...	10 "
Chloride of potassium...	...	...	40 "
Lemon juice	...	...	250 drops

The tapioca is first made into a paste by pounding in a small quantity of cold water, and the other materials are then added gradually, having been previously dissolved in the litre of rain water, which has been made to boil. It is kept heated during the adding of the tapioca, and until the liquid becomes clear. When cool, it is spread on the paper by means of two pieces of sponge, as in the preparation of arrowroot paper. If exposed to the atmosphere, this paper very quickly assumes a reddish hue, and mottled stains often show themselves on the surface; but these defects disappear when the sheets are sensitized.

The silver bath is composed of—

Rain water	...	...	1 litre
Nitrate of silver	...	...	60 to 100 grammes
Citric acid	...	...	5 "

The strength of this bath should be reduced if the negative be dense, and increased if the negative be soft.

The exposure must be prolonged until the outlines of the picture appear on the sensitive paper. It is then developed in a solution composed as follows:—

Rain water	...	...	4 ounces
Saturated solution of gallic acid	...	...	1 ounce

Immersed in this bath, the proof will there become gradually stronger, and will assume a sombre brown tone. It should be raised from time to time by the corners and examined. When it has attained sufficient strength it must be taken from the bath and made to float on a water bath, to prevent the gallic acid from sinking into the paper. After some minutes the sheets should be plunged into the water and well washed; it is then toned in an old gold bath, and finally it is fixed in the ordinary manner. After the mounting the proofs may be treated with cretaustic paste or varnished if brilliancy is required.

## PHOTOGRAPHIC PRINTING IN SILVER, THEORETICAL AND PRACTICAL.

BY W. T. BOVEY.\*

I HAVE frequently been asked by photographers of tender conscience, how I contrive to tide over the evil which, say they, must arise from the presence of free acid that is borne by the prints from the toning to the fixing solutions. I reply, "If any scruples are entertained, by all means add a little carbonate of soda to the preliminary washing water; it can do no harm. I doubt its power to effect good; it may, however, neutralize all the free acid conjured up by your imagination." In point of fact, it might be set down as a certainty that with the employment of the double salt of gold and sodium, together with an addition of free nitrate of silver to the bath, the toning solution is neutral; at least, with the most sensitive of litmus paper I have failed to detect acidity. Indeed, to add an acid in an appreciable quantity is to inaugurate disaster. In my own practice I simply remove the prints from the toning bath to a tray of water when they are ready for fixing, which last operation demands our next consideration.

Concerning the strength of hypo solution to be adopted for the proper fixation of silver prints, a diversity of opinion exists, and, as a natural sequence, each practitioner thinks his particular method the best. At a first glance over the matter it would appear a subject of small importance what strength of solution is adopted, as long as the unreduced

silver is dissolved out of the paper. Nor would it occasion any difference if the fixation of the picture was the only condition to be considered. But allow me to point to an hitherto unrecognized fact, that the formation of blisters is frequently caused by the adoption of a fixing solution of excessive density—in other words, by the employment of an over-dose of hyposulphite of soda. Considering the matter by the light of common sense, has it never occurred to those who advocate such excessively strong baths that they overstep the bounds of economy by using an amount of hypo altogether disproportionate to the actual requirements, as the amount of the fixing salt they provide would afford hyposulphurous acid sufficient to combine with a thousand-fold more atoms of silver than the prints supply? I readily admit that to consider only atomic combinations would, under the circumstances, be worse than dangerous, as the resisting power of the albumen and paper has to be provided against. But I contend that at the extreme outside, 3 ounces of hypo to an imperial pint of water are ample for fixing any number of prints that quantity of water can comfortably contain.

With a paper weakly albuminized, no fear of blisters—even with the strongest of fixing solutions—need be entertained. It is when the albumen surface is raised above the paper by reason of its thickness—when the pores of the paper are sealed and rendered air-tight—it is then, and only then, blistering requires guarding against, and the avoidance of the evil depends on the density of the hypo solution, for the following reason. Up to the moment the prints leave the hypo bath, despite the handlings and washings the prints have been subjected to, they have failed to dislodge minute quantities of air imprisoned in the pores of the paper. Now with a slight coating of albumen, or when a coarse-textured paper is used, the outer portion of each pore remains open, so that, on immersing the prints into the final washing water, a quantity of air-bells forming on the surface of the paper go to prove that air is escaping; but when that air can find no outlet, it stands to reason that any application of considerable force must separate such portions of the albumen as have no firm hold on the paper. Physical science proves that such force exists—a force that finds in the conditions provided by an albumen surface a fitting field for action. The agent in question is allied to capillary action, and is known by the outlandish name, endosmose, which in commonplace English may be interpreted as meaning that when two liquids capable of admixture with each other are separated by any surmountable obstacle, the lighter fluid makes a rush to unite with the heavier. On consideration, it will be perceived how this force acts on an albumen print. The pores of the paper act as capillary tubes, through which the hypo solution enters as far as the confined air will admit it. So far there is no extra pressure; but when the prints are removed from the hypo to the washing water, this last makes a rush on the hypo, and the hypo solution gives an extra squeeze to the air, which, in its efforts to escape, dislodges the albumen, and blisters result. The remedy is obvious: reduce the strength of fixing solution, and you do something towards removing the difference of density between the hypo bath and water. I have followed up some interesting experiments in the direction here indicated, and I might say that I have produced blisters at will. Bear in mind I write of albumen surfaces, and on pure albumen surfaces only I experimented. As a wind-up to the subject of the fixing bath, I append the formulae I adopt:—

Pure hypo	...	...	2½ ounces
Water	...	...	1 imperial pint

Time of immersion, thick paper, quarter of an hour; thin paper, ten minutes.

And now for the final washings. What a deal of fuss has been made about this and that washing machine! What horror of feeling has been experienced when it has been told, of some careless brother, he puts his prints from the hypo bath direct into his washing trough! I freely confess myself

\* Continued from p. 511.

guilty of like error, and believe myself much in the right. I drain the prints thoroughly from the hypo before immersing them in water; and my chief care is to have an abundance of water to start with, and I see that the water has made a move through the syphon before the prints are immersed. Depend on it, much of the fading we hear so much about often arises from excess of care in moving the prints from the fixing bath into a small dish, from that dish into a second, and so on. The waters employed in the earlier stage are converted into weak sulphurous compounds, which attack the whites of the prints, decomposition in latent form is set up, and a damp atmosphere, or other causes, will finish the destructive work, perhaps months subsequent to the formation of the germ. If any one would see what a dilute hypo solution can do, place a print or two in such a mixture for a few hours, when, ten to one, the print will go through all the stages of decay which silver prints are heirs to; or, at least, so their character is described by many. After all that has been said concerning the carbon printing process, until some process is discovered that enables the operator to work with his eyes open—such as silver printing admits of—silver printing will doubtless remain the favourite. By no other known process could Mr. Robinson's beautiful composition pictures be produced; by no other process can the sun be employed to remedy defects present in the negative.

Therefore, as silver printing is destined to enjoy a long lease of existence, let me, in conclusion, beg of my readers to do what they can to master all the difficulties connected with printing operations. I have faithfully offered reliable formulæ and instructions, in which I have examined existing theories, and offered others of my own. The formulæ I have recommended are all based on sound and economical principles, and the whole, if intelligently worked, yield unerring results. I here dismiss the subject of albumen printing, so far as theory and formulæ are concerned. My next paper I purpose devoting to the collodio-chloride process and printing by development. Until then, *Au revoir!*

#### ANSWERS TO CORRESPONDENTS.

B. A.—The addition of plain water to the bath is not, as you suppose, to replenish waste; it is intended to keep the solution in constant working order. The surplus solution so occasioned should be thrown away.

NEMO.—You are inclined to display some amount of irony. I have, as you are doubtless aware, studiously avoided puffing my own or any other person's goods. "Fair play" is the motto I adopt, believing there are many in the world more able and not less honest than myself.

S.—Add a little very weak chloride of lime solution to the toning bath, which will enable you to obtain the black tones you are sighing for.

### Correspondence.

#### SALTING FORMULÆ OF ALBUMINIZED PAPER.

DEAR SIR,—A paragraph extracted from an American journal has recently been going the round of the London daily press, in which a satirical squib is set fizzing in honour of M. Dumas, the celebrated French novelist, whose announced visit to Yankee Land has inspired some witty journalist to improvise an anticipatory programme of the eminent Frenchman's probable performances, according to which, commencing with readings from his own works, M. Dumas will successively exhibit his versatile abilities as player, gastronomer, chemical demonstrator, velocipede driver; and the finale will consist of a grand distribution of photographs of the performer, accompanied with a packet of stuff for the cure of madness. My advice to M. Dumas would be: "For charity's sake present the first package of your madness eradicator to the writer of the paragraph in question."

To the thoughtful every incident conveys some useful moral, and the paragraph alluded to has impressed my mind with thoughts I deem most apposite to the subject on which I am anxious to address you in the present communication. A

fertile genius is unquestionably one of God's greatest gifts to man, but its versatile powers require no ordinary amount of care to control them, for the plain reason that a man of genius, feeling strong in his superiority, is frequently but too apt to make a trip when he puts forth his powers to manage matters publicly before he has mastered the *pro's* and *con's* embraced in general details. The unhappy result of his temerity is, he is laughed at by those who, for the once, are his superiors in knowledge, and, when compelled to retrace his steps, the erring genius finds that confidence in the integrity of his teachings has been grievously shaken. How many a man of genius has made shipwreck of his fame by deserting well-mastered fields to wander o'er untried ground—to venture hapazard on work perhaps not above his ability, but beyond the embrace of his previous practice and study! Among painters the name of such fallen ones is legion. Writers I briefly sum up ditto. In short, among every class of toilers, whether of hand or brain, are to be found men who have cause to regret their having entered on some ill-considered undertaking, the failures in which offer forcible proof that nature sternly demands from all a sober use of such powers as a good God has bestowed on them, also that teachings should proceed only from teachers who by much labour have been taught.

Turning towards photography, I find versatile actors there who oft cut queer capers, men who probably would be qualified to adorn some humbler sphere, setting themselves up as art-teachers. Of a truth, art pretenders are they, stringing together quotations from books ancient and modern, affecting to commence with Homer, and to follow up with Plato, to make a show of learning, and really drawing largely upon the pages of Ruskin, as is fashionable with dabblers in art, forming in the whole an *ensemble* most bombastically erudite and fantastical. I say, "Heaven forbid that I consider such sorry performances efforts of genius!" Robinson in the *News*, Davies elsewhere, have given us art lessons in good, plain, hearty English, and they are readily acknowledged the right men in the right place.

Setting art teaching aside, we discover science instructors seeking notice, some of whom would perhaps do well to select fields that need more of imagination than patient investigation and reasoning. Yet, from time to time, turn up among us men of real genius, who are wont to startle us by their originality of conception, and arouse our feelings of admiration by the acuteness of their logical powers. Let me name one: Mr. Nelson Cherrill, a gentleman I heartily admire, and truly respect, on account of his philosophic intellect. An original thinker, a man of cultivated tastes, a thoughtful and intelligent observer, possessing a skilful hand and able pen, take him all in all, he has all the requisites to mould himself into a photographic star of the first magnitude; but, alas! human vanity will peep out to make fools of the wisest; and human weakness tugs hard on the most assailable side of Mr. Cherrill when that gentleman is tempted to write or speak on printing matters. I take his last paper, read before the members of the North London Society, which contains some able, original, and well-considered remarks on the true relationship of tone with intensity; and had the paper concluded with the writer's comments on these subjects, I fain would have clapped my hands over the pages of the *News*, and cried, "Bravo, Mr. Cherrill! you have hit it cleverly." But the unfortunate supplementary remarks thrust me from the climax of enthusiasm down into the depths of sorrowful cogitation; for well I know that Mr. Cherrill has all the ability needed to make an intelligent and successful printer; but he has wisely chosen the better path, where present fame is his, and future laurels await him; where he will never, I trust, have reason, after years of toil, to say, "I have been pursuing a labour of love in a vale of emptiness; I have endeavoured to benefit my art and its followers, and now, when too late, discover that I have wronged those little ones who laugh and prattle around my ain fireside." Mr. Cherrill, I repeat, might, if it so pleased him, have made a thoroughly practical printer, but he sagely turned aside, and is not one; hence, when touching on printing matters, he presumes on his versatility, and exposes his weakness.

A word or two on the point at issue. In his comments on the supposed variations that exist in paper from the same maker, he unconsciously unfolds to the gaze of the initiated his imperfect acquaintance with the subject he attempts to discuss. He objects to making negatives to suit paper, and to pursue no end of experiments to discover the treatment papers prepared

by the same hand and from the same formula require, and dwells on the difficulty of getting paper that will print *a la Salomon*, and on advantages innumerable to be derived from a knowledge of salting formulae. If Mr. Cherrill had spent half the years of toil and experimental research over the matter that I have done, he would know that a practical printer, worthy of the name, needs no knowledge of the exact amount of salt contained in the paper he uses; the first print satisfies him on that point sufficiently for his purpose and the satisfactory progress of his operations. Besides, he could undertake to produce half a dozen kinds of prints from one ready sensitized sheet of paper and from one negative. It is not a knowledge, derived from the dealer, of salting recipes that would bribe grim Charon to row the perplexed printer on the sunny side of the photographer's Styx, that bubbles and heaves with lesser troubles. Experience, and good, hard study, form the talisman, and until that experience is gained, paper and paper albuminizers will be the scapegoats of those who fail of uniform success. Years have such spent in fruitless grumbings, and, except indirectly, their complainings have extracted no response. But the gauntlet has now been hurled by a strong arm. The accusing knight is Mr. Cherrill; his herald, yourself, sir, whom I have the honour to address. To hesitate longer would savour of pusillanimity; I therefore, on behalf of my craft, accept the glove with kind intent, and am ready and willing to do battle. Meanwhile, if your readers think it would prove advantageous to themselves if the salting formulae I adopt were made known, they are welcome to the information:—

No. 1.—Chloride of ammonium	...	...	5 grains
Chloride of barium...	...	...	3 "
Albumen (fresh and pure)	...	...	1 ounce.
No. 2.—Chloride of ammonium	...	...	10 grains
Chloride of barium...	...	...	6 "
Albumen (as before)	...	...	1 ounce.

Now go to work on the information, and ease you of your troubles. It is not, you will find, the amount of salt used which makes the pudding light; it is the manner in which the ingredients are mixed and stirred; and to expect good prints because you know the amount of salt the paper contains is similar to expecting tender beef and mutton because the soil on which the animals fed is familiar to you. I would undertake to produce prints scarcely differing in tone and quality from any half-dozen samples of paper prepared by any half-dozen honest dealers.

In conclusion, I hope all my brethren in the paper trade will respond to your courteous invitation, and freely pronounce their opinions concerning the true cause of the torments they are being daily subjected to. Requesting that you will kindly insert this letter in its entirety, I remain, yours respectfully,

Willesden, October 26, 1868.

W. T. BOVEY.

#### DISTORTION AND PERSPECTIVE.

SIR,—I am obliged to Mr. Winstanley for setting me right in that part of my letter relating to reflection from the surface of a mirror; and as the fallacy was mine, I hasten to make the "amendo honourable" to Mr. Cherrill. I trust, however, that the subject involved in the latter part of my communication—viz., the pseudo-perspective effect produced by the too near approximation of the lens to the object to be copied—may still be worked out for the benefit of the many to whom the establishment of some simple laws embracing all the conditions would be a great boon. Fond as I have ever been of photography, I have always seemed to recognize that the photographic representation in portraiture was seldom or never as the eye would see the natural object. If the plane of the sitter's head was absolutely vertical to the optic axis, the representation of the head would be passable; but let the forehead project over so little, and there would be exaggeration of that part in the picture; or, on the contrary, recline the head back, even slightly, and although all the details might be fully rendered, yet the prominence of the jaw and the narrowing of the forehead would be something more than unbecoming; they would have properties and give effects which certainly the human eye would not recognize in the figure itself when so posed. A figure may be "foreshortened" in nature without producing the idea of distortion. Why should it not be so in a photograph? Swing backs have been adapted to cameras to assimilate the plane of the picture to the general plane of the object, but they only partly overcome the difficulty; the eye detects

that there is a fault in the representation, and the ingenuity of the photographic artist is taxed to dissimulate the deformity. It must not be forgotten that a perfect rendering of the detail of the several parts of a picture is proved to be perfectly compatible with a pseudo-perspective representation of that picture as a whole, as witness the performances of panoramic lenses, where near objects seem shown as much too large as the distant ones appear too small; and I hold that we have this in a modified degree in our portrait photography. It seems to me that the points I have named are nearly, if not quite, independent of the spherical aberration of the lens; and I think the natural and practical question arises for discussion, How far should we be from the anterior plane of the objects we wish to represent, in order that the lens should not only give the proper amount of detail, but should render all the parts in harmonious proportion?—Yours, &c., JOHN ANTHONY, M.D.

Washwood Heath, near Birmingham, October 24, 1868.

SIR,—Your correspondent, and my good friend, Mr. David Winstanley, corrects John Anthony, M.D., for an alleged error in that gentleman's communication to you on the above subject. It appears to me that Mr. Anthony is right, and Mr. Winstanley mistaken. As a practical proof I would suggest the following experiment.

Place a man twelve feet behind some transparent partition, as a sheet of glass or transparent gauge, and let him hold out his hand before his body, say at three feet distance. Let him be photographed from a lens placed at twelve feet on the opposite side of the partition, so that the subject of the photographer is twenty-four feet from the lens. Then let a mirror be substituted for the sheet of glass or gauge, let the same man take up his position by the side of the lens, twelve feet from the looking-glass, and let the photographer reproduce him (with his hand stretched out as before) from his reflected image in the glass. I will venture to say that the relative sizes of the hand in proportion to the head in the two photographs will be totally different; that is, in the first, the hand will appear enlarged to the proper proportion, considering it is three feet in advance of the head and body; in the latter, the hand will appear as if it were six feet in advance.—I am, sir, yours truly,

AUGUSTUS DULCKEN.

#### MR. FRY'S MODE OF MASKING.

SIR,—The new method of masking described in your last, as practised by Mr. Samuel Fry, seems to be very ingenious, but I fear more ingenious than practicable. It seems to me that there are several difficulties in the way of using it to good purpose. Putting aside the fact that the loss of sharpness which must arise from the use of a mask placed outside the negative must have an injurious effect, there is, I think, a still greater difficulty arising from the nature of the mask. Let me explain, for to understand the case clearly it is necessary to follow the operation carefully to its ultimate issues.

As you have described, a transparency from a negative must be exactly the converse of the negative, and a print taken from the transparency would be a negative blackest in the highest lights, lightest in the darkest shadows. When, therefore, a print wanting in half-tone, because printed from a hard negative, is placed under a transparency from the same negative and exposed to the light, it will not be the missing half-tones which will be impressed, but the lights which will be degraded. The high lights in the mask, being the most transparent, will permit the light to pass through first, gradually producing in the print a dark spot, or a series of dark spots, in the very places which should be kept as pure lights. In the parts adjoining the pure lights, the transparency admitting a little less light, the print will acquire a little detail, but in inverse ratio to its requirements, the gradation being darker towards the lights and fainter towards the shadows, an effect which must be destructive of modelling. One allusion in your article implies a knowledge of this, but the matter required, I think, more fully elucidating.—Yours,

R. F.

DEAR SIR,—I think that photographers are greatly indebted to Mr. Fry for a valuable suggestion for improving defective prints, but I think that it should be made very clear that it is only available in case of very hard negatives, and that the dodge should be applied with great judgment, otherwise a

singularly pseudoscopic effect will be produced. I fancy that the transparency should, in truth, be only used as the basis of a mask which should be judiciously worked upon, stopping parts out; and that instead of placing it outside the printing-frame, it should be placed upon the print after it has left the frame, moving it about a little, if necessary, to prevent excess of sharpness.—Very respectfully yours,  
ZETA.

October 24, 1868.

#### THE ENAMELS AT THE CORNWALL POLYTECHNIC EXHIBITION.

SIR,—In your report of the award given by the Royal Cornwall Polytechnic Society for enamel photographs you omitted to say that the medal was given for coloured enamels, no medal being given for plain enamels. In justice to Mr. Barnes and myself please correct this omission. I beg to inform you I did not exhibit any coloured enamels; what I exhibited were purely untouched pictures, not even spotted.—Yours respectfully,  
A. L. HENDERSON.

October 28th, 1868.

#### STATUS OF PHOTOGRAPHERS.

DEAR SIR,—I think it would be very desirable to hold a meeting of photographers from all parts of Britain, to assemble in London during the Photographic Society's Exhibition; it would be interesting and pleasant to meet our photographic brethren. November is generally a dull month in many respects, consequently the time to photographers is not of so much value.

Several things demand our attention which it will be well to discuss: first, the Relief Fund; then we want to devise some means to avert the ruin which stares us in the face through the ridiculously low prices which prevail in many places. While incompetent hands kept the low prices to themselves it did not matter, but when able men descend to 6s. a dozen it becomes a very serious thing. I enclose an advertisement which bears out this statement. All honour to Williams, Mayall, and a few others, for keeping to a respectable price.

Another question is, Can anything be done to raise the status of photographers? I fancy it is through a sort of Cheap-Jackism that many of us are now threatened with ruin. I should like to see a photographic college founded, at which all young photographers should pass examinations at the end of their apprenticeship; then M.P.C., or some other initial, might be taken, indicative to the public of their having been properly qualified for the position they aspire to fill. A collection of photographs and things interesting to photographers might be kept in the college, so that provincial men, when they happen to be in London, might see what is done and doing.

I fear to trespass further on your space.—Yours truly,  
PHOTOGRAPHER.

#### Talk in the Studio.

LOW PRICES, OR GOOD WORK?—A correspondent mentions a case tending to answer the question as to whether low prices, or good work and high prices, most tend to business success. He says:—"The world-famed potter, Wedgwood, when giving advice to the clay workers of Staffordshire, might, from the aptness of the remarks, have been offering counsel to the photographers of England. He cautioned the potters as a body to steer clear of the dangerous reef of low price competition, and the low price rock, but to strive, by introducing *originality and improvement*, to keep the public patronage and demand afloat. A notable instance of this is now in operation at a fashionable watering place, where prices have been for some time on the seesaw or wavering scale, where an artist—not a dauber—has appeared on the scene, and offered the world of fashion enlarged porcelain portraits at prices ranging from upwards of ten guineas each; the consequence is, that the beauty and superiority of the work cause the studio of the artist to be crowded with customers, fully demonstrating that really good work will ever maintain its way, and meet with support. The peculiarity of the medium on which these magnificent pictures are painted and worked up is a guarantee of their capability of resisting the ravages of time."

PRELIMINARY COATING OF INDIA-RUBBER.—In the course of a letter received a few days ago from M. Constant-Dellessert, of Lausanne, he remarks that he has recently used a solution of india-rubber for a preliminary coating for dry plates, in which the benzine had been so imperfectly rectified that, notwithstanding that the film was well dried at the fire, it was dissolved again when the collodion was applied, mixing with the latter and producing disastrous results. We have found that, unless the benzine be absolutely pure, chloroform is the best solvent for india-rubber for a preliminary coating. Coal-tar naphtha is an excellent solvent for india-rubber, but it should be avoided, as not sufficiently pure for preliminary coatings.

A PHOTOGRAPHER'S WIDOW.—Mr. Beattie, of Clifton, writes as follows:—"I enclose a list of those who have deemed it a duty to assist Mrs. Pearson. To-morrow I will hand over the amount to Bishop Anderson for her use. Receive my thanks for so kindly making the appeal, both in your advertising and other columns, free of all charge." The list stands as follows:—Burgess and Grimwood, Norwich, £2; Thomas Ayers, Yarmouth, 10s.; F. Davies, Dawlish, 2s. 6d.; G. E. Chertsey, 1s.; J. E. B., Cowes, 1s. 6d.; W. Mathews, Bury-st.-Edmunds, 1s.; F. B., Clifton, 2s. 6d.

PHOTOGRAPHY IN RUSSIA.—The correspondent of a daily contemporary says:—"The Czar has consented to allow photographs to be taken of all the treasures of art contained in the Imperial Gallery of the Hermitage." Photography has generally been in favour in Russia, and some of the finest photographs we have seen have been taken in Russia. We were recently favoured by General Count Nostitz with some instantaneous photographs of the Emperor's favourite riding horse, taken with a 3½ lens. Count Nostitz is an ardent amateur, and produces some exceedingly fine photographs.

MR. SOLOMON'S LAMP AT FALMOUTH.—We have pleasure in adding to the list of awards already announced in connection with the Cornwall Royal Polytechnic Exhibition, the intimation that a medal was awarded to Mr. Solomon for his magnesium lamp.

MAKING A BATH.—Mr. C. Quin gives the following minute instructions to an amateur for making a half pint nitrate bath:—"Place a piece of clean writing paper, about three inches square, in one of your scale pans, and a similar piece as a counterpoise in the other. Weigh out exactly 300 grains of nitrate of silver, taking care not to touch the salt with your fingers. A sheet of white paper should be spread on the table to catch any of the crystals that fall. The salt should be conveyed to the paper in the scale pan either with a piece of clean cardboard folded so as to form a little shovel, or else shaken out carefully. The nitrate of silver should next be thrown into a perfectly clean bottle, which is kept expressly for the purpose, and dissolved in two ounces of distilled water. When fully dissolved, weigh out a grain of iodide of potassium, dissolve it in half a drachm of distilled water, and pour it into the nitrate of silver solution. A strong deposit of yellow iodide of silver first forms, but is immediately redissolved on stirring. When once more clear, throw in a morsel of blue litmus paper and stir. If, at the end of two or three minutes, the litmus paper has not turned red, it is a proof that there is no acid present; but if, on the contrary, it changes colour, add a few drops of solution of carbonate of soda (10 grains to the ounce) and stir. The white precipitate formed will probably be redissolved. If so, add another drop or two of carbonate of soda solution until the solution remains slightly turbid after being well stirred. Next dilute the solution with eight ounces of distilled water, stirring all the time. This will produce distinct turbidity, and you must filter the solution into another bottle. Filtration is generally performed by passing the liquid through filtering paper; but as it is always best to keep nitrate of silver and organic matter apart as much as possible, a plug of cotton wool inserted in the neck of a large funnel will form the best apparatus for the purpose. A little practice will soon show you the amount of pressure to be given to the plug. The liquid should pass through in a succession of quick drops. If it does not pass clear at first, a second filtration will be necessary. Never spare any pains in filtering your bath; it is of the utmost importance that it should be perfectly clear and free from floating particles, otherwise spots and streaks will be infallibly produced."

GENERATING CHLORINE.—A Belgium chemist has devised a new process for generating chlorine. He first forms trisulphate of sesquioxide of iron, by the direct combination of this oxide

with sulphuric acid, and then mixes the trisulphate obtained with three equivalents of chloride of sodium or other convenient chloride. Upon heating the mixture in dry air the chloride of sodium yields all its chlorine.—*Chemical News.*

**MANUFACTURE OF PERMANGANATE OF POTASH.**—Some facts worthy of attention concerning the manufacture of permanganate of potash have been pointed out by M. Staedeler. In the preparation of this salt, by heating a dilute solution of the manganate, a third of the manganic acid is reduced to the state of peroxide without taking part in the reaction; the case is the same when hydrochloric acid is used to effect the transformation, notwithstanding that this process permits of the use of concentrated solutions. Things happen differently when chlorine is employed. The following is a convenient method of operating:—The crude pulverized manganate is abandoned in its own weight of water for several days; then a similar quantity of water is added, and a current of chlorine transmitted until the liquid becomes red; the solution is frequently agitated, diluted with four times its volume of water, filtered through coarsely powdered glass, and reduced to one-fifth of its original volume. At this point the permanganate crystallizes; it can be obtained in a state of purity by recrystallizations. The yield is 90 per cent. of the weight of peroxide of manganese employed.—*Ibid.*

## To Correspondents.

**BAB.**—Where two solutions have to be used in succession on the plate in developing or intensifying, they should each contain the same amount of alcohol, or such amount as will make each flow evenly without causing greasy-looking marks, caused by the imperfect mixture of the two liquids of different densities. See a short article on the subject for fuller explanation.

**A. B.**—The enquiry you make is a very important and useful one, and the answer, fully given, would be very instructive, but would, unfortunately, require several pages of our Journal, as it would involve an explanation of the difference between good work and imperfect work in almost every detail. The Bristol pictures are good examples of good workmanship throughout: well lighted, well posed, developed properly, printed and toned with taste, and, finally, well mounted and well rolled; whilst the others are faulty in all these particulars. In the Pontypool pictures the figure is, in the first place, taken on much too large a scale, giving an effect of clumsiness to the figure. The camera requires moving further from the sitter. The figure is not well lighted, too much top-light being used. The negatives are a little under-exposed and over-intensified, causing black shadows and chalky lights without detail. They are toned a little too black; not neatly mounted, and not well rolled, if rolled at all. The backgrounds and accessories are not good. The background screen should be more even and free from marks, and should be further from the figure.

**W. ANDREWS.**—The number of the *News* containing the description you require has been forwarded. You cannot do better than follow out the instructions in all respects. 2. Yes; let the bath into the bottom of the box. 3. It is customary to mount stereoscopic pictures so that any two points (say the centres of each picture) shall be about  $2\frac{1}{2}$  inches apart. Of course, if the centres are that distance apart, there will be also that distance between any two points in the pictures. The best and truest effect is obtained by leaving on a little more of the right-hand side of the subject in the right-hand picture, and of the left-hand side of the subject in the left-hand picture.

**A. SEELEY**, who seems a little inclined to indulge in badinage, sends us the following:—"Now that so much is being said about photo-engraving, I enclose two specimens of a process to be called photosketchitblackvarnishengraving, and shall be glad of your remarks thereon. It is not patented." The specimens enclosed are examples of a process introduced seven or eight years ago as photographic etching. A plate of glass is covered with an etching ground, either of black varnish or other suitable substance, and a drawing is then executed with an etching-needle, by which means an etched negative is produced, from which a print may be obtained on excited paper by the ordinary photographic printing process. The specimens enclosed, which are good examples of what may be termed the slate and pencil school of art, appear to have been executed by such a process.

**GULIELMUS (Sheffield).**—The markings you describe are very suggestive of over-iodizing. Collodion, when over-iodized, is very apt to yield just such markings as you indicate. If this be the cause in your case, the addition of a little plain collodion to the sample in use will effect a cure. Somewhat similar markings will sometimes proceed, however, from other causes. The use of a very old bath is sometimes a cause. The immersion of the plate

before it has well set is often a cause, especially at this period of the year. Moving the plate rapidly the moment it is put into the bath, and keeping it moving for half-a-minute or a minute after, proves a cure when the defect arises from other causes than over-iodizing. 2. It is a somewhat difficult task for us to say when a certain article appeared, of which you can only tell us that it was a good developing process, without giving us the title, as we have published so many, and are so frequently publishing such processes. You will find one in the present number of the *News*.

**W. J. A. G.**—By care and perseverance in the plan you describe you cannot fail of success. 2. Mr. Rejlander's address is 129, Malden Road, Haverstock Hill. You are right in your conjecture as to the "authority" it was necessary to correct, and also in your estimate of its character.

**NEW SUBSCRIBER.**—With the dimensions you propose the arrangement generally is good; but we should prefer at least three feet more glass at the north side, and one or two feet more in the north roof. In some respects No. 2 would be the best form, but the sun would trouble you in summer, so that on the whole No. 1 will be attended with the fewest troubles.

**OLD DEVELOPER.**—You can obtain a solar camera through most dealers. Mr. Atkinson, of Liverpool, will certainly supply you, and general instructions for its use will accompany the instrument. We shall have pleasure in assisting you through any specific difficulties which you may find on trying it.

**HENRY LAMB.**—The stereoscope described by Mr. Blanchard is of American manufacture. Whether it has yet been made by any one in this country or not, and if so at what price, we have not yet learnt. The amount of magnifying power in the instrument Mr. Blanchard exhibited was pretty good; but that is a point depending on the lenses with which the instrument is fitted; within a suitable range, any power of lens might be employed. The great advantages of the stereoscope in question were perfect illumination of the slide, convenience for use, facility in adjusting the focus to any sight, and some other mechanical advantages not usually possessed by existing and more expensive forms of box stereoscope. We think it will very probably be taken up by some manufacturer, in which case it will doubtless be noticed and advertised in these pages.

**F.**—Any chloride soluble in alcohol may be used. We have not noticed any special difference in the results of different chlorides. We prefer citric acid to any organic substance for the purpose which we have tried. We saw the letter to which you refer. The name was, as you conjecture, an interpolation, to cause a false suggestion. We had a letter from the writer of the letter a few days after it appeared.

**R. N. F.**—You will see some further explanations of the method of masking in question on another page.

**B. F.**—Very dilute sulphuric acid (say one part acid and four parts water) may be employed to clean lenses. Take care to rinse well afterwards, and dry thoroughly. 2. No. 3 of your list is preferable.

**M. D.**—The simplest mode of ascertaining the equivalent focus of a portrait combination is that which we suggested some years ago. Focus an engraving sharply on the ground glass, getting the image precisely the same size as the original. Then remove the lens, and measure the distance exactly between the ground glass and the engraving. One-fourth of that distance is the equivalent focus of your lens. Thanks for your good wishes.

**SILEX.**—The proportions of the room certainly present some difficulty, but such as may, we think, be overcome. The greatest is the great height of the wall—twelve feet—in which you can have no side-light. There is a method, however, of dealing with this. If you raise the floor of the room three or four feet, and so bring the sitter nearer the skylight, you will be able to submit him to a much larger volume of light, and avoid slowness. If the premises answer well in all other respects, we should be tempted to try this method. We should put in a good length of skylight, broken up with as few sash-bars as possible on the north side, and a smaller skylight, for use in dull weather, on the south side. Thanks for the paragraph, which we shall use.

**E. SAWYER.**—We have written to our correspondent, and will let you know the result next week.

**STEREO.**—Received. Thanks.  
Several Correspondents in our next.

### A PHOTOGRAPHER'S RELIEF FUND.

#### SHALL IT BE ESTABLISHED IN SIX MONTHS?

ONE of the chief obstacles to the establishment of a Photographer's Relief Fund, as to many other good projects, is the difficulty of securing a beginning. All are agreed that to commence such a project and fail to carry it to a successful issue would be mortifying in the last degree to all concerned, and would injure rather than promote the cause of charity; and as success in such a purpose cannot be quite certain, it is probable that this uncertainty may in some degree account for the inaction in the matter of practical men. We propose, therefore, to those interested in the matter, a test operation, by which some idea may be obtained of the success which will follow the completion of a satisfactory organization for the administration of a Benevolent Fund. Of the more complex machinery involved in a Provident Fund we say nothing at present.

A generous photographic amateur offered, in our columns a fortnight ago, to give fifty pounds to a fund, if within six months a satisfactory committee were formed for its administration. We simply propose to work out that idea to its legitimate issue. Let those of our readers who believe that such an organization is desirable, and that it should be formed as early as possible, follow the example of the amateur just referred to, just in such proportion as they feel disposed to contribute. They will simply have to write, undertaking to contribute as many shillings or as many pounds, either as donations or annual subscriptions, as they think right to give, on condition that a satisfactory committee be formed for its administration within six months. We shall neither receive subscriptions nor publish names at present, but shall preserve a record of the offers, and in due time publish the result—that is, the amount of money conditionally promised. If the promise of success justify further action, we think that it will not be difficult to induce a committee of capable and trustworthy men to undertake the necessary steps for forming a permanent organization for administering the fund. This done, a treasurer would be appointed, to whom the contributions might be forwarded direct, and who would duly publish his acknowledgments. If, on the other hand, the response to an invitation like this be insufficient to justify any permanent organization, that part of the question will be set at rest for the present.

This plan will, we think, afford a practical means of testing the question as to how far a general conviction prevails as to the need of such an organization, and how far a widespread willingness to contribute to such a fund exists. Besides tending to settle these questions and some others raised by a correspondent whose letter appears on another page, it affords an opportunity for those interested in the question to commit themselves at once to some tangible step. We shall hope to hear from many of our readers.

### THE EFFECT OF MANIPULATION ON THE CHARACTER OF NEGATIVES.

MOST experienced photographers have observed in the course of their practice that the mode of manipulation has some effect on the character of the finished work: not merely in what may be termed the mechanical character of the result, but also on points that might be supposed to be due to chemical action. Of course it is natural enough to expect that careless manipulation should produce such defects as uneven films, stains, and other irregularities; but it would scarcely, at first glance, appear a matter of course that hardness or softness, excess of detail or intensity, should be largely due to purely manipulatory causes. There are, however, various modes in which manipulation may influence the character of the result, some of which are familiar to practical photographers; but we are about to point to one which is, we believe, unfamiliar—at any rate it has not before been pointed out.

The fact to which we are about to refer was pointed out to us by one of our most successful professional photographers, who, having observed the circumstance accidentally, proceeded, in the course of considerable experience during the summer with large plates, to test the matter carefully, so as to leave no doubt as to the certainty of the results. His position is this: that in using precisely the same materials, in the same proportions, with the same exposure, a negative in which harmony and softness shall prevail, or one in which contrast and intensity shall prevail, may be produced at will by the mode of manipulating during development. Some operators will be disposed here to exclaim, "Of course it will depend upon whether the free silver solution be driven off the plate, or retained when the developer is poured on." It is true that this would affect the result, a less vigorous negative being produced when the silver solution is driven off by the mode of applying the developer; but this is not what is meant. The difference to which we refer, between the prevalence of contrast or detail, will depend upon the mode of holding the plate, and whether it is held still or kept in motion. Assuming that the chemicals, &c., are in good condition, and the exposure right, if the plate be held still after the developer is applied, a soft harmonious negative full of detail will be the result; whilst, all the conditions remaining the same, if the plate be kept in constant motion after the developer is applied, a negative in which contrast and intensity rather than detail prevail will be invariably obtained. These are the facts brought under our attention as the result of careful observation, no theory being offered in explanation of them.

The facts, it must be admitted, at first glance, seem singular enough, nothing in the means being apparently adequate to produce the end; but we think we can offer an explanation of the probable causes in operation which will account satisfactorily for the result. When an ordinary developer is applied to the exposed film, it will be observed that the high lights appear first, the half lights following, and so in regular succession, the least illuminated details being developed last. It will also be observed that in the process of development there is a natural tendency to aggregation in the deposit of silver: wherever light has most acted, there silver will be most readily precipitated, and hence, in an under-exposed picture, the lights acquire great density before imperfectly illuminated details are brought out at all. It must be borne in mind that whilst the haloid salts of silver in the film—the iodide and bromide—form the initial image, appreciable thickness and printing power are obtained from the free nitrate on the film. If these facts are borne in mind, then, it will be seen that after the developer is applied a double action is in progress, the image formed by light on the bromo-iodide of silver is in course of development, and the free nitrate of silver present is in course of precipitation on that image, giving it a certain degree of appreciable density, the rapidity of the precipitation of silver being in the ratio in which light has acted. If, then, the plate be kept still, the free nitrate of silver, being equally spread over the surface of the plate, is gradually precipitated, and the lesser lights, commonly called the detail, slowly but surely acquire sufficient density from the precipitation of the nitrate of silver immediately in contact to give them printing value; and the higher lights, only securing the precipitation upon them of as much free nitrate as is in contact with them, do not acquire excess of density. The result is a negative in which detail rather than intensity prevails. But if, on the other hand, the plate be kept moving, the tendency to aggregation is brought into active operation. The free nitrate solution being kept in motion over various parts of the plate, the lights, which are brought out first, having secured the precipitation upon themselves of the silver solution in immediate contact with them, find themselves in constant contact with a fresh supply, which in turn is precipitated upon the parts which in virtue of the greater action of light have the greater attraction for it. The lights thus go on rapidly aggregating the deposit of silver. In the meantime the minor lights, consisting of the detail in the shadows, suffer in two ways: first, they are robbed of the silver which should have helped to build them up; and in the next place, the high lights quickly acquiring sufficient density, the development is stopped, of necessity, before the less illuminated portions have had time for full development.

We think that on this view of the case it will be seen that it is perfectly natural that keeping the plate in motion should tend to give intensity to the lights, and keeping it still should tend to give full value to the less illuminated details. We have before pointed out that the use of a weak developer tends to the production of contrast, and the use of a strong developer to harmony, the tendency in both cases being due to causes similar to those we have just explained: a weak developer, acting slowly, permits of the aggregation of deposit by the lights, whilst a strong developer, acting quickly, brings out the detail rapidly, and, at the same time, precipitates the full proportion of silver thereon.

Our own observation has confirmed the view of the effect of manipulation which we have here set forth; and we doubt not that it will be borne out by the observation of intelligent photographers, especially where large plates are used, which of course afford the best illustration of the facts involved. A knowledge of facts of this kind will not only frequently be found useful, but will go far to explain the production of discrepant results with the same materials by different operators.

## ECHOES OF THE MONTH.

BY AN OLD PHOTOGRAPHER.

PRESENTATION PRINTS—MR. FRY'S MODE OF MASKING—PHOTOGRAPHIC EXHIBITION—PHOTOGRAPHERS' RELIEF FUND—FALSE REPORTS—SOCIETIES.

It has often struck me that the distribution of presentation prints is one of the most useful, as well as one of the most pleasant, of the duties of photographic societies. If the office of the committee of selection be exercised with judgment, the prints so distributed may possess a highly educational character. Examples of novelty in process, of skill in mechanical or chemical treatment, or excellence in art, thus distributed by societies, often teach more forcibly and practically than many papers or the discussions thereon. The North and South London Societies have both admirably carried out this function of a society. They have both been amongst the first to present examples of carbon printing to their members. They have both aimed at giving examples of the work of the great masters in photography, men who excel alike in the technical and the artistic qualities of their work. I find the names of Bedford, Mudd, Rejlander, Robinson, Lake Price, Blanchard, Bingham, Wilson, Vernon Heath, Frank Good, Cherrill, and Woodbury amongst those whose works have been distributed amongst the members of these two societies.

The last distribution of the North London Society is surely the most extraordinarily liberal one which was ever made under similar circumstances. Let it be remembered at the outset that the subscription to this Society is but half a guinea a year, and that after the payment of necessary expenses the balance only can be devoted to the purchase of presentation prints. The prints distributed this year must, however, estimated commercially, have been worth three or four times the amount of the annual subscription. First, there was a magnificent 12 by 10 subject-picture by Lake Price, entitled "The Falconer," never before published; next, a 16 by 12 landscape by Mr. Cherrill, with the most glorious clouds ever produced, I think, in so large a photograph; and next, two whole-plate studies by Rejlander, printed by Woodbury's process. All these were mounted on good cardboard—not plate paper—with India tinted mounts. The South London present their members with one of Rejlander's charming studies, and a splendid carbon print, 16 by 12, from one of Robinson's subject-pictures. The members of the London Photographic Society have their prints yet to receive; but prints from Mayall, England, and Robinson are promised.

The suggestion of Mr. Fry for a novel mode of masking is very ingenious, and may doubtless, in many cases, prove eminently useful. A photographer will, of course, always try to produce harmonious negatives, through which the printing of all parts will go on in due order, without masking or retarding in any part; but, despite the greatest skill, over-dense negatives will sometimes be obtained, and special subjects will at times present special peculiarities which render masking imperative, and the transparent positive undoubtedly presents the best bases for a mask which can possibly be obtained. I say bases for a mask, because I apprehend that, in the majority of instances, the photographer of taste will see something in the light and shade of his picture which may be modified and improved by working on the mask.

I have been gratified to find generally prevailing amongst photographers whom I meet a pleasant anticipation of the forthcoming exhibition of the Photographic Society, and of the social reunion with which it is to open. It seems to be a general opinion that the easy absence of formality which prevailed at the last exhibition meeting rendered it much more agreeable than a conversazione at which evening dress is *de rigueur*. I look forward with interest to the display of pictures, especially in the department of portraiture, in which I expect to see a considerable revolution

since last year, the change being in many respects for the better. There will doubtless be a considerable prevalence of what a facetious friend terms "Salomoniac" pictures. I have seen many capital examples, and heard of many more. The first impulse of many English photographers was to wonder at the photographs of the artistic Frenchman; next to derry them; and since then has come the better phase, and the tendency is to profit by them, and we shall see the results, doubtless, at this exhibition. Some have been deterred from attempting anything of this kind from a feeling of dislike to the notion of imitating. I do not think that adopting a new style and aiming at a new phase of excellence should be regarded as imitation. If it were so, every one who has taken card portraits is an imitator. But it is quite possible to adopt a style without imitating individual examples of that style; and such adoption is not only permissible, but is often praiseworthy. Taking a high place amongst the specimens of this new style will be found the contributions of Mr. V. Blanchard, many of which are most admirable. M. Fradelle will, I believe, exhibit similar pictures, in the production of which I am told he is doing a very large business. Mr. Fry will, I believe, exhibit some fine examples of the same kind. Mr. Leake has done exceedingly good work in this direction, and I hope he will send some specimens to Conduit Street. I have seen some examples by Messrs. Robinson and Cherrill, which have been mistaken for Salomon's pictures; and I am told that they have a fine series which I have not seen, some of which will doubtless be sent to this exhibition. Mr. N. Briggs, of Leamington, will doubtless send his prize picture and others of the same kind. He contributed to the Falmouth exhibition something styled in the catalogue "Emolliotypes," specimens of which we may hope to see, and learn something of their character. Robinson's "Returning Home" will doubtless be there; and examples of Mr. England's last summer's work, produced by the wet process, by the way, to which, for this season, at least, I understand, he returned. I believe we shall have some examples of the charming works—both in portraiture and shipping—of Mr. Hughes; and of the summer's work of Bedford, and of Gordon, and scores of others, so that the exhibition can scarcely fail to be an attractive one.

The offer recently made in your pages of a donation of fifty pounds towards a benevolent fund will surely stimulate effort to initiate a society of some kind; but it appears to me that the proposition for forming such a fund has not excited the universal interest which might have been expected. Letters have appeared from time to time in your pages referring to it as a desirable thing, but it has not been discussed in detail. It has not been brought forward at photographic societies, nor talked of much in the circles in which photographers most do congregate. Is it because photographers, as a rule, are not poor, and do not see the prospect of poverty, or because the number of those amongst them most likely to feel the pinch of necessity do not make their voices heard?

Apropos of some false reports which the editor deemed it right to contradict, I was struck with some remarks of a cynical philosopher in a recent number of *Belgravia*, on the subject of false reports. I suppose it is at times necessary to correct special misstatements, but I cannot help agreeing considerably, on such subjects, with the philosopher, whose words I will, with your permission, quote:—"If," says he, "you wish to get on comfortably in this world, it is best to allow your brother, and your sister too—by whom I mean everybody—to lie themselves black in the face; so long as they refrain from forging your name, and so getting you into pecuniary trouble, they can't do you much harm. Leave it to Mr. Carlyle's Eternals in their own good time to proclaim the truth. As a rule, it is impossible for any man thoroughly to disprove nine hundred and ninety-nine out of a thousand falsehoods;" and hence, he argues, it is not worth the trouble to try. Dan O'Connell used to say,

"Give a lie ten days' start, and the truth will never overtake it." I object, however, to this pessimist doctrine; I fancy that lies, as well as curses, are like chickens, and come home to roost, and that "ever the truth comes uppermost, and ever is justice done." So mote it be.

The societies generally have recommenced their meetings. The North London had a capital paper from Mr. Cherrill, of a character a little too abstract, perhaps, for discussion generally, although a somewhat animated discussion arose incidentally out of it, regarding the quality of albuminized paper, and the proportion of salt employed. Some of the members thought if they knew the proportion of chloride used with the albumen in preparing paper they could more readily determine the proper strength of silver solution necessary to begin with, and the proportion of silver necessary to maintain that strength. Albuminizers seem to think that such information is not necessary: that the skilled printer will quickly learn by experience the kind of treatment necessary for any sample of paper, and that the unskilled printer is scarcely worth considering. The argument is bad, I think, in both cases; and the time will come when the proportion of salt used will be marked on the paper as a matter of course.

At the South London a somewhat unusual subject for a photographic society was discussed. Mr. Blanchard exhibited and described an American stereoscope. It possessed three especial points of superiority over most of the instruments familiar at this side of the Atlantic: it was perfectly open; permitted the slide to be well illuminated by artificial light, which few ordinary instruments permit with any convenience; it permitted ready and extensive adjustment to the focus of various eyes; and it was simple and cheap. Mr. Blanchard thought that the introduction of such a stereoscope to the public would give a new stimulus to the demand for stereoscopic pictures. I hope that the instrument will be shortly introduced into commerce. The Liverpool and Edinburgh Societies have had good meetings, but no point of especial novelty was introduced.

## BACKGROUNDS AND ACCESSORIES.

BY J. MARTIN.

MUCH has been said and written upon the management and painting of scenic backgrounds and accessories for the studio, and many complaints have been made (with good cause) of their unnatural and disjointed effect. I think the great requisite—truth of perspective—has been overlooked and neglected; often, I fear, from a want of knowledge, both in the photographer and the painter. It need cost no more trouble or expense to make them correctly designed than otherwise.

I consider the greatest requirement with pictorial backgrounds and accessories is that they should be painted *en suite*, meaning from the same point of distance. This will be determined by the distance the camera is to be placed from them; this, again, must be governed in most cases by the length of the studio in which they are to be used. Thus executed they will, when arranged in their proper situations, appear together in true perspective from one certain spot which is the true point of view. At this place the camera should stand, and, whatever the size of the photograph to be produced, should always remain there, and never be shifted either nearer to or further from the background, or from side to side, as is often done. Following this method it is necessary to use cameras and lenses of various sizes, but not so various as might be expected, as pictorial backgrounds and accessories are seldom needed except for full or three part length figures or groups. Heads or busts, for vignetting, are best executed on plain backgrounds of a light colour. Half or three part length portraits look well with a graduated plain background, so arranged as to bring the shaded side against the light side of the head. If any accessory is used, let it be, in such pictures, some simply

designed *solid object*, placed in half shade; in these cases the camera may be moved *ad libitum*, as in plain backgrounds; there are no perspective lines to distort, and solid accessories vary their perspective with truth according as the point of sight is altered.

To prove that this proposition is founded on correct theory, let the reader, by way of experiment, study the appearance of solid and painted objects from various points upon the ground glass of the camera, and he will find that solids will retain their truth of perspective when seen from any angle of view, whereas painted ones will, from any other than their proper point of distance, appear distorted. How ridiculous, then, must be the effect of a number of such articles, each having its own point of sight, jumbled together in one picture! The most perfect scenic representations are to be found at the theatres; from them we should borrow our theory, and, as far as possible, follow their practice in these matters. Stage painters always arrange their perspective from what is sometimes called the painter's point: this is the front box, in the lower tier, behind the pit; from this

spot the scenery and side slips all unite in pictorial effect so naturally as to appear marvellous. Now step into one of the side boxes near the stage, and the enchantment will vanish, the scenery will appear badly arranged, and the perspective false, for you are no longer looking at it from the proper point of view; before, however, leaving this box, notice the stage floor, and you will find that it slopes upwards towards the horizontal line of the scene, and is so arranged as to make the stage appear much longer than it really is. Thinking that this principle might, perhaps, prove of service where scenic effects are required, I send you a diagram and explanation of the method of finding the correct inclination of any floor, for any proposed increase of apparent length. The diagram will explain the principle whereby the appearance of increased depth is given to the stage by theatrical painters, and which, I think, might be used to some advantage by photographers.

Suppose, for example, a studio which will allow 30 feet in length from the camera lens to the background; place the camera at A, the lens being 4 feet from the floor

or base-line B, which must be drawn to scale of such a length as the stage is required to appear, which we will suppose, in this case, to be 60 feet. The height of the lens from the ground will give the height of the horizontal line in the scene. Now mark off from the lens upon the base-line 15 feet, and make a mark; this will give the space requisite for general convenience, which in a theatre would represent the pit or space between the front box and the stage. Make also a perpendicular line at 30 feet; this gives the real length of the studio between the lens and the background; draw a line down from the lens to the end of the base-line at 60 feet, and where it crosses the perpendicular line made to represent the real distance of the background from the camera is the height to which the floor or stage is to be raised, and it will correspond with the horizontal line at the height given for the camera lens. The real length of the stage is not arbitrary, but may be varied in proportion to that of the pit; but the rise in the floor should not commence nearer to the lens than the width of the scene to be represented. In short studios the apparent increase of length will be circumscribed, as the greater the apparent length in proportion to the real length, the greater the rise of the floor must be, and therefore the more acute the angle of the floor from the base-line. A low horizontal line will be found preferable in scenic effects as accessories to portraiture for many reasons: it gives, for instance, a nobility of appearance to the figure; the head and shoulders are thus placed against the sky, and are not cut by the horizontal lines in the scene; the camera is not tilted, and the faint colour of the sky and distance gives relief to the head without needing its shadows to be heavy; it avoids, also, the chance of the comical effect which might be produced by the conical summit of some neighbouring hill appearing as a cap of liberty on a gentleman's head, or, in case of a profile, a too strongly-marked representation of a river issuing from his mouth. Care should, in all cases, be taken by the painter that the scene is not too pronounced. Painters provide a platform or high chair on which they seat their patrons, and by this means the horizontal lines are made to conform with the picture to be painted. The horizontal line is an attribute of vision, and its laws are unalterable; photographers should understand that as they do not use their heads as cameras, or their eyes as lenses, but instruments made by the opticians, they therefore delegate the power of seeing and representing the intended picture to

these instruments; hence, under whatever circumstances and in whatever position they place them as regards the scene before them, so accordingly will they represent the picture they produce, and not as they themselves may view it. Such being the case, they can only hope to obtain scenic representations in correct perspective by placing the camera always at the painter's point, at the same time taking care to have their scenes and slips executed correctly to suit it.

I cannot well leave this subject without saying a few words upon light and shade; these are, in fact, parts of the study of perspective, and the correct application of their laws is essential to truth in scenic effects. Studios, if happily situated, do not admit the entrance of direct sunlight, or, by the arrangement of blinds and shutters, it is prevented. These arrangements ought to be capable of producing a variety of effects, and of throwing the light at such angles upon the sitter as the artist may think fit; as the lights and shadows of scenic backgrounds are not produced by projecting angles, but painted in by light and dark colours upon a flat surface, they will not alter according to the angle of the light in the studio. Therefore, before having his backgrounds painted, the photographer should experiment in his studio until he finds the most agreeable angle of light under which he can generally operate, and then direct his scene-painter to throw the lights and shadows on his backgrounds. Accordingly, thus having the perspective and light and shade of his scenes and of his figures agreeing according to rule, he may hope to achieve a great success in truth of pictorial effect, provided the camera is placed at the proper point.

#### INSTRUCTIONS FOR POSING.

In a letter to the *Pulletin Belge de la Photographie*, M. Omer Bordeau communicates the method adopted by one of his professional photographic friends for the purpose of rendering sitters tractable when under the influence of the camera. The plan followed by this gentleman is to hang up in the studio a large placard of instructions, which may be read and thought over by those who frequent his establishment; and the short and concise nature of these rules, as also the ludicrous final warning held up as a punishment to evil doers, no doubt very materially contribute towards the creation of the cheerful and natural faces of the portraits to be seen among his collection. For this reason we do not

hesitate to give our readers a copy of the instructions in question, for the end justifies the means, and in photography, especially, all methods are good which lead to good results.

1. Choose your own natural position, without inconvenience, affectation, or constraint.

2. Do not condemn yourself to painful immobility before the photographer desires you to remain quiet.

3. When the time of exposure commences, which will not last very long, preserve an absolutely immovable position, looking steadily at any object that the photographer has pointed out. Assume an easy attitude, and put on a pleasing expression, so that the lens may not reproduce a fatigued, stern, and solemn countenance which will certainly not be your own.

4. Do not omit to close your eyes if you should feel it necessary so to do; but be careful to assume the same look and expression as before immediately afterwards.

5. Ladies will do well to avoid perfectly white dresses or bodies, which appear in the photograph as a hideous white patch without detail.

6. The success of the portrait depends upon an intelligent execution of these instructions.

7. In case of infraction of any of these rules the criminal law of photography condemns you to receive a portrait without a head. BEWARE!

### COLLODIO-BROMIDE DRY PLATES.

BY M. CAREY LEA.\*

I PUBLISHED last spring an extremely simple and easy process for preparing dry plates. During the interval I have had inquiries from several who had tried the method, and who had found the plates comparatively insensitive. Never having had much trouble myself with them, I was surprised at this complaint, but was able, however, to say that probably the sensitive mixture had not been left to stand long enough before using. On returning to the city recently, after an extended absence, I proceeded to prepare some of these plates, and having previously had regular and unvarying success, I took them out with me without the precaution of trying the plates. I found them to require long exposures, and to give a weak and poor image.

Now, having traced out without difficulty the source of the trouble, I find it to be exactly such as must meet almost every one who tries the process, at the very start, and this may deter many from prosecuting a process that might, after all, suit them perfectly. I shall, therefore, show the way of obviating this insensitiveness with ease and certainty.

Those who practise any collodio-bromide method always sensitize with nitrate of silver about twice as much collodion as they want; the residue only requires the addition of a little plain collodion to keep for many weeks. The corresponding quantity of nitrate of silver to the plain collodion so added can be put in twelve hours before wanted.

The secret lies in this residue, which, if in good sensitive order, has the property of bringing up the fresh collodion added to a proper condition. It is where one starts afresh after a long interval, and has no such residue to begin with, that the trouble of insensitiveness shows itself. And this is exactly the position of every one who tries the process for the first time.

In order, therefore, to get a fair start, the following will be found useful:—

Take 8 ounces of the plain bromized collodion as below, and sensitize it with  $21\frac{1}{2}$  grains of nitrate of silver to the ounce, viz., 172 grains. Let it stand, with occasional shaking, for ten or twelve hours. Next add some of the same plain collodion (say 4 ounces), and let it stand, with occasional shaking, for two or three days; then, about ten or twelve hours before coating the plates, add the nitrate of

silver corresponding to the last addition of plain collodion (if, as above, it were 4 ounces, add 86 grains); shake several times at intervals of an hour or two; let it stand six or eight hours, and either decant or filter.

After use, add about the quantity of plain collodion that will replace what has been consumed. Have thick, brown paper pasted over the bottle, and on this mark the quantity added. Shake, and set aside. Ten or twelve hours before the next occasion for using, add nitrate of silver according to the quantity of plain collodion last put in and noted.

A curious change takes place in the collodion after sensitizing. After some times it gives a bluish film, transparent enough to allow exterior objects to be plainly distinguished through it. Then it changes and gives a film so opaque that I have often been unable to distinguish the bars of the yellow window through it. This is the sensitive condition. It is acquired without difficulty when there has been a residue of a previous lot, but this opaque condition requires several days, sometimes, to appear with entirely fresh material, even when the collodion is six months old.

All the above is applicable to all the varieties of the collodio-bromide process, not especially to mine. My form of the process is the simplest of all modes of preparing dry plates, as there is but one bath of any kind needed, and no washing. As I have modified my formula, I give that here which I now use:—

COLLODION.				
Alcohol	...	...	...	15 ounces
Ether	...	...	...	20 "
Bromide of cadmium	...	...	...	375 grains
Bromide of ammonia	...	...	...	60 "
Pyroxyliue	...	...	...	210 "

Let it stand two weeks.

The cotton must be very intense. I prefer "Helion No. 1," to be sensitized with very finely pulverized nitrate of silver,  $21\frac{1}{2}$  grains to the ounce. Fused nitrate answers best.

The bath is prepared as follows:—

*Lead Solution.*—Dissolve a quarter of an ounce of acetate of lead in 2 pounds of acetic acid No. 8. Filter.

*Gallic Solution.*—Dissolve 1 ounce of gallic acid in  $4\frac{1}{2}$  ounces of alcohol. (Pour  $4\frac{1}{2}$  ounces of alcohol into an ounce bottle of gallic acid, and let stand twenty-four hours). Filter. For 4-4 plates, or smaller, take—

Water	...	...	...	6 ounces
Lead solution	...	...	...	1 ounce
Gallic solution	...	...	...	$\frac{1}{4}$ "

Mix well; filtering is unnecessary. I have already explained the usefulness of adding litmus to this, to colour the plates, and prevent blurring. To such as have not the former paper at hand I may say, briefly: Cover one quarter pound of litmus with boiling water, and set away in a warm place, covered, for a day or two. Throw on a filter, and pour on hot water till about 20 ounces have run through. Add 4 or 5 ounces alcohol to make it keep. Into the above bath pour as much of this as will render it, in consequence of the acetic acid contained, blood-red, 2 or 3 drachms, depending upon the quality of the litmus. The plates should be rendered light-pink.

Into this bath of lead, gallic acid, and litmus, plates coated with the sensitized collodion are plunged as soon as they have set, precisely as if they were being placed in a negative bath. May remain in till all redness disappears, and then, without any washing, before or after, are simply dried. Nothing can be briefer or simpler.

I have generally found it necessary—or, at least, useful—to edge all dry plates with india-rubber dissolved in benzine, 5 or 6 grains to the ounce. A camel's hair brush is held to a glass rod, which extends one half inch below the point of the brush. This is run round the corner of the plate so as to leave a rim about 3-16 inch wide. In five minutes the plates may be coated. The brushing off with a wide brush,

\* From advance sheets of the *Philadelphia Photographer* for November.

to get rid of dust, should be done immediately before collodionizing, not before edging.

Since I first published the process I have had an excellent opportunity of testing the keeping qualities of the plates.

Some plates prepared and intended to have been used at once were left for near six months in the slides, and, in spite of the almost unexampled heat of July last, were found in September to be in good condition, and to have lost none of their sensitiveness. In fact, they could not be distinguished by their behaviour from plates prepared a few days before. The importance of this quality does not need to be dwelt upon.

## PICTORIAL EFFECT IN PHOTOGRAPHY;

BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.

BY H. P. ROBINSON.

### CHAPTER XL.

IN some of the later chapters I have introduced complicated groups of figures with landscape backgrounds, which, to those who are unacquainted with the scope of our art, may appear impossible in photography. Indeed, some of those who do not hesitate to show in print how limited is their knowledge, have pointed out that a group on different planes could not be secured by the aid of lenses and chemicals, and that it was impossible to pay proper attention to the individual constituents of a large group of figures. I may answer, that my object in introducing these groups from paintings has not been to offer to photographers examples for exact imitation, but that it may be shown how immutable laws exist in all good works of art, whether that art is exemplified in the lowest subjects or the highest; that the laws of balance, contrast, unity, repetition, repose, and harmony, are to be found in all good work, and that the arrangement of the general form of nearly all pictures is based on the diagonal line and the pyramid. I have thought it of more consequence to fix these facts on the mind of the student than to set before him examples for imitation, however good, which he would have blindly to follow without understanding and without profit.

But the scope of photography is wider than those who have only taken a portrait or a landscape suppose. There has not been a single group introduced into these lessons that could not have been reproduced from life by the means our art places at our disposal. I do not mean to assert that a subject containing so many difficulties as Goodall's "Swing," for instance, has ever been done in photography, but it is not so much the fault of the art as of the artists, that such a picture has not been successfully attempted. It has not been the failing of the materials, unplastic as they are when compared with paint and pencils; it has been the absence of the requisite amount of skill in the photographer in the use of them, that will account for the dearth of great works in photography.

To show that large groups are not only possible, but comparatively easy of execution when they are considered seriously and with a determination to succeed, I introduce, for illustration this week, one of my own pictures, taken some years ago, when photographers had much less facilities for producing good work than they have at the present time. The engraving is a reduction, by Mr. Fruwirth, of one which appeared originally in the *Illustrated London News*, but of a larger size,\* and is the only one I have given

of my own works, one of which I should not have given as an example at all had I been able conveniently to obtain a picture by any other photographer that illustrated my proposition so clearly. But photographers shun this kind of work more, I believe, because they think it less profitable than portraits, than from inability in some of them to do much better work than I here take for illustration. I also take this picture because the engraver has more nearly given the effect of the photograph than some others of mine that have been engraved. The original photograph is 22 by 17 inches in size, and was taken in seven negatives, and afterwards printed together by combination printing.

This plan, besides other advantages—such as the obtaining objects on different planes, and getting larger pictures than by any other method, with the exception of enlargement—enables the operator to devote all his attention to a single figure or sub-group at a time, so that if any part is imperfect from any cause, it can be substituted by another without the loss of the whole picture, as would be the case if taken at one operation.

I shall leave the now advanced student to determine for himself the principles on which the composition is based, and to do, I hope, better things in the same direction.

## ON INTENSIFYING WEAK NEGATIVES.

BY M. H. A. ECKERT, OF PRAGUE.\*

I DEVELOP my plate with the ordinary iron solution, and after it has been thoroughly washed, I proceed at once with the fixing. After this, the plate is again well washed, and placed in a porcelain dish containing sufficient clean rain or river water to cover the negative; the water should, if possible, be filtered. Every negative taken during my day's work, which lasts five hours, is treated in this manner, and

facts already existing; and, however we may doubt their ever attaining to the perfection they aspire to, so as to supersede the pencil or the graver, we must admit that some of the things they have lately done are of great merit, and strikingly effective in the result. Mr. H. P. Robinson is one of the most successful labourers in this field. His painfully real little group-picture entitled "Fading Away," representing a young girl leaning back in an arm-chair, apparently in the last stages of decline, for a short season attracted groups of admirers round the windows of the photograph dealers. This year he produces a pleasanter and also a more extensive and elaborate subject, which is deservedly hung in the place of honour in the exhibition of the Photographic Society, and which he entitles "A Holiday in the Wood." We give an engraving of this picture, the subject of which is a party of rustic children amusing themselves in a thickly shaded spot on the outskirts of a wood, on a bright day in summer. In the centre, seated on a bank, are three young girls, one of whom is weaving garlands of wild flowers, whilst a younger companion peers over her shoulder, watching the process with engrossing interest; the third, a healthy specimen of rude country life, is carelessly lying on the ground, and laughing heartily at the harsh airs of a pretty little child in the foreground, around whose head another of the party is intently engaged twining a wreath of woodbine. Further back, and on the very top of the mound, is a girl with her back towards us, vigorously hailing some of her companions who are newly arriving at the wood. In the mid-distance, two other little girls are seen advancing through a woodland path, basket in hand, to join the holiday party. The whole scene is closed by a picturesque background of oak and other trees, which give a character to the situation in complete harmony with the sentiment of the little incident commemorated.

"We must award high praise to Mr. Robinson for the judgment and eye for effect with which he has arranged his figures, and for the graceful combination and plan of outline which is the result. The little sisters themselves, also, are to be commended for the attention which they have obviously paid to his instructions, and the efforts they make to appear as much at ease as possible. Complete self-obliviousness and spontaneity of action were, of course, not to be looked for; but as much has been done towards their realization in the present production as could be expected.

"This interesting specimen of the photographic art measures twenty-two inches by seventeen."

The *Daily News* of January 14, 1861, had also a long and appreciative notice of this picture, from which we make a few brief extracts. After some remarks on the great "artistic knowledge" displayed, and the power which the artistic qualities had to make the picture "dwell on the memory," it describes it as follows:—"A number of children are playing in the recess of a wood, which is one inextricable tangle of wildly picturesque and luxuriant vegetation. The three central figures seem hatched in sunshine, their flaxen hair flowing like a golden halo. Placed upon a turfy pedestal, they are arranged in attitudes of perfectly natural rustic grace, yet, without, the group they form has a chaste elegance almost Greek and monumental. The other children are posed with almost equal felicity, and the harmonious grouping of such subjects is quite marvellous. We think, without exception, this is the choicest and most beautiful photograph we have ever seen." Praise of this kind from an accomplished art critic is gratifying to all photographers who are proud of the triumphs of their art.—ED. PHOTO. NEWS.

\* *Photographische Correspondenz.*

\* As any comment on the picture itself is manifestly inadmissible from Mr. Robinson's pen, it may probably interest the reader to know how such a picture was received, seven or eight years ago by the art critics of the outside press. The *Illustrated London News* had the following remarks on the picture when it first appeared:—

"A HOLIDAY IN THE WOOD": Photograph from Nature. By HENRY P. ROBINSON.

"PHOTOGRAPHERS are every day making determined efforts to apply their art as a direct means of producing original pictorial compositions, showing the mind and will of the artist instead of the mere accidental condition of

laid one upon the other in the dish until the whole number of negatives has been completed.

I now proceed to intensify by means of two solutions prepared as follows:—

1. Two ounces sulphate of iron dissolved in 3 pounds of water, and filtered.

2. Half an ounce of nitrate of silver dissolved in 20 ounces of water.

The first plate is taken from the water bath, and if, on inspection, more density seems desirable, it is treated thus:—

The negative is first rinsed in clean water and allowed to drain for ten or twelve seconds, and solution 1 is then poured on; the liquid is allowed to flow equally over the plate, and when the latter has been sufficiently impregnated with it, the negative is again drained. Solution 2 is now applied in such a manner that it is made to cover the surface quickly and evenly. The manner in which the iron solution acts upon the nitrate, changing the latter into metallic silver, and thus strengthening the image, may be easily observed during this operation.

By proceeding in this manner the most successful effects may be obtained, as the operation is carried on in the light, and may be repeated as often as necessary, until the desired amount of density is obtained. The shadows remain very deep, the lights are brought out, and yet the picture does not become hard or possessed of too much contrast, as is often the case when pyrogallic acid is used for intensifying.

To those who employ hyposulphite of soda as a fixing agent I would strongly recommend the placing of their negatives, after fixing, for some time in filtered rain or river water, as by this means the fixing material, and especially soda, is totally removed, whereby the film is guaranteed from splitting after it has been varnished; for it is well known that such plates are most liable to injury in this manner which have been insufficiently washed, from the fact that the trace of cyanide of potassium or hyposulphite of soda still attached to them is apt to absorb moisture from the atmosphere.

Formerly I always used soda as my fixing agent; but I now use cyanide of potassium, the employment of which I certainly recommend to all photographers. Many gentlemen would, no doubt, object to keeping plates for a whole day in water, for fear of the collodion film becoming separated; but my experience goes to prove that only those films are liable to separation from the glass where the collodion has been poured upon an insufficiently cleaned plate, or where the collodion used has a tendency to become acid. As a matter of course, care must be taken not to employ water for washing which is even slightly acid.

## Correspondence.

### A BUNDLE OF OLD LETTERS.

#### ALBUMINIZED PAPER AND PRINTING—NORTH AND SOUTH LIGHT—PHOTOGRAPHY AND PERSPECTIVE.

SIR,—Time flies apace. Here we are in November; only two months more, and then for another year!—then for the anxious watching for the lengthening of the days!—then again for the glorious work out of doors, over hills and dales, with the summer breezes flapping the tent-cover as a delicate intimation to goats and other winged "varmint" that the operator is at work, and must not be disturbed, even if they are hungry!

But, meantime, the winter—the long, dreary winter—has many a charm to the photographer. There are the glorious meetings of the societies, the reports of all that was said and done at them in the journals, and then, a week or two later, the clumsy cribs from more respectable papers by the little ones, who are as yet too small to have reporters of their own, or who are too fierce, or unfair, or untruthful, in their juvenile enthusiasm, to be allowed to send reporters to the meetings. All

this is great fun to those who take a real, hearty interest in the profession. And then, too, infinite good is done by the liberal discussion of various topics which are turned up from time to time, either in the papers or the meetings of the societies.

I do not think that as a profession photography would get on well without the winter. It is a time of comparative rest; a time when one can sit down quietly at one's own fireside, and think over the next year's pictures; when the study of art can be continued with so much advantage from books; when comparisons can so well be made between what the work of the year has been, and what it should have been. Winter should, in fact, be a time of repentance for all the sins and failings of the past, and also a time for making high resolves for the ensuing season.

Besides all this, however, winter is, above all, the time for recording the experience gained during the season which is past; and I hold it the duty of all who wish to promote the advancement of our art freely to tell, for the good of others, all the experience they have gained, and especially when their gains have been in a great measure the result of the liberality of others. There is no photographer of position or ability in the art who would not thank even the humblest operator for a suggestion which might prove useful, and therefore none need fear, however small the amount of information they may have to communicate, for it is sure to be accepted with kindly feeling by all those whose acceptance is worth the having. It is only those ignorant snarlers who have never made a suggestion worth listening to who try to decry everything which does not emanate from their own little pens; who, incapable of understanding topics of general interest, are bound to keep secret processes and improvements which they cannot explain; or who, having found a process in full and successful operation in the hands of others, hasten to relieve them of their burthen of credit, and to claim the invention as their own.

But to turn to the matter on which it was my intention to write. Several letters have recently appeared in various papers, in which matters of which I have spoken or written have been referred to with various degrees of approbation or disapprobation, generosity or ungenerosity, according to the character of the persons who wrote the letters. I will only refer to some of these.

My first shall be the letter of Mr. Bovey in last week's News. Mr. Bovey is a gentleman whose acquaintance I have not yet had any opportunity of making personally. I esteem him as one who has a decided opinion of his own (and that, in these days, is a matter of great consideration), and as one who will put forward his opinion boldly and without fear. I was certainly not aware before last Friday that I held so high a place in the esteem of this honourable member of our profession, nor had I the faintest notion that in my paper before the North London Society, on November the 7th, I made such a complete shipwreck of my reputation in his eyes. A careful perusal of Mr. Bovey's letter shows me, however, that I am not so far in the wrong as he would imply. In the first place, Mr. Bovey has mixed up in his mind my paper and the discussion which followed therefrom. I did not start the discussion, and, as far as I remember, I only took a very limited part in it. I said nothing about salting formulae, nor do I wish ever to know anything at all about them. The question of formulae cropped up in the discussion, not in my paper. I do not care a pin whether there are ten or twenty grains of salt in a sheet of paper, so that it works to my satisfaction. I did, however, in the discussion, admit that to know the equivalent quantity of salt in the paper would be a matter of convenience, as a means of knowing how much silver was used from the bath by each sheet. What I want in practice is, a paper that I can depend upon for a certain class of work, not only from one maker, but from all makers. As an instance of what I mean, take the following little bit of experience. When M. Adam-Salomon was in this country some time back, he paid us a visit at Tunbridge Wells, and Mr. Robinson secured a very fine "Salomon-sized" negative of him. To print from this negative in perfection we used a sample of Rive's paper sent us by Mr. Bovey himself. The Saxe paper sent from the same quarter would not, with that particular negative, give us the same quality and richness of tone, and no other paper of any other maker which we have yet tried will give the same result absolutely. Now, if we take a negative much weaker than the one I have referred to, and another much stronger, and print them on the Rive's paper I have mentioned, we shall not find the quality o

the result so good as the Salomon; therefore, we knew that in order to produce the same effect again we have only to make a negative of the same intensity, and print it on the same paper; in fact, keep up the same conditions, and all is right. If we make softer or weaker negatives, we have to use another paper to get the best result. Mr. Bovey says that a skilful printer can from one sheet of paper and one negative make half a dozen different kinds of prints. Many photographers know to their cost that much less clever printers than Mr. Bovey can do the same, and do it every day, too; but I venture to say that *one* of the half dozen will be better than any of the other five. Now what is wanted is, when a ream of paper is sent out, *some idea* of how much silver it will consume to excite it, and also what class of negative will best print upon it. Photographers, when they needed the information, found that a few pelite notes, stating that unless collodions were dated they would deal elsewhere, or go without, seen brought the date neatly stamped on the bottles. It will be the same ere long with paper albuminizers. They, too, when asked, will give us the information we require.

Turning from Mr. Bovey and printing matters to the consideration of negatives, the form of glass hence is a subject of continual discussion. I do not intend, however, to enter upon any detailed consideration of the various remarks which have been made upon my article on north light. I would prefer making a few general observations on the subject. In the first place, I do not think it can be a necessary condition of success in portraiture to place the sitter in an abnormal position in regard to external things. That cannot surely be the best form of studie which involves the painting of the walls black. No one by preference would sit in a room with black walls. Then why, in order to be photographed, should one be put in a black hole? My idea of a studio is *a room*, not a place where people may only come for a minute or two, and then with a feeling of mystery and awe, as if it were something wonderful. With regard to the amount of light from the north in comparison with the south, as I have had no experience of the latter I am not able to give a decided answer; but I can say the time that pictures take with a well-arranged north light. The longest exposure ever given yet in our studio was forty-five seconds, which only happened on one occasion, and that was on a dull afternoon, with a picture which, from its peculiar arrangement, required the use of a very small stop in the lens, and 10 by 8 plate. But this is very much the longest exposure we have ever given. We often take 15 by 12 portraits in fifteen seconds, and twenty-five is the longest time ever given practically to any sized picture. Carte-de-visite pictures usually take from five to twelve seconds, and never so much as sixteen seconds. From these facts it will be seen that though the light may come from the north, there is no reason why it should involve slow working in the studio; indeed, quite the contrary, for I believe that a rapid exposure and mere general lighting are capable of producing better results than long exposure and that quality of lighting which is obtained by an intense beam of light with no reflections in the room.

Before closing the present chapter, I must allude to the courteous letter of Dr. Anthony. The letter which this gentleman published in the *News* of the 9th of October was certainly to some extent condemnatory of my argument. However, I only proposed the looking-glass experiment as an illustration of a general principle, and not as being of itself absolutely accurate. It seemed to me a convenient manner of showing an increase in the amount of perspective, distortion, or enlargement, as the distance from which the object is viewed is lessened. Dr. Anthony was certainly right to correct an error when he saw it, and I thank him for the open and gentlemanly way in which he wrote upon the subject. It seems now, however, from a letter of Mr. Winstanley, that the Doctor is not absolutely correct. I confess that on first reading the remarks of Dr. Anthony I did not see his error, probably because I did not see my own; it was near enough for me to illustrate a general principle without entering into absolute accuracy of detail. However, I am glad to find I am right after all; and I would take this opportunity of thanking Dr. Anthony for his kind and honourable letter published in the *News* of last Friday. How much better it would be for photographers generally if all acted on the noble, generous principle adopted by this gentleman, which stands in fine contrast with the conduct of some hangers-on to the profession! There are said to be black sheep in every profession; but I fear in photography

there are a few in it—or hanging on to it, like parasites—more like wolves in garments darker than black velvet.

NELSON K. CHERRILL.

1, Grove Villas, Tunbridge Wells, October 31st, 1863.

#### A PHOTOGRAPHER'S RELIEF FUND.

SIR,—In compliance with your wish in a recent "Answer to Correspondents," I send you a few brief remarks on points which I think deserve consideration in connection with any effort to establish a Photographer's Relief Fund. For brevity's sake, I will put a few points categorically.

1. Is the time ripe for such a thing? I do not say it is not, but I want the matter considered; and when I ask, Is the time ripe? I mean, Do photographers form a sufficiently distinct, numerous, and consolidated body to make the formation of a provident society solely on their behalf desirable and practicable? Trustworthy statistics are not readily accessible, but it is well known that in the provinces a considerable number join the profession of photography to some other trade, such as chemist, bookseller, actor, carver and gilder, hairdresser, &c. Would these contribute to a provident fund, or would they be fit candidates for the aid of a photographer's benevolent fund? I do not say they would not, but the questions are worth consideration.

The transitional stage which photography, as a profession, at present occupies, and to which you have already alluded, is another reason for asking, Is the time ripe? But I need not further dwell on that part of the subject now.

I am led especially to ask, Is the time ripe? by another consideration. I have just been referring to my back volumes of the *News*, and find that it is four years since you first mentioned the desirability of forming such a fund, and pointed out its importance in very forcible terms. Since then it has been advocated from time to time in articles and letters, but not one practical step has been taken to realize the idea. If the time were ripe, and photographers really believed in the importance of the thing, surely some attempt of a practical kind to embody the idea would have been made ere now.

2. If the formation of some fund be desirable, surely it is of the utmost importance that the nature of the organization should be first discussed, if not determined. That discussion can be much better managed by letters in the journals, if you, sir, will give space for such discussion, than it could be at committee meetings, should a committee be formed to manage such a matter. I think that it is very desirable that we should have the opinions of at least some of the representative men in photography on such a subject. To aid in determining such a question, statistics are of vital importance. Are there any means of obtaining trustworthy figures as bases of calculation in such a matter?

3. If it be determined, on consideration, that some benevolent or provident organization is desirable and possible, and that the time is ripe, how is it to be initiated, and who are the men to do it? Here comes the practical difficulty. After the fullest discussion in the journals, personal effort will be required, and that effort must be made by trustworthy men. I once knew a project of the kind fail because one of its chief advocates was a man notoriously in debt, in a chronic state of insolvency, and no one trusted him or any scheme he advocated. In photography we have men of great ability and unimpeachable character. Will they undertake the hard work of beginning? "Twere good they did so much for charity," and I think that if a good plan were projected, good men would not be wanting to carry it out. All such action must have a beginning, however, and this necessity is often difficult to meet. Two possible ways occur to me of beginning: First, if the Photographic Society of London could undertake the matter, and appoint a committee to take steps, I think the organization might be secured; or, second, failing this just named, if you would open a subscription list, eventually a committee might be formed out of the subscribers.

4. Finally, if the time has not come, or photographers are not sufficiently numerous to form a provident or benevolent organization of their own, is it possible for them to join some cognate body already established for the purpose of relieving some class? Existing provident societies would, of course, accept them, but would some benevolent association accept contributions especially endorsed for photographers, and undertake to administer to indigent photographers in the ratio of their necessity and of the extent of funds available for them?—Your respectful reader,

STEREO.

## MR. FRY'S METHOD OF MASKING.

SIR,—My attention being attracted to the leader in last week's NEWS, I at once proceeded to put in practice the suggestion communicated by Mr. S. Fry. Having a negative that had been intensified with mercury, and which by constant exposure to the light in printing had become unmanageably dense, and having some time ago obtained a transparency from it, I placed the transparency over the negative as directed, and was delighted to find that this, like many other suggestions of Mr. Fry, is a really valuable one.

Should this hasty note be considered worthy of insertion or notice in your columns, my desire to serve my brother photographers will be answered. I enclose a print, that you may see the effect.—I am sir, yours truly, H. C.

October 27th, 1868.

[The print enclosed is an admirable illustration of right application of the principle of masking referred to; and a round, delicate, and well-modelled print has been obtained from a hard negative.—ED.]

DEAR SIR,—The letters of "R. F." and "Zeta" are both founded on erroneous premises. Each assumes, in the first place, that my invention for masking negatives is theoretical only, and also that it is intended merely for the improvement of bad or too hard negatives.

First, then, I have used it in my ordinary portrait practice for about eight months with great advantage and high appreciation from the public, and it has created an entirely new branch of business with me, although no announcement of any speciality has ever been made. If your correspondents will write to me, a specimen of the result shall be sent to each. I think I have shown that this is a simple, practical business matter.

Second, with regard to the negative, I find the finest negatives are most amenable to this method. The difference between a print before and after treatment is very great. Take a small transparency of a negative, and a paper print from the same, the difference in detail is enormous; this experiment exactly illustrates the difference in value between a plain print and one treated according to my method. Should any further information be necessary, I shall be happy to afford it.

Specimens of the results of this method of working, with the negatives and also the transparencies employed, will be exhibited at the exhibition next Tuesday, at Conduit Street. I am not a producer of specimen pictures, and therefore those shown will be the results of ordinary business work. The application of the transparency at the proper place and time is as simple as possible, and is readily effected as an ordinary detail of printing. As a matter of private opinion, I never by any chance entrust printing of negatives to any but thoroughly qualified persons who have undergone a long and careful training under my own eye and according to my own notions. I do not believe in letting just any one do it.—Yours faithfully, SAMUEL FRY.

Surbiton, November 2nd, 1868.

## TO STRENGTHEN VARNISHED NEGATIVES.

DEAR SIR,—The best method of giving additional density or printing power to varnished negatives which may be somewhat wanting in these qualities has sometimes been discussed in your columns; but a plan I have lately adopted with much success, and which, in my hands, is simple, efficient, and does not destroy half-tone, I have not seen mentioned. I claim for it no originality, for it is almost too simple not to be well known and often practised. I seldom have to alter any negatives, but occasionally it is desirable to modify them; and when I err in intensifying, it is generally on (I fancy) the safer side of not carrying it quite far enough. A ready method of adding intensity to a varnished negative is no doubt a valuable reserve power to have at command.

A varnished negative that needs strengthening is to be treated slightly with spirits of wine, but not absolute alcohol, for that dissolves the film, as does also the impure methylated spirit. When dry, the surface will be dull, and the intensity of the negative much increased. I enclose two prints illustrative of the effect; the one taken from the negative before alteration, the other after.

The other carte portrait—the little girl sitting—is a specimen of my gold and mercury intensifying process pure and simple.

It is a very delicate intensifier, and in the case of a thin negative should be followed by a weak solution of iodide of potassium.

These hints are at your service if you think them worth publishing in the NEWS.—Yours truly, C. T. WINTER.

Cheltenham, November 2nd, 1868.

[The difference between the prints taken before and after the treatment described is marvellous. Before treatment, the negative yielded a poor, feeble print; after treatment, the print obtained is brilliant, round, and vigorous, without loss of delicacy. The print from a negative intensified by the gold and mercury solution, which Mr. Winter has before described in our columns, is very admirable.—ED.]

## PROPORTION OF SALT IN ALBUMINIZED PAPER.

DEAR SIR,—I have often been struck with a singular propensity in the tradesmen I may happen to deal with, to know a great deal more about what I want, or what I should want, than I know myself. My tailor tells me, when I remonstrate with him for making a garment contrary to orders, that "it is worn so." My butcher replies to a remark that the joint is too fat, that "the fat is the best part of the meat;" and so on with regard to almost everything used in domestic life.

Well, sir, in these matters I grin and bear it; but when the same practice is applied to the tools or materials of my profession, I feel disposed to make a stand against it. At one time my optician met my request for certain improvements in lenses by a brusque reply to the effect that photographers must improve their processes, as the lenses were perfect. *Mais nous avons changé tout cela.* But now albuminized paper makers seem disposed to adopt the same tactics. At the North London meeting Mr. Hart complimented photographers by saying that nine out of ten of them could make no use of the knowledge of how much salt was used in their albuminized paper, as though that were a justification of the practice of withholding the information from those to whom it was valuable.

Mr. Bovey goes further still; and because Mr. Cherrill has ventured to wish for some uniformity in the quality of paper, and some knowledge of the amount of salt used, to guide him in making and strengthening his nitrate bath, Mr. Bovey tells him that he is incompetent and inexperienced in printing. I fancy that is not true; but if it were, it would only be a stronger reason for supplying information to aid the inexperienced printer.

Now, sir, I respect and esteem both Mr. Hart and Mr. Bovey very highly. Mr. Hart has often published valuable suggestions in your pages. Mr. Bovey's practical articles are full of valuable matter; he is only dangerous when he loses his head and gets into wordy rhapsodies. I have used the paper of both gentlemen, and know it to be excellent. But is it not too bad that I cannot ask a reasonable question without being told by one that I cannot make any use of the information I seek, and by the other that I am incompetent because I ask it?

I think, on reconsideration, that both these gentlemen will feel that they have been less considerate to photographers than is wise, polite, or politic.—Yours, sir,

ONE WHO DOES NOT LIKE TO WORK IN THE DARK.

## PORTRAITURE "ON APPROBATION."

SIR,—My object in writing to you is to protest against the custom which appears to be creeping in of taking portraits on approbation.

People come and occupy your time for an hour or two, as the case may be, pay nothing, and request that "proofs may be sent." They reject the whole as "not approved," although as photographs they may be unexceptionable; and, when expostulated with, say "it is the practice among other respectable photographers, and that of course they cannot think of paying for portraits they do not like. This has happened to me more than once of late. Truly photographers are their own worst enemies.—I am, sir, yours obediently, GEORGE DOWNES.

Bedford, October 28th, 1868.

## THE PHOTOGRAPHS OF THE LATE ECLIPSE TAKEN IN INDIA.

SIR,—With reference to an article that appeared in your impression of the 23rd. ultimo, entitled "Failure of Photographing the Eclipse in India," in which you have unjustly

expressed an opinion that the photographers of the Royal Engineers detailed for that expedition were not "experienced" in the art of photography, I beg to inform you that Sergeant Phillips, R.E., the senior photographer, has been employed in Palestine on two expeditions under the auspices of the Palestine Exploration Committee, and that his name is well known in connection with the photographs published by that Society. He had, therefore, great experience of photographing in a hot climate, but, in common with other photographers, he had not had much experience in photographing eclipses, especially in cloudy weather.

I may add that Major Tennant has expressed an opinion that his six negatives are equal in scientific interest to any that have been obtained in Spain, and he has valued them at £150 each.

The following extract from the *India Gazette* speaks for itself:—

"The services of Sergeant Phillips, and Sappers Talbot and Conway, of the Royal Engineers, have been great. They have had a good deal of hard and harassing work in making everything ready. Sergeant Phillips, in particular, has been most useful, and I have much of the success of all preparations to thank him for. The partial failure of the plate operations has been from causes beyond these men's control, and I would respectfully solicit that His Excellency in Council would be pleased to grant a month's donation of pay to each.

(Signed) "J. F. TENNANT, Major R.E."

"As recommended by you, His Excellency in Council sanctions the grant of a donation of one month's pay to Sergeant Phillips, and Sappers Talbot and Conway, of the Royal Engineers."

In conclusion, I may be permitted to add that even if this "comparative failure" had been the fault of the men, this would not have been logical ground for hinting that the Royal Engineer photographers are "not familiar with photographic operations." Lord Napier, in his despatches, repeatedly mentioned the success obtained and good service rendered by the Royal Engineer photographers under most trying circumstances in Abyssinia. In that expedition photography was the field printing press. Staff officers' reconnaissance sketches brought in during an afternoon were at once photographed, and reduced to a uniform scale during the operation, in order that different sketches, if they overlapped, might be subsequently joined together. The sensitized paper was prepared during the night, and impressions struck off in the morning. The prints were finally mounted on linen, and distributed throughout the force. This was the principal work of the photographers, who had also to take care of the mules, carry their arms, and march as other soldiers. In addition to the large collection of negatives of plans, they have brought home a most valuable collection of about eighty negatives of general views, prints from which will be exhibited before the Photographic Society this month. Sergeant Harrold, R.E., the senior photographer, shortly before taking the interesting views of Magdala, was detailed as one of the storming party, and for his conspicuous gallantry at the assault of Magdala has obtained a medal for distinguished conduct in the field.—I am, sir, your obedient servant,

S. ANDERSON, Lieut. Royal Engineers,  
Assistant Instructor in Photography, &c.

*Royal Engineer Establishment, Chatam, Nov. 4, 1868.*

[We are glad to learn that the photographic operations in connection with the recent eclipse observations in India were more successful than the first report indicated. Our correspondent must remember, however, that our remarks were based upon the statements of Major Tennant himself, who described the whole of the plates as "covered with spots," and as "showing but faint traces of the corona;" and he attributed this to the "concentration of the nitrate of silver solution" by heat. Now this is a condition of things in no wise attributable to the eclipse. It could only have arisen from want of care or want of knowledge, and it is fair to assume that it was to lack of experience, and not any more culpable cause, that such a result was due. If we do the Engineers in whose care the photographic operations were placed any injustice, we regret it, and can only point to Major Tennant's report, and the contrast furnished by the results of the German expedition, in justification of our remarks. Our correspondent mistakes us in fancying that we imply that skilled photographers are not to be found amongst the Engineers. We have before spoken highly of the skill and success of Sergeant Harrold in Abyssinia, and we have had reason to believe that it was owing to the absence

of the most accomplished Engineer photographers in Abyssinia that less able men were at the service of Major Tennant's expedition. In our allusion to the Engineers we merely put a hypothetical case, saying *if* the men told off were not familiar with photography, &c., &c. It is much more pleasant to us to believe that this expedition was in some degree successful than that it was a complete failure.—Ed.]

## Talk in the Studio.

**OBITUARY.**—We regret to announce the death of another of the old and valuable workers in photography. Mr. T. A. Barber, an able chemist, well known at one time as one of the most active and useful members of the North London Society, died on the 29th ult., aged fifty-three. Some excellent contributions to the chemistry of photography by Mr. Barber will be found in our former volumes.

**PHOTOGRAPHY AND POPULARITY.**—The Russian correspondent of a daily contemporary regards photography as a tolerably accurate gauge of popularity. He says:—"The coming of Mdlle. Patti is looked forward to with vast impatience by the opera-going world, and photographs of the *Diva* already inundate the shop windows; while Lucia, about whom all Petersburg went crazy last winter, is relegated—in photographic form at least—from the 'line to a higher region.'"

**PHOTOGRAPHY AT THE HAVRE EXHIBITION.**—The *Standard*, speaking of English photography at the Havre Exhibition, says:—"This last (photography) is an art upon which the French, with dominant vanity, plume themselves. Our specimens at Havre were few, yet they are admitted to be scarcely less than incomparable. Now it might be invidious to select the names of individuals or of firms without analysing the entire list; but upon examination it will be found that out of three thousand exhibitors—a very small proportion being British—a magnificent allotment of awards fell to our share."

**"SCIENTIFIC OPINION."**—The first number of the new issue of this interesting resumé of news on current science is just out, and promises well. It contains a capital selection of articles from the scientific press generally, at home and abroad; brief but sufficient notices of the proceedings of scientific societies; reviews, correspondence, and condensed information in the shape of "Notes, Queries, and Memoranda." It is well edited, and, as it fills a new field, it will, we doubt not, become a favourite with the scientific public.

**FINE CLOUD EFFECTS.**—Mr. H. Sampson, of Southport, has favoured us with stereographic examples of two magnificently fine cloud effects, in which the sinking sun is behind grand masses of cumulus cloud, the edges of which are gilded by the light, which also streams in fan-like rays beneath, and is reflected in the sea. A tiny vessel forms a touch of black just in contact with the most brilliant light, and is very effective. Mr. Sampson says:—"I have pleasure in sending to you by this post a couple of cloud effects, taken on the evening of 7th ult., therefore, as you will see, 'storm clouds.' At the time they were taken the wind was blowing strong from the south-west, so as to require three of us to keep the camera rigid; during the night heavy storms of hail fell, which continued at intervals for eight days. I have several others taken the same evening, but send these two as being most effective." The practice of securing passing effects is one highly commendable, and should be followed by all who have opportunity.

## To Correspondents.

**H. S. R. H.**—The fault in your transparencies is the presence of a deposit in the portions which should be clear glass. This deposit may arise from over-exposure, or from fog. In transparencies for the lantern, the parts intended to be white should be represented by bare glass, not by the grey, foggy deposit present in yours. This deposit obstructs light, and prevents a brilliant image being thrown on the screen, especially when using a paraffine lamp as the source of illumination. Give a shorter exposure, use more acid in your developer—or use the gelatino-iron developer—and take especial care to avoid the presence of diffused light in your camera or dark room. One of the transparencies was broken into a score of pieces. It is not safe to send glass through the post unless packed in a box. If a couple of strips of wood had been attached to the packing boards employed, so as to bear off any pressure, and practically form a box, there would have been no danger.

**VENATOR.**—The exhibition will remain open for a week, and the public, after Tuesday evening, will be admitted free. 2. The best remedy we can suggest for turbid collodion is to allow it to stand, and then decant off the top portion. 3. When wax is applied to a plate of doubtful cleanliness to give it a thin film of a neutral substance, it is simply necessary to apply the wax solution, and then rub it nearly all off with a clean cloth. After it is so treated, it will generally yield a clean negative, although it will not look even and clean when breathed upon. A preliminary coating of albumen causes risk of injury to the silver bath.

**PETER SIMPLE.**—Without some slight preliminary knowledge of the subject—such, for instance, as a knowledge of what an enamel is—we fear that you will not succeed in producing burnt-in pictures. An enamel picture is a picture formed of vitreous colours which have been submitted to sufficient heat to slightly fuse them. A “flux” consists of a mixture of powdered flint and borax, or similar materials, which readily vitrify under the action of heat. A flux is added at times to the colours used to aid in the process of vitrifying. Porcelain colours generally consist of metallic oxides, which assume a vitreous form under the action of heat. Vitreous colours, fluxes, and enamel tablets can be purchased ready for use. We cannot tell you where; but your London dealer will doubtless procure them for you. Our Fifth Volume contains a good deal of information on the subject of enamels.

**WM. CORBOLD.**—The pinholes in your case most probably proceed from excess of iodide of silver in the bath. To test this, take an ounce of the bath and add half an ounce of distilled or boiled rain water. If your silver bath be already saturated with iodide of silver, this addition will make it turbid. The remedy is to dilute the whole bath with an equal bulk of water, and then, after filtration, add sufficient nitrate of silver to bring the solution to the proper strength.

**W. J. A. G.**—You will best understand the directions for developing the dry plates if you bear in mind the respective offices of solutions 1, 2, and 3. No. 1, the pyro solution, is the developer proper; No. 2, the ammonia, aids the action of the pyro; whilst No. 3, the bromide, retards somewhat, its especial function being to prevent fog. These are mixed in the proportions indicated for the purpose of bringing out the image; and when this is effected the pyro and ammonia are used to secure intensity. The bromide will not aid in this, and should not be used unless there is some tendency to abnormal deposit on the shadows, in which case a little of it may be added. We have found, as a rule, that dry plates were not satisfactory with any amount of exposure in a bad light, and we should recommend you not to waste time and court disappointment by exposing dry plates except when the light is clear and bright.

**GULIELMUS.**—As you have, as you state, carefully read all that has appeared in the *News* on the subject of pinholes, it is difficult for us to give you any fresh information. Your remark that your difficulty generally occurs during the process of intensifying suggests a possible remedy. We have found pinholes occur in intensifying from several causes: where, from thinness in the image, or from under-exposure, the intensifying has required pushing considerably; where a portion of the nitrate bath is added to the pyro instead of a fresh solution; and where excess of nitrate has been added to the pyro. Aim, by the use of suitable materials and full exposure, to get a good image in the first process of development, and the risk of pinholes will be much reduced. Either citric or acetic acid may be used; but we are not aware that any difference in the result, as regards pinholes, will follow. 2. The different statements you find as to the proportion of silver taken up by a sheet of albuminized paper doubtless arise from the use, in the experiments recorded, of different samples of paper, in which different proportions of salt have been used. The proportion of silver absorbed is chiefly regulated by the proportion of salt added to the albumen; and as the proportions used by different persons vary from 5 grains per ounce to 20 grains per ounce you will see how impossible it is to give any general statement on the subject. The following calculation may help you:—One sheet of paper takes up nearly an ounce of albumen solution. Suppose it contains a proportion of 8 grains of chloride of ammonium, the salt on a sheet of such paper will take up about 25 grains of nitrate of silver, the albumen will take up a little, and the solution on the surface, suppose it to be a 40-grain bath, will amount, probably, to 10 grains more. In such a case you would have nearly 40 grains of nitrate of silver consumed by one sheet of such paper. We are glad our last advice enabled you to remove your difficulty.

**J. SMITH (Halifax).**—Grasshoff's Manual of Instruction for Retouching Photographs is published in German, by L. Gerschel, Berlin.

**M. A. WANDERSON.**—We do not know of any one who makes a collodion specially for enamelling photographs, except Mawson and Swan. To make some for yourself you would probably require to make the pyroxylene also, as toughness much depends on the character of the pyroxylene. It should be made with moderately weak acids, and at a low temperature.

**LUX ET SALUS.**—Thanks. You will probably have opportunity of calling on some other occasion. Your letter in our next.

**J. T. (Fife).**—Either Mr. Bovey's toning bath, the lime bath, or the acetate bath will, as a rule, answer; but double albuminized paper is generally somewhat slow in toning. If you immerse the prints in the toning bath without previous washing, or with but slight washing, they will tone more readily.

**Z. H. A.**—The formula you state will yield you a good solution of chloride of gold; but as it contains a large proportion of acid, it will not be suitable for use with an acetate bath. Your best plan of using it will be to neutralize the portion required with chalk, whenever you wish to use it, a few hours or a day beforehand. If you want it for immediate use, neutralize with chalk, and add to an ounce of the solution 5 ounces of hot water; when cool, it will be fit to use. It will always require a few ounces of water adding to each ounce, as the strength you name,  $1\frac{1}{2}$  grain per ounce, is much too strong for toning purposes. 2. The story is a myth. Publishers of engravings generally get as good a subscription list as they can before publishing a costly plate; but they are under no legal obligation to destroy the plate at any time. They sometimes make a compact with subscribers that the plate shall be destroyed after a certain number have been printed, with a view to prevent the subject becoming too common; but this is purely a matter of choice. The notion that Graves and Co. make money by prosecuting pirates is very foolish. They have been, perhaps, a little vindictive in these prosecutions because they have been much wronged, and suffered much loss.

**PHOTO.**—Marion and Co. are the largest photographic publishers. The Stereoscopic Company also publishes largely. C. E. Elliott, Spooner and Co., and some others, both publish photographs and deal in them; but we cannot furnish you with anything like a complete list of such publishers. 2. If you develop your solar camera image sufficiently, then wash, and immerse in an ordinary hypo bath, you will not lose the image.

**W. T. WATSON.**—Received. Your request shall have our attention. The specimens are very good. We shall have pleasure in learning further particulars of the mode of producing them.

**B. A. GILBERT.**—Acetic acid once added to a silver solution is very difficult to remove. Nothing short of boiling to dryness will effect it thoroughly.

**E. SAWYER.**—We ascertain from our correspondent that your pictures arrived at Falmouth two days after the opening of the Exhibition, and as his notice was written on the first day, no notice of your contributions was possible. Those to which you refer as possibly yours were both by Mr. Douglas, of Edinburgh. Our correspondent, speaking of yours, states that they are superior to the average of coloured enlargements, and that the likeness is admirably preserved.

**“PERMANENT PHOTOGRAPHY.”**—A correspondent has sent us a paragraph cut from the *Daily Telegraph* with this heading, with some severe strictures upon what he terms a “shameless puff of Poncey's process,” and his claims to the origin of carbon printing. The subject is not worth re-discussion. It has been thoroughly canvassed in our pages more than once, and we have shown that M. Poitevin produced carbon pictures and patented his process three years before Mr. Poncey was heard of. The oil or printing-ink process has many good features, and we have seen good results produced by it. It is a pity that a good process should be prejudiced by the injudicious claims of its inventor. Six hours' boiling, and six days' baking in a furnace, are burlesque tests, and are of no value if true.

**F.**—Thanks: in the main you are correct. We simply answered two specific points raised by our correspondent; we have no concern with common gossip or its retailers, nor should we dream of having any discussion with persons who do not hesitate to invent their facts and their correspondents to meet any case. We are familiar with the aliases you mention, and many more; but neither they nor their owner possess any interest for the public.

**A. B.**—The plan of iodizing by the addition of a little collodion to the bath is not to be commended. The pinholes in your first essay are probably due to that. So far as we can see, there is not much defect about the second bath. It is difficult to say from which of two or three causes the fog may arise. It may be that a little more nitric acid may be required in the bath; there is not much danger of adding excess when you are using bromo-iodized collodion. It may be the want of a little more acid in the developer. Possibly the use of the gelatino-iron developer would meet the case. The fog may possibly be due to the presence of a little white light in the camera or dark room. It has somewhat of that effect. Try excluding white light carefully, and try the gelatino-iron developer, and let us know the result. We are glad our advice helped you out of toning difficulties.

**DEALER.**—You need be under no apprehension. The first clause in the new Act, from which we made an abstract some months ago for our readers, distinctly states the date of its operation as “from and after the 31st of December, 1868;” and no “judge” has stated anything to the contrary. A blunder on the subject was made in a police court, which has been perpetuated by some of the more careless or less informed portions of the press. Several Correspondents in our next.

### EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

THE success and satisfaction which have attended the second experiment in opening the winter session of the Photographic Society with an exhibition of pictures and a social reunion of the members and their friends justify us in regarding these as henceforth established institutions, and we find in the fact the solution of a difficulty which had before seemed as insuperable as it was deeply to be regretted. The advantage of exhibitions of photographs in aiding and stimulating progress was a thing universally admitted, and the interest of such exhibitions was everywhere recognized. But the cost, as they had been hitherto conducted, was simply ruinous to the Society. Modelled, as it was natural they should be, on the principles followed in exhibitions of pictures generally, the cost was not less, whilst the income was of necessity incomparably smaller. The rent of a large gallery in a central position for a few months, with added cost of gas, attendance, printing, and advertising, amounted to a heavy sum, whilst the payments for admission from the public—members and their friends generally entering free—and the amount of commissions on sales, did not amount to the tenth of a tithe of the amount usually taken in an exhibition of paintings, in which the expenses were but little more, so that the annual loss to the Society became very serious, and it had become apparent for some years past that the exhibitions, with all their advantages, must cease.

The project conceived and so successfully carried out last year just met the difficulty, however, and an exhibition for a limited period, with simple and economical arrangements and much volunteer labour, was found not difficult to secure, when a few willing workers and influential members of the London Society took the matter in hand. The full educational and stimulating influence of an exhibition is secured, without taxing the resources of the Society unfairly and beyond the bounds of legitimate expenditure.

The exhibition which opened on Tuesday evening was beyond precedent satisfactory and pleasant. On all hands it was pronounced to be one of the best, if not the best, of exhibitions ever opened, the contributions being full of excellence and full of interest. A very large attendance of members and their friends, many of whom had come from the country to attend, materially contributed to enhance the pleasure of a reunion which every one present seemed to enjoy.

One of the first facts which strike us on glancing round the exhibition is the illustration afforded by the large number of contributions, of the healthy vitality of the art, and the unflagging interest in its progress maintained by the majority of its devotees. Here is an exhibition, an-

nounced with little circumstance, to be kept open for a week only, offering no honours or awards, yet the most able, and the most skilful, and the most successful exponents of the art, professional and amateur, are sufficiently interested in witnessing and aiding progress to produce one of the finest collections of photographs ever brought together. Some few honoured names were, from various causes, not represented, but amongst the work of about a hundred contributors were found the pictures of most of the representative men associated with the art.

The next fact which struck us, after examining the pictures exhibited, was the general excellence that prevailed. We remember that in many former exhibitions the mass of the contributions were of a very commonplace character, the examples of great merit standing out as brilliant exceptions. Here the bulk of the contributions are of very high standard indeed, and indicate a very great general advance, both in artistic and technical excellence. The progress in portraiture since last year is almost startling, and we may fairly state that we never saw so much good portraiture brought together before. As we had anticipated, the influence of the works of M. Adam-Salomon was abundantly manifested, not only in the large number of portraits in which his characteristic style was adopted, but in forms of portraiture, distinct in their characteristics from those of the great French artist.

We may remark here, in passing, and without any egotism that we feel considerable satisfaction in this result, because we have been mainly instrumental in calling the attention of photographers to these pictures, and in affording them opportunity of becoming acquainted with them. Believing that they possessed not only a higher excellence than prevailed in this country, but that they possessed some elements of excellence scarcely dreamed of as possibilities by English photographers, we felt assured that we were doing them service in pressing this subject upon their attention with a degree of iteration which risked being tiresome; and we did this because we equally felt assured that English portraitists only required the standard bringing under their attention, and the spirit of emulation awakening, to induce a resolve to hold no second position in attainable excellence. We think the result, as illustrated in this exhibition, has fully justified our convictions. It is not necessary to enter into comparisons, or estimate how far English photographers have advanced in the race for excellence; certain it is that they have attained a position which few would have anticipated twelve months ago.

It is impossible, in the brief time since the exhibition, to enter into a detailed notice of contributions so numerous and excellent, but we may briefly allude to a few names as an inducement to many to avail themselves of the remaining few days which the gallery remains open to pay it a visit. In landscape work we may mention a charming collection

of Mr. Bedford's recent pictures, and we may add the interesting intimation that the pictures are now described as those of G. Francis and William Bedford; Mr. Bedford's son promising worthily to maintain the reputation of his father. Mr. England sends a frame of the capital results obtained during the summer in the Savoy. Messrs. Robinson and Cherrill send some large landscapes with such grand clouds as are not often seen, still less often secured in the camera. Mr. Wardley sends some magnificent 16 by 12 landscapes by the collodio-albumen process. Mr. R. Manners Gordon contributes a few of the most exquisite little photographic gems ever exhibited. No one should fail to see a charming little landscape with groups of sheep, which is as nearly perfect as possible. A view of Carnarvon Castle just above it, taken with the gum process he has described in our pages, ought to be seen by all who are interested in dry processes. This plate was kept upwards of a month before exposure, and upwards of a fortnight more before development; and, notwithstanding the perfection of the detail in every part, it only received fifteen seconds' exposure. Mr. Vernon Heath sent a fine collection of his admirable landscapes. The Hon. W. Petre, a gentleman quite in his novitiate as regards photography, has sent some very capital artistic landscapes. Some mountain and waterfall scenery by Mr. Crofton Atkins, Mr. Beasley, Mr. Howard, Mr. Whiting, Mr. Brownrigg, Mr. Spode, Mr. Best, Mr. Clarke, Mr. A. Irving, Mr. Bowen, the Royal Engineers, and others, send landscapes well worth inspection.

In portraiture, perhaps, the exhibition is richest, and it would be somewhat difficult to assign the order of precedence. There is a large collection of examples of Adam-Salomon which need no comment, art qualities and technical excellence abounding in greater or less degree in every one. A portrait of M. Salomon is exhibited by Messrs. Lock and Whitfield, and another by Messrs. Robinson and Cherrill. The only other portrait exhibited by the latter firm is a magnificent Salomonesque portrait of Mr. Hain Friswell, wonderful for its life-like and fine expression. Mr. Robinson's successor at Leamington, Mr. Netterville Briggs, exhibits a collection of 12 by 10 portraits, furnishing admirable examples of the same style, one of which is the prize portrait of the Falmouth Exhibition, and which we have already noticed. Some very fine cabinet portraits with natural landscape backgrounds, and some pretty vignette pictures by a new process, styled "Emolliotype" (of which more hereafter), are exhibited by the same gentleman. Mr. Blanchard has some very satisfactory examples of the Salomon style of portraiture, brilliant, delicate, rich, and well modelled. Mr. Fry has a fine collection in the same style, which have the additional interest of illustrating the results of the mode of masking recently described in our pages. Mr. Mayland has some brilliant examples of the same style. Mr. Leake has some very satisfactory specimens. Mr. Burgess of Norwich, Mr. Slingsby of Lincoln, Mr. Fradelle, Mr. Ashdowne, and others, send some fine illustrations of the same style, some of which we must return to next week, as well as to other styles of portraiture.

In subject-pictures the exhibition is rich, but we can only now mention, as contributing interesting examples in this department, the names of Mr. Rejlander, Mr. Robinson, Mr. Twyman, Mr. Hubbard, Mr. Jewell, Dr. Wallich, Mrs. Cameron, Mr. Crawshaw, Mr. Slingsby, Mr. Rump, and others. We shall return to this subject next week.

The Autotype Company had some magnificent examples of pigment printing; Edwards and Co. exhibited many very fine, interesting illustrations of varied applications of pigment printing. Mr. Henderson, Mr. Bailey, and Mr. Barnes, and an amateur, exhibited enamels which afford satisfactory illustration of the progress which this branch of the art is making. Collodio-chlorides, coloured pictures, Piercytypes, apparatus, and many other things, must receive attention another week. Meanwhile, we may mention that the exhibition will remain open at the Gallery, 9, Conduit Street, until Tuesday evening.

## SIMPLE PLAN OF OBTAINING PLAIN PAPER PRINTS.

OF late years the use of albuminized paper has been all but universal amongst photographers, in many establishments such a thing as a plain paper print never by any chance being produced. The rich, engraving-like plain prints of Heunah, with their deep, velvety blacks, are things of the past; and although a protest is entered now and then against the vulgar gloss of albuminized paper, yet photographers and the public have become so accustomed to it, and the practice of printing upon it has attained such a high degree of perfection, that it is not likely to be deposed from its present position of universality.

It happens, however, now and then, in many establishments, that a plain paper print is required for some special purpose, and the printer is sometimes under the necessity of making several experiments before he can produce anything sufficiently perfect. The enquiry not unfrequently reaches us from persons who say that they have never worked with plain paper, "How shall I proceed to get a few presentable plain paper prints?" Some time ago a sample of paper was in the market entitled "Amorphous albuminized paper," which had a matt surface, and gave all the vigour of ordinary albuminized, without its gloss. We generally recommended the use of such paper when unalbuminized prints were required, as it required no treatment different from ordinary albuminized paper. The demand for the amorphous paper has not, however, been sufficient to induce its maker to continue the supply; and we were informed the other day by Mr. Rejlander, with whom this paper was a great favourite, that it could no longer be procured.

The plan we are about to name is not, we believe, strictly new, but is, we fear, very little known. Our attention was recently called to it by Mr. Blanchard, who finds it answer admirably. It consists in floating a piece of ordinary albuminized paper on the silver bath with the plain side in contact with the solution—treating the albuminized surface, in fact, as the wrong side. The albumen and salt applied to one side of the paper appear to permeate the whole substance sufficiently to form a vigorous image on the other side when treated as we have described. The print is toned and fixed in the same manner as those with an albuminized surface. The plain paper print thus secured is rich, vigorous, and of excellent colour, and the nearest approximation to those yielded by the amorphous albuminized paper, of any plain paper prints we have seen for some time.

## OUR PRINTING ROOM.

BY NELSON K. CHERILL.

SURELY by this time there are no secrets in the printing room! Surely the Photographic News and other journals have not reached their twelfth volumes and yet not have exhausted so simple a subject as printing! Still I suppose it is so, if, at least, one may judge by the vast amount of ignorance which exists in the photographic world upon printing matters. Perhaps there is another way of putting it, which is better: all that can be said of printing may have been said; aye, may have been said many times over, and yet it may never have reached the understandings of some "intelligent printers." There can, at any rate, be no harm, and may be some interest, in describing somewhat in detail the operations which are daily carried on in our printing rooms. Those who know all about it need not read this article; but I trust that there may be some one or two points worthy of note even for the wise ones.

The first operation after taking a negative, before printing, is the varnishing process. For my own part, I greatly prefer the use of hot water for the necessary warming to the old plan of holding the plate to the fire. I am indebted to Mr. England for the suggestion, by whom, if I am not mistaken, it was first made. The apparatus I use consists simply

of a zinc foot-warmer, filled with very hot water; this is placed leaning against the wall and resting on the table so as to present a sloping surface, whereon to place the negative; there is room for two  $7\frac{1}{2}$  by  $4\frac{1}{2}$  negatives at a time. As soon as one is warmed through, the varnish is poured on, and another plate is then put on the warmer; the plate on which the varnish is poured is well drained, and then again placed on the warmer till quite hard. As soon as the negatives are varnished, the paper for the next day is prepared (I am taking up the operation at four or five in the afternoon at this time of the year). As I lately explained in a letter to these pages, we use three sorts of paper, being one very strong, rich paper for large pictures, and also for those small ones which do not work so well on the weaker papers; another, medium quality, for general use; and yet a third, to use when prints of an exceptionally delicate character are required. These papers are known to us by the names of their makers, but it is not necessary to mention them in this place. Our silver bath consists of—

Nitrate of silver ...	...	...	40 grains
Nitrate of soda ...	...	...	20 "
Water (not distilled) ...	...	...	1 ounce
Sugar (a little) ...	...	...	<i>à la</i> Bovey.

We have tried the use of the silver bath with gelatine, but without finding much advantage from it; the above is the best formula for a printing bath that I know of for general purposes. Before use it is filtered, and about ten grains of nitrate of silver are added for each sheet prepared the day before; the strength of the bath is thus supposed to be kept up to its original standard. As I sometimes find, however, when using a quantity of weakly-salted paper, we add too much silver in this way, and then the prints begin to assume a more brilliant character, and the relation between the character of the negative and the quality of the paper becomes upset: a negative which would have printed absolutely right on our medium paper would then be too brilliant, and would have to be done on some other paper. I should also mention that we keep up the quantity of the silver solution by adding water, and if there is any reason to suppose that the bath is weaker than usual, we make up its strength, not with plain water, but with fresh silver solution.

The papers being floated on the bath for three minutes, as a rule, or five minutes in the case of very thick Rives, they are hung up to dry by two corners, so as to drain into the filter through which the bath was passed. As soon as another sheet is ready, the first one is removed to another place, and a small piece of blotting-paper is pressed against the drop of silver solution at the lowest corner. This piece of blotting-paper adheres to the sheet, and greatly assists the process of draining; besides, by absorbing the solution, it prevents any mess from its dropping about, and aids in saving the waste. The drying is finished off by the fire, and the sheets are then rolled in tight bundles, each sort by itself. Thus prepared, the paper keeps perfectly till the next day, and even to the second day, but after that it becomes very yellow, and we do not like to use it for any but unimportant work. The sugar does not, in our hands, very much aid in keeping the paper from discolouration, but it is certainly of some use, though by no means so much as we should have been led to expect from the very favourable accounts of it which have from time to time appeared in your columns.\* The negatives being varnished, and the paper being prepared, the work of the day is so far finished.

Next morning the negatives of the day before are taken up to be named and looked through. The name of each is neatly stuck on the back on a slip of gum paper, and each

negative is carefully examined, not only as to its intensity, but in order to detect any little defects which may be obviated, or improvements which may be effected.

The printing operations are now proceeded with, and at this time of the year it is necessary to begin early and end early, as the light falls off very soon after the middle of the day.

There are many matters connected with the actual printing which time must compel me to abbreviate as much as possible. For vignettes we always use a simple arrangement, consisting of a hole in a piece of card, and cotton wool placed round it; this, being placed outside the frame, gives at once the most perfect means of securing a good vignette, having the especial advantages of being easily made, great cheapness, and, above all, of being easily adapted to any size or shape picture which may be required. For oval pictures we use the ready cut masks made by Mander; and nothing could be better for the purpose. One thing only is needed more with them: they should be numbered, so as to render it easier to order from them, and to refer to them, when the work is going on. We have found great difficulty in getting the makers of printing-frames to make the backboards fit properly; they generally make them so very tight; it seems to be "pride of the workshop" to make things very accurate, and so one gets punished by frames with backboards made so beautifully that you can hardly open one to look at the progress of the print without being almost certain of disturbing its position on the negative.

When the printing for the day is finished, the prints are looked through, and all extraneous dark edges of paper cut off, to save the gold; they are then immersed rapidly, one by one, in the washing water before toning. As soon as all are in, they are once turned over, and the water is then poured off, the dish again filled, and the prints again turned over; they are then removed to a second dish of clean water, and from this they are transferred, a few at a time, to the toning bath.

On some occasions during the summer we used—when printing large composition pictures, requiring some days' printing in the sun—a little alcohol in the first washing water, and with very good effect; it seemed to aid considerably in restoring the paper to its normal condition after the long-continued baking in the sunshine, and it thereby rendered the toning more certain and easy.

For toning we use the old acetate of soda bath, and until it fails us we do not intend to use any other; it is the most certain of any, and gives better tones than, or at any rate quite as good as, any that can be brought in competition with it. The amount of gold which it uses is not extravagant, but it is somewhat more than is given with some formulae. One grain of gold will, with our bath, tone two sheets of paper printed dark with massive shadows and but a small quantity of high light, such as are, in character, the pictures of M. Adam-Salomon; but when lighter prints are being made, the amount of work done by one grain of gold is more in proportion. We made our gold solution ourselves, and find it works very much better than any we could buy; it was made from pure gold and pure acids, and is a fine rich reddish yellow in solution; it does not as yet show the least tendency to precipitate from the stock solution, which we keep carefully excluded from the light. I have often heard it stated, by men whose experience should lead them to know what they are speaking about, that one grain of gold will tone from five to ten sheets of paper. I believe then it does so in a very improper manner. The object of the gold seems to me not only to be to give a fine colour, but also to make a preservative layer over the silver forming the print, and so to preserve it from the action of evil influences; and, therefore, I think it is especially necessary to use a toning bath which will ensure a thick coating of gold. One grain to a sheet used to be thought a proper proportion, but now some men are called foolish who use more than one-fifth of that quantity. For my own part, I think they are the more honest who look as

\* Mr. Cherrill, we think, somewhat overlooks the nature of the service sugar is alleged to yield. It does not prevent a slight discolouration of the paper, but secures a condition in which the discolouration disappears in the fixing bath. This we find to be the general experience, even with paper kept for many weeks.—Ed.

much, or more, to the chance of a print being permanent than to its cost of production.

After the prints have been toned, we pass them through two changes of water, and they are then put into the hypo solution, which is made up of a strength of 5 ounces of hypo to a pint of water. The prints are immersed in this solution one by one, each one being turned over two or three times to ensure the absence of air-bubbles; this done, they are kept moving by rocking the dish, and occasionally by turning them over in it for fifteen minutes. They are then taken out one by one, drained, and plunged for about five minutes more in a *fresh* solution of hypo, the same strength as before. This second solution is used again the next day as the *first* fixing bath. By this process of double fixing I believe the prints are rendered more permanent than if they had only one bath of hypo. I am looking out constantly for the supply of hyposulphite of ammonia which has been promised so long, and as soon as that comes I hope to have some more experiments on fixing to report. After fixing, the prints are thoroughly washed in a dish by repeated changes of water, and are then consigned to the "washing machine" for the night. I have already described our apparatus for washing in these pages, and therefore need not again refer to it. The prints in the morning are removed to a dish of clean water, and brushed over, back and front, with a large camel-hair flat brush, to remove any little impurities which may have come upon them in the washing trough. They are then set in a heap on a sheet of glass, and sent up to be dried, first between blotting-paper, and then by being spread out on a table. Starch is used for mounting, and when waxing is required, the formula which we first tried—and which was published in the *News* in a leading article shortly after M. Adam-Salomon's visit to England—is preferred to any other. Indeed, I cannot get any other used at all, as our own is so much preferred.

### RETOUCHING THE NEGATIVE.

BY JOHANNES GRASSHOFF.\*

THERE are many methods extant for retouching negatives. I myself have essayed several, but shall confine myself in the following remarks to the mode of operating which in my opinion is the best and simplest, and which I have for a considerable time made use of; excellent results may be obtained with it after suitable practice, but, as a matter of course, perfection can only be secured by a sufficient amount of skill and experience.

To facilitate the manipulation of the negative it is as well to provide oneself with a retouching frame, to be had of any dealer in photographic apparatus. The frame is placed at the window, the negative is screwed into it in a slanting position, and the looking glass so arranged as to reflect the light upon the image; by this arrangement the negative is clearly and distinctly seen without inconvenience. At the same time the operator must be careful to seat himself with the frame in a dark locality, and not, therefore, in the glass room; if it is necessary to work in the evening, the mirror in the frame cannot be used for reflecting the light from the lamp, and it is best to have recourse to a light placed upon a low stand furnished with a globe of ground glass, so that the negative may be lighted up with diffused illumination.

The most difficult negatives to operate upon are generally those of large portraits, and it is the face of these in particular which especially needs attention. To render the task easier, several pieces of stout opaque paper of the same size as the negative should be provided, all of them having round or oval openings of different sizes cut into them; with these the portrait is covered, with the exception of the head (which should be visible through the opening), and thus one's sight and attention are concentrated upon that portion of the plate to be operated upon, and one is not

irritated with stray light which penetrates through the transparent portions of the clothing, &c. Besides, by this means the varnish is protected from friction, a matter of some importance if the coating is still fresh.

It has often been proposed to gum the negative after being fixed, then to retouch it, and finally to cover it with varnish. This method of operating gives, it is true, in skilful hands, very excellent results; but it often happens that in varnishing, the varnish only partially penetrates the thin film of gum, thus rendering the negative frequently useless from the spotted character of its surface. Beyond this it is necessary that especial care should be exercised in the touching up of a gummed negative, as the point of a pencil easily penetrates the film, and thus causes the formation of holes: for these reasons, therefore, it is much more desirable to do the retouching upon a varnished film.

Negative varnish which contains an appreciable quantity of shellac does not always bear manipulation with a pencil, which, in this description of work, plays a very important role; I would recommend, therefore, the employment of a varnish the composition of which I give below for the purpose; it will be found to answer admirably, and may likewise be used with advantage upon positive pictures. My formula is as follows:—

Powdered sandrac	...	...	2½ parts
Camphor, broken up small	...	...	½ part
Venetian turpentine	...	...	1 "
Oil of lavender	...	...	¾ "

The above is dissolved by means of considerable agitation in

Absolute alcohol	...	...	15 parts.
------------------	-----	-----	-----------

When used, the varnish is diluted, according to circumstances, with a more or less quantity of alcohol which has been previously mixed with water in the proportion of 10 or 12 parts of alcohol to 1 of water.

The older the varnish on the negative becomes the harder it gets, and the quality of the pencil is regulated by the state of the varnish upon the plate, a hard pencil being required for a hard varnish, and *vice versa*. The first thing to be done is to work up and equalize any unevenness upon the face of the portrait, as, for instance, summer freckles and other dark spots; these are manipulated with the pencil until they are not to be distinguished from the surrounding parts of the negative; and in like manner the large shadows may be worked up, and particularly the abrupt glaring gradations sometimes seen upon negatives; strongly marked folds and other similar parts must also be softened down, in order to render the whole picture more harmonious.

Elaboration with the pencil is, however, not always successful, for in very transparent portions the lead is not sufficiently opaque, as, for instance, under the eyes, &c. In these instances a black crayon or so-called *Creta polycolor*, may be used with much advantage, being employed in the same manner as a pencil; better results still are obtained with ordinary black lithographic chalks, and, as the latter are generally very soft and the particles easily disintegrated, they impart more opacity than black lead, and answer the purpose admirably.

When these means are unavailing, a circumstance which sometimes happens when the pictures print too deeply and contain shadows of too dark and heavy a character, other methods of improvement must be tried. Ordinary black indian ink mixed with gum arabic, and used of the consistence of a syrup, may be applied with advantage. It is well to add a little glycerine to the gum in the proportion, perhaps, of two to four drops of the former for every ounce of gum solution; it then becomes easier to manipulate, and when dry is not so brittle upon the varnish, and not so liable, therefore, to peel off from the film. By using larger or smaller additions of gum, the opacity of the colouring matter may be regulated with the greatest nicety; and in parts where one coating is insufficient to render the plate of the requisite density, a second or often repeated application

\* Extracted from Grasshoff's Manual on the "Retouching of Photographs."

of the pigment may be resorted to until the transparent film has been worked up to the satisfaction of the operator. One layer of colour must always be perfectly dry before another is placed over it, and care must be taken that but very little of the pigment is taken up in the brush at a time.

With this gum pigment it is possible to effect an even coating over any large surfaces which may appear too transparent, as, for instance, the hands or arms, light clothing, or hair which has not been previously treated with powder; light brown beards or whiskers which print too deeply, particular parts of uniforms or costumes, when not too large, may all be treated with this description of colour. The manner of operating is to draw a large and well-filled brush as evenly as possible over the surface, without paying very particular attention to outlines; then, after breathing upon the same, to keep the pigment in a perfectly fluid condition, a softening brush is used to distribute the colour as much as possible, to form a perfectly even coating. Some practice is necessary for this description of work, but after a few experiments the operator will have no difficulty in succeeding. When dry, the extraneous colour is removed from the outlines by the application of a moist brush.

Any spots or patches which may be present in the coated parts of the negative are afterwards worked upon and removed. By applying a thin solution of a black pigment upon the reverse side of the negative (on the glass, therefore) in certain parts, those portions may be made to print lighter; but in this manner, owing to the thickness of the glass, the sharpness of the outlines cannot be very well controlled. If greater body is required, the pigment may be used without the addition of gum. When the colour has been applied, the surface is breathed upon and manipulated with the finger until a pretty even grain has been produced. On the reverse of the negative one need not be so particular in the softening down of the colour.

For producing uniform tinting upon the negative, sap red, sap blue, Prussian blue, burnt sienna, and gummy gutti, are very frequently used, by reason of their transparency and the ease with which an even coating may be produced with them; but it is much more difficult to judge of the intensity of these colours than of black, which, when mixed with gum, is almost as easy to manipulate as the blue and red colours just named. It depends very much upon what one has been accustomed to, for when well acquainted with the character and intensity of the tints employed, the desired results are easily obtainable.

With regard to the fine pinholes and other imperfections of the negative, these are best treated with ordinary indian-ink without gum; but the moistening of the brush with saliva should be avoided, as the pigment thus loses its binding properties, and does not furnish so opaque a coating.

There remains yet to be mentioned the method for retouching negatives of oil paintings. Plates of this description are, as a rule, very difficult of improvement, especially when they chance to be of a very transparent nature. It sometimes happens that the different colours of the original produce the most startling contrasts upon the negative, and in these instances it is best to cover the whole surface of the plate with a uniform coating of dilute colour mixed with gum solution; this should be applied upon the varnished side of the negative, although in very large plates the glass side may also be coated, and when dry those portions of the picture which appear too darkly covered may be again freed from the tint by rubbing over with a moist brush or cloth.

Small imperfections in the gradation of tone may be improved by means of a lead pencil, which can be used with special advantage in those parts of an oil painting negative where the direction of the brush is traceable in the shadows and darker portions of the picture.

Finally, a few remarks are necessary on the treatment of landscape negatives. It is not always the case that the sky—or, rather, the atmosphere—is so transparent as it ought to be, and then a little aid from the brush is necessary. When, however, the atmosphere is sufficiently clear and

transparent, but somewhat detrimental to the effect of the picture, owing to its even and monotonous appearance, which is very often the case, its aspect may be improved by painting in a few cloud effects. This is best done, especially when the form of the clouds is a matter of no importance, and it is desired only to obtain a few different tints in the sky, by applying to the reverse side of the plate a little Indian ink mixed with gum in such a manner that a cloud-like gradation of tone is produced; this need not be done in a very elaborate manner, but may be roughly sketched out. By crossing the strokes, and laying one over the other, a greater or less opacity is produced, which, in the picture, will appear as light portions of clouds. A more beautiful effect may be obtained, and in an easier manner, by employing a fine black oil pigment mixed with a little linseed oil or varnish, together with a small quantity of siccativ (driers). The advantage of using a colour of this description is, that it remains longer in a moist state, and may be graduated to the finest degree, thus permitting of the elaboration of the finest cloud effects, which may be modelled from a pattern cloud negative taken for the purpose. The method of actually printing in clouds from another negative does not always yield satisfactory results, as it not infrequently happens that the clouds do not harmonize with the picture to which they have been adapted; with painted clouds an alteration can at any time be effected. Although the thickness of the glass allows of the painting being of a rough description, still the beginner will do well to soften down his work before finishing; it must also be remembered that a negative treated in this way cannot be used until the oil colour on its surface is perfectly dry. Sap red and blue are often used for painting in cloud effects, but, as previously stated, I always prefer to employ a black pigment for the purpose.

When it is considered desirable to cover over the whole of the sky by means of an opaque pigment, so that the atmosphere is represented perfectly white, red is the best colour to be used—as, for instance, cinnabar, English red, Vandyck brown, &c. A good black may also be employed. The colour is rubbed upon a glass plate as finely as possible by means of a glass rubber and water, and then some gum and a drop or two of glycerine are added; it is again thoroughly mixed to the consistence of a salve, and then placed in a saucer ready for use. But a moderate quantity of gum only should be used, and the colour, when applied to paper or glass, should not be inclined to rub off; the glycerine is to prevent the pigment from becoming brittle. The red colour is preferable for employment, as it possesses great body, and its manipulation, especially in regard to outlines on the varnished side of the negative, is easily controlled; and if any portion of the plate should not be very thickly covered or marked, the red tint prevents the transmission of light much more than a film of black pigment. Thus it will be seen that red or Vandyck brown are particularly suitable for the purpose, and also for stopping out pinholes, &c. Ordinary Indian ink is simply used for covering the sky, a pigment which in many cases is amply sufficient for the purpose, a few drops of glycerine should always be added, for reasons above stated.

It may be mentioned that instead of using gum pigments, tempera colours may be employed; these latter never separate or split from the surface of the plate, an accident which not unfrequently occurs with other pigments during great heat. Some yolk of egg is mixed with about one-third of its volume of an oil of some kind or another, and stirred vigorously in a glass vessel; a little water is also added, and then the mixture is used with the colour instead of gum and glycerine. Linseed oil, poppy oil, or Florence oil may be employed for the purpose, but linseed oil varnish is the most suitable. These tempera colours allow of the application of several layers, one over the other; one coat does not dissolve off the other so long as the first one is tolerably dry, and as the pigment is somewhat difficult to dissolve in water it should be stored away in as moist a condition as possible.

PICTORIAL EFFECT IN PHOTOGRAPHY ;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.

CHAPTER XLI.

WHILST Turner is usually supposed to depend for his excellence upon the rendering of the more subtle and chromatic effects of nature, a careful examination of his pictures will show how strict was his adherence to the recognised laws of composition and chiaroscuro. The *Temeraire* and *Ulysses*, pictures essentially associated with the glowing effects of colour given by the setting and rising sun, yet, when reproduced in monochrome, will be seen to be singularly accurate

illustrations of the most simple forms of artistic arrangement.

There is scarcely a picture or sketch by Turner but which will afford a lesson in composition to the student, as I have had frequently to point out. This is especially noticeable in his great book of lessons, the "*Liber Studiorum*." In a former chapter an example from this magnificent work (the "*Stackyard*") was given, and in Chapter 29 I gave a sketch showing the arrangement of light and shade only of one of the finest pictures in the collection, that known as "*Norham Castle*." This drawing is so fine, and affords such an admirable lesson in effect to the photographer, that I have thought it worth while giving a more accurate and detailed reproduction of it, reduced by Mr. Fruwirth from an admirable woodcut in the *Illustrated News*, together with

the critical remarks appended to it in that journal, which forcibly indicate its chief points of excellence and interest:—"In the '*Stackyard*' we see the painter's power of imparting interest to the humblest incidents and homeliest occupations of rustic life by judicious choice of the point of view, skilful composition and distribution of light and shade, and suggestive handling—the last noticeable especially in the masses of foliage. In the '*Norham Castle*' we are reminded of Turner's marvellous versatility. Although the cows drinking at evening, the boat, the skiff, and hut are as familiar and commonplace as any of the elements of the first-named drawing, yet every one must feel that this is as different in its dominant sentiment of solemn serenity and impressive repose as it is in its leading subject of a venerable, brave, and sturdy stronghold, preserving its dignity and grandeur, and even gaining in awfulness, in ruin and decay. This drawing illustrates, also, one of Turner's most favourite expedients for securing powerful effect, with a real perspective, in which he has never been approached. We allude to the placing of a tree or building immediately before or near to the source of light. A painter thus secures not only the power of accenting the mass and contour of the

object so relieved in the most powerful way, but he obtains the utmost limit of effect by the opposition of his highest light and profoundest dark, and, by this mode of giving, so to speak, the extremities of his gamut, he enables the eye to be sensible of and measure the tenderest tones and semitones in other parts of the picture. We trust the reader will appreciate, by looking at our engraving, the variety afforded by this artistic principle to the gradations throughout, and the luminous and aerial quality imparted to the sky. Of the appropriateness of relieving against the setting sun that frowning ruin and that watchtower, which has seen the same sun sink beneath it for centuries, it would be idle to speak."

ON THE EMPLOYMENT OF MIXED COLLODIONS.

BY M. OMER BORDEAU.\*

IT is by no means of unfrequent occurrence that a photographer is sorely tried by the capricious behaviour of a collodion which to-day yields unsatisfactory results, while yesterday it was perfection, and may be so again to-morrow.

\* *Bulletin Belge de la Photographie.*

The cause of these variations in the results obtained are not in any way to be traced in a scientific manner by analysis or otherwise, and we have, therefore, no remedy but that of patiently bowing down before our tormentor. It is not my intention on the present occasion to make known an infallible remedy for the cure of this evil, which we all bear with more or less resignation; I desire only to indicate to my readers a method which has done me good service from the first, in order that any one who wishes to experiment with the same may do so if he deem it sufficiently worthy of trial.

My collodion is a compound of three collodions. No. 1 is made up of the undermentioned ingredients:—

Rectified ether...	...	70 grammes
Alcohol...	...	30 "
Gun-cotton...	...	1 gramme
Iodide of cadmium...	...	0.5 "
Iodide of ammonium...	...	0.5 "
Bromide of cadmium...	...	0.3 "

The above formula produces a liquid of thick consistence, and perfectly colourless.

No. 2 is thus compounded:—

Ether ..	...	60 grammes
Alcohol...	...	40 "
Gun-cotton ..	...	1 gramme
Iodide of cadmium ..	...	0.5 "
Iodide of ammonium ..	...	0.5 "
Iodide of potassium ..	...	0.3 "
Bromide of cadmium ..	...	0.2 "
Bromide of ammonium ..	...	0.2 "

A small quantity of sublimed iodine is added sufficient to give a pale yellowish tint to this collodion, which is more strongly iodized and bromized than the former, and likewise more liquid, on account of the large proportion of alcohol which enters into its composition.

No. 3 collodion is thus made up:—

Ether ...	...	55 grammes
Alcohol...	...	45 "
Gun-cotton ..	...	1 gramme
Iodide of ammonium ..	...	0.8 "
Iodide of cadmium ..	...	0.3 "
Bromide of ammonium ..	...	0.5 "

This last formula resembles that of M. Inglis, which is a very quick-acting material; it is indispensable for the production of children's portraits, so beautiful when they prove successful, so detestable when they are failures.

The mixture of these three collodions is made at the time of their employment, equal parts of each liquid being taken, excepting when working under certain conditions, as every photographer will understand. Thus, in very cold weather, a somewhat larger proportion of No. 1 is used, which contains one-third of alcohol to two-thirds of ether; in very hot weather I augment the proportion of No. 2, in which the large amount of alcohol prevents the too rapid evaporation of the ether; and finally, in dull and rainy weather, or when children are to be photographed, the proportion of No. 3 is increased by reason of its greater rapidity, and of the larger amount of bromine in its composition.

It is regarded by many as a foregone conclusion—without, indeed, the existence of any absolute proof—that bromide of silver is more sensitive to weaker rays of light than the iodide of the same metal. Everybody may have his own opinion on this subject, pending a positive solution of the problem; and we are inclined to believe that the sensitiveness is due solely to the presence of iodo-bromide of silver with an ammoniacal base, produced by means of a double decomposition. The third formula employed by itself presents all the characteristics—both advantages and disadvantages—displayed by preparations in which iodide of ammonium predominates. For the purpose of comparison in a practical manner, I prepared a collodion of the proportions above indicated, so as to participate equally in the three formulæ, but the liquid thus obtained yielded unsatis-

factory results, whereas a mixture of the three compounds prepared separately continued to work wonderfully.

The explanation of the fact I have mentioned reminds one of the elaborate scientific researches which have been made for the purpose of obtaining wider information in respect to the formation of the photographic image. The action of light upon iodide of silver, the existence of an invisible image upon the sensitive plate, the action of the reagents which render the picture visible, all these are problems not yet solved. Notwithstanding the ingenious theories put forward by such men as Monckhoven, Poitevin, Davanne, Vogel, Carey Lea, and others, the phenomena are still unexplained.

It is for this reason, on account of this black screen placed against the horizon of photography, and completely shutting out the view beyond, that no formula for a collodion can be recommended as practically and theoretically good. The mathematician, by calculating the details of his work, is able to obtain a very correct idea of the total, as the partial inaccuracies on one side or the other mutually destroy one another. The mixture of the three collodions is based upon this principle, and it gives, we repeat, the best results.

### ON THE SENSITIVENESS OF PHOTOGRAPHIC PREPARATIONS.\*

WHEN the approach of autumn warns us that the fine weather and the long, bright days are coming to an end, and that we must prepare ourselves for the dull and feeble light of winter, it is a source of regret to those among us who do not possess an open, unconfined studio, that our present process of negative-taking necessitates so lengthened an exposure. It seems quite superfluous to make any remarks upon the great value of short exposures, and it, on a recent occasion, an English gentleman has stated that he prefers results obtained with long exposures to those taken with shorter periods, on account of the less astonished and less forced expression of countenance exhibited by such portraits, we can only regard such statement in the light of a joke, for, as a matter of course, as soon as an efficient, instantaneous process has been discovered, no extraordinary skill will then be requisite on the part of the operator to secure any desired facial expression. We believe that it is matter of importance, now that we are enabled, after some experience, to obtain pictures of any description we may wish, whether vigorous or soft, sharp or bold, to turn our attention to this subject, and to commence researches which shall have for their end the devising of a method for increasing the sensitiveness of our photographic preparations. Researches in this direction are the more desirable inasmuch as very recently great improvements have been made in photographic optics, and we are now in possession of lenses which, in regard to depth of focus, sharpness, &c., are something perfectly wonderful, although, unfortunately, a longer exposure is necessary by their employment.

One need not be a very great enthusiast in order to prophesy a warm and eager reception to a thoroughly practical, instantaneous process; every photographer who has essayed children's portraits will admit this. It would then be scarcely necessary for an artist to expose in his studio the usual notice, worded something like the following:—  
"Cartes-de-visite, ten shillings per dozen. Children pay double."

When we remember that the long exposure which was necessary in the early days of photography was considerably shortened, first by the introduction of collodion, and afterwards by the employment of iron development, and that during the last ten years very little has been done, except in a slight degree (by more strongly iodising the collodion), to increase the sensitiveness of the negative, although the subject was one that photographers have continually hoped to improve, we must admit that our progress

\* Photographisches Archiv.

has of late been very tardy; and we cannot but side with the optician, who, when he is asked by the photographer for a quicker-acting lens, replies, "My lens is a good one, it is your plates that should be more sensitive," thus referring to the chemist the solution of the all-important problem. Our present collodion process with bromo-iodide of silver and iron development is not so sensitive in its action as the bromide of silver collodion with alkaline development. By the employment of an iron developer a much shorter exposure is necessary than with a weak pyrogallie acid solution, and in the same ratio is gallic acid to pyrogallie acid. Can we not discover a substance, or even several substances, that are to sulphate of iron what that compound is to gallic acid? Or must we look for other silver compounds, or for some other totally different material? Bichromate of potash has in the printing process proved itself to be three times as sensitive as chloride of silver; is it impossible to find a salt which is three, or even ten, times as sensitive as iodide or bromide of silver?

## Proceedings of Societies.

### NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Society was held in Myddelton Hall, on the evening of Wednesday, November 4th, Mr. G. WHARTON SIMPSON in the chair.

The minutes of a previous meeting were read and approved, and the following gentlemen elected members of the Society: Messrs. Maltby, Leunig, F. Hunt, J. Marham, A. Short, G. Colling, Thomas Hawkin.

Mr. WOODBURY exhibited some fine examples of his relief printing process, consisting of 10 by 8 reproductions of paintings issued by Goupil and Co., which were much admired.

THE CHAIRMAN called attention to some fine enamels by Mr. Henderson, brought by Mr. Taylor. He remarked that the enamels of M. Lafon de Camarsac had always been regarded as types of perfection in photographic enamelling; but some of Mr. Henderson's came very little short indeed, if any, of the excellence of the Parisian photographer, and he thought it matter for congratulation that such first-class results were produced in this country in a branch of the art hitherto much neglected.

No paper having been provided, the meeting resolved itself into a conversazione, in the course of which some amusement was excited by an extract from a daily paper, to which a member called attention, in which some curious statements were made on boiling and baking as tests for permanence in photographs.

The proceedings then terminated.

### EDINBURGH PHOTOGRAPHIC SOCIETY.

THE eighth annual meeting of the Edinburgh Photographic Society took place on the 4th November current.

The Council's Report, which is a very satisfactory one, states that twenty subjects have been brought before the Society during the year, including three of the popular meetings for which the Society is famed. The number of members added to the roll during the year has been thirty-five, which gives a present muster roll of 184, excluding thirteen who have died or left the Society from various causes. Six new members were balloted for and elected unanimously during the evening.

The following office bearers were appointed for the ensuing year:—

*President.*—Sheriff Hullah.

*Vice-Presidents.*—Messrs. George H. Slight, James G. Tunny.

*Hon. Secretary.*—Mr. William H. Davies.

*Hon. Treasurer.*—Mr. John Hurry

*Curator.*—Mr. John Peat.

*Auditor.*—Mr. A. J. Niven.

Assisted by a Council of twelve gentlemen as under:—James Blackadder, Mr. W. D. Clark, Mr. Hugh Rose, Mr. John Scott Maccrieff, Mr. Archd. Buras, Mr. Jas. Bryson, Mr. Jas. Ross, Mr. John McNan, Rev. D. T. K. Drummond, Mr. Norman Macbeth, Mr. J. D. Marwick, Mr. Richard G. Muir.

The business sketched out for the next session promises to be full of interest, and we shall take care to keep our readers apprised of the various meetings as they occur. One feature of great interest in this Society is its so-called popular evenings, at which, by the aid of a powerful oxyhydrogen lantern, the pictures of the members and others are exhibited to large audiences. The idea is worth the attention of some of the more energetic societies.

## Correspondence.

### A PHOTOGRAPHER'S RELIEF FUND.

SIR,—I am willing to subscribe a pound or two, or more, a year to such a fund as soon as a satisfactory committee be formed. But who are the proper persons to subscribe to and receive from such a fund? in short, who are photographers? In this town the profession is represented thus: Branch of a Loadou firm, painter and glazier, shoemaker, hairdresser, glover, milkman, lodginghouse keeper, legitimate photographer. So you see there are eight likeness shops in this town; but I cannot count more than three or four persons who ought to be designated photographers—one who has practised sixteen years, and two or three others who are employed as operators. Such as stationers, chemists, hairdressers, &c., who add to their business that of a photographer, certainly ought to be excluded.

My suggestion is simply this: Let one in every town who has been long known to some London house in the trade confer with his brother legitimate photographers in his neighbourhood, with a view to ascertaining their feelings on the subject, and communicate the result to yourself, for the purpose of its being laid before any gentlemen who might be willing to constitute a committee. Should you think my plan worth consideration, perhaps you will give this a place in your valuable Journal.

I have only to add that I would at once confer with the one or two working photographers in this town who I consider to be the only persons who ought to subscribe to, with a view of participating in, such a fund.—Yours obliged,

November 9th, 1868.

W. MATTHEWS.

[Our correspondent very aptly illustrates some of the practical difficulties which, as we have suggested, require consideration, and which render necessary an examination and a full discussion of the question in its practical bearings as a preliminary to organization. We shall have pleasure in giving publicity to practical suggestions.—Ed.]

SIR,—The matter of forming a Relief Fund or Provident Society has once more become a matter of consideration. As a provincial photographer I can only recapitulate what has been said. I shall have great pleasure in aiding or assisting in any good cause that tends to benefit my fellows of the profession. Be he artist, photographer, operator, assistant, or printer, all within our circle, or linked to our profession, should have our warmest sympathies. Why should we raise any objection, to exclude any connected with the art? I may say, nothing like the time present. We cannot commence too soon in any good cause, so let us at once give our names in to you, Mr. Editor, and make a commencement, and those desirous of forming such can then have a meeting called; and if we reside out of London, we can pen our thoughts and send them, and have a voice in the matter. I would suggest a provident society on the same principle as the Oddfellows; it would be more independent for its members. I would not object to a special fund for emergencies or particular cases; and I feel fully confident we could have a photographic bazaar, and enlist the ladies to assist us. I am sure, Mr. Editor, if we only commence, we shall succeed. However, let us try; let some of your generous readers suggest a subscription as entrance money or voluntary free gift; I am quite willing to chime in and say yea with the rest. Hoping that this time the matter will not be lost sight of, I ask all connected with photography who can afford it to come forward and tender their mite in such a cause, or send their names for membership; and, Mr. Editor, I feel fully confident you will be most happy to publish anything any subscriber would suggest for the future welfare and progress of a Photographer's Provident Society or Relief Fund.

Thanking you for past favours, and apologising for trespassing on your valuable pages, I remain, &c.,

LUX ET SALUS.

SIR,—Entirely coinciding with the suggestion of your able correspondent "Stereo," in reference to establishing a Photographer's Relief Fund, that it is desirable to have the opinions of some of the representative men in photography on the subject, especially as you have so kindly opened your columns for recording such opinions, and being myself deeply concerned in the welfare of such a fund, and believing all who are interested in our art progress need only be appealed to for furthering so desirable an object, I take the liberty to suggest that advertisements in the daily press should be inserted, requesting that all persons connected in any way with photography, and who are in favour of assisting in the establishment of a relief fund for the above object, should send in their names, through post, to a secretary *pro tem*. I should think there would be no difficulty in getting a gentleman who would kindly undertake so laudable a duty. Then, after a sufficient time, which of course would be mentioned, a public meeting should be called in London for the purpose of forming a provisional committee for the purpose of drawing up the necessary constitution of the society; which being done, another meeting should be convened, to pass such rules and regulations, if approved of; and then some well known gentleman or firm should be appointed as treasurer for all donations and subscriptions received.

The party desiring relief should be recommended by those residing in his immediate neighbourhood, and should have had his name inserted in the society, either as a subscriber or donor.

In the meantime, as funds would be required for the payment of advertisements, &c., all persons desiring to aid the good object should send a donation to some trustworthy person appointed, until such time as the first public meeting should be called, when collections might be made as a nucleus for the general fund.—I am, yours truly,

J. NORRIS.

5, Church Road, Norwood.

#### PORTRAITS ON APPROVAL.

SIR,—Mr. Downes made a very just complaint in his letter to you last week when he said that people come and occupy your time for an hour or two, as the ease may be, pay nothing, and request that proofs may be sent, and eventually do not or will not approve of anything, however good, that may be sent them. The plan I adopt to avoid this is that of many photographers; that is, to have a notice fixed in a conspicuous place, in unmistakable language and type, to the effect that "Visitors are requested to pay before leaving;" or, "Prepayment is the rule." This notice brings the servant girls up sharp, but the "missusess" often do not seem to see it. When this peculiar exhibition of amaurosis presents itself, it is the duty of the photographer to explain in a bland (that's the word) and gentlemanly manner that, &c., &c. I do not do this, although it is very proper, and probably profitable, but let them have it hot or cold, according to the diagnosis I form of the offending subject.

Let photographers respect themselves and their art more, and not permit any man or woman, whatever their social position may be, to impose upon them, and such troubles as Mr. Downes complains of will not be so frequent. The other day a great swell, in appearance and his own estimation, brought a lady to my studio to be taken. While she was taking off her bonnet in one room, he observed in the reception room a notice that prepayment was the rule; he demurred at this, said Mayall had recently taken his portrait, and he (Mayall) did not require it of him. The lady had to put on her bonnet again, and they were both politely bowed out by—Your obedient servant,

November 9th, 1868.

PAS-TROP.

#### ALBUMINIZED PAPER AND PRINTERS.

DEAR SIR,—It affords but a humiliating testimony to the much vaunted intelligence of the present age, when "one who holds decided opinions of his own" is regarded as a rare phenomenon, who is favoured with the "esteem" of none but the discerning few. And it is a subject for gloomy reflection that in the event of such opinions running contrary to popular

ideas, no small amount of moral courage, to overcome feelings of self-interest, must be called into requisition ere the newly-conceived thoughts may be exposed to the jealous scrutiny of the narrow-visioned multitude, who desire progress, but insist on the retention of old notions that have long been favoured because of their respectable origin. Those pseudo-progressionists, apparently oblivious of the fact that genuine progress is the offspring of original conceptions, would have the world stand still rather than allow their self-esteem to suffer the momentary pang inflicted by the advent of any opinion that strikes at the root of unsuspected ignorance. I readily concede that an idea might be strictly original, yet decidedly useless; but it must be admitted that thoughts, however valuable their import, remain comparatively worthless until such time as they can be introduced into their natural sphere of action. And if we accept the dictum that all who can do so, should add their mite to the general fund of knowledge, why, I enquire, should any boldness be needed to enable the donor to perform a duty which the world claims as just? Why should the performance of such duties create fears of probable displeasure and pecuniary losses? "But the world should be wooed into complacency with softly-moulded sentences," observes the well-drilled disciple of the polite Chesterfield school. "Call not a spade a spade, which jars on the ear, and sounds harsh and unseemly; rather name the implement a rural excavator, and you exhibit proofs of gentle breeding. By the same rule, if the world lack knowledge, hold thy peace, and you set a value on your future fortune." To those who consider self to be the alpha and omega, the doctrine thus laid down might prove profitable; but, speaking in my own behalf, nature never fashioned me to act the part of courtier. Having struggled through what little knowledge I possess in a stern matter-of-fact school, I am unable to robe my words in wool, or to dip my pen into the ink of flattery or of fulsome prevarication. I write what I believe to be the truth, and I never advance a statement which is not borne out by an abundance of argument ready to be "called to the front" if required. If I am wroth to "lose my head in wordy rhapsodies," my readers might depend on the fact that I never go beyond the proofs I have at command when I venture on personalities during the absence of my wits without leave.

Now, sir, with reference to remarks offered by Mr. Cherrill in your last issue, permit me to observe that my comments on that portion of his paper which treated on printing matters were not the results of an intermingling of Mr. Cherrill's observations with the discussion which followed; but any argument bearing on that point need not now be urged, as I find the inferences I drew from Mr. Cherrill's words are now recorded in plain language in that gentleman's reply to my last communication. Mr. Cherrill considers that photographers should know the amount of salt contained in the papers they employ. He deems it a duty to be observed by paper albuminizers that their customers should be told what kind of negatives they must produce, and the quantity of silver each quire of paper will consume; and, to bring his remarks home, he threateningly foreshadows a revolution which will extort from the albuminizer secrets he never valued—information he does not possess. I venture to predict that when such change occurs, it will soon be found that the change has changed nothing. Speaking for myself, I would gladly adopt the hints thrown out by Mr. Cherrill at once, but I am bound to confess myself ignorant of knowledge I fain would impart; I therefore ask of that gentleman, as a man of science, distinct replies to the following queries:—

1st. The amount and description of chlorides added to each ounce of albumen being known, by what means can the quantity of albumen absorbed by each sheet of paper be ascertained? In his calculations I would have Mr. Cherrill bear the fact in mind, that an average summary would not accurately solve the problem, as papers differ in texture, and, consequently, in powers of absorption; and albumen may be said to change strength after the floating of each sheet thereon.

2nd. Supposing the amount of salt each sheet contains could be ascertained by an impracticable process of weighing before and after its being albuminized, what amount of silver must the albumen be credited with?

3rd. In what manner is the silver bath to be constructed, that in order to prevent a loss of uniformity a uniform adjustment of free nitrate may be provided for throughout?

I think I might, without egotism, pronounce my practice, as

described in a recent article on sensitizing baths, more practical and infinitely less troublesome than any scheme that may be extracted from the above series of problems.

Again, Mr. Cherrill asks uniform working qualities in the papers supplied him, and he cites, as an instance of the uncertainties that attend the papers he has in stock, his experience with articles supplied him by myself. I heartily thank him for information which bears so forcibly on the argument I adopt. I declare, on my honour, that both papers described, Saxe and Rives, were coated with a similar quality of albumen, and in both instances the same salting formula was adopted; yet results differ widely. Why? In the one case (the Saxe paper) the albumen rests on the outer surface; in the other (the Rives) the albumen was absorbed by the paper, and a surface more readily penetrated by the silver solution results; hence the Saxe paper yields an image of lesser vigour than can be secured with the Rives sample.

The "Salomon negative" is doubtless a repeat of Salomon's grand style; ranging in harmonious gradation from comparative opacity to clear glass. To secure the best results from such a negative a paper moderately salted is needed, and the printing should be executed in a bright but diffused light. "Now," observes Mr. Cherrill, in substance, "if we could depend on a uniform supply of a similar kind of paper, we could adopt this Salomon negative as a standard of intensity, and produce all our negatives in unison." Query. Could such a plan be made practical? If so, would such treatment be at all times judicious? How about the negative of that imaginary scene "where the sun shines low over a calm summer sea, and the only faint shadows are obtained from the darker sides of the tiny ripples"? Observe the two extremes: one all vigour and full of contrast; the other a combination of flatness with weak effect. Would a uniform paper with the most uniform treatment suit both subjects? Unquestionably not, except the paper was aided with judicious treatment and the requisite modification of chemical solutions. Fact of the matter is just this: it is not a uniform paper really needed, neither is it any information concerning salting formulae that will remove the plague of bad pictures; what is really requisite is, an honest recognition of the comparative ignorance that prevails in connection with the printing department. As I have observed elsewhere, the art of printing in silver is held in too low an estimation. The work is entrusted to boys, or to no less incompetent men; and as long as unskilled labour is employed in the production of silver prints—as long as the employers remain blind to their own imperfect knowledge of a subject which requires a very large amount of experience to master—so long will demands be made on the paper albuminizers, who are unfairly set down as the authors of every ill their productions meet with.

In conclusion, I would just state that it involves a heavy tax on my time to prolong this discussion; but as long as useful matter can be elicited from the remarks of those who may desire to discuss the question with me, I am open to all comers. I remain, yours respectfully,

W. T. BOVEY.

Willesden, November 10, 1863.

#### MR. FRY'S MODE OF MASKING.

DEAR SIR,—I am much pleased with the prospect of great improvement in the printing quality of negatives likely to be realized by Mr. Fry's new and improved method of masking. Individually I beg to offer him my grateful thanks for his liberality in making it public. I desire now to take advantage of his kind offer, in last week's issue of *THE PHOTOGRAPHIC NEWS*, of giving all further information to anyone requiring it; and, before doing so, I feel that an apology is due to him for my troubling him for information which to professionals would, probably, appear quite simple and plain; and I have only to plead as my excuse that of my being an amateur in the art, and consequently, not learned in matters photographic, although I must confess to being of very many years standing.

1. I would enquire of Mr. Fry how I am to make the necessary transparency—whether by superposition on a dry plate, or any other way? And if by the first-named plan, what process would be the most simple and effective?

2. As the transparency would be on the same sized plate as the negative from which it was printed (with myself it would be a quarter-size one), how am I to get the transparency into immediate contact with the back of the negative, seeing that

it—i.e., the transparency—would be kept at a considerable distance from the negative by the front projecting part or rim of the usual little quarter-plate printing frame? This is my present greatest difficulty.

If it be not trespassing too much on Mr. Fry's very great kindness, I should feel myself under an additional obligation to him if he would oblige me with a carte size specimen of his new method of double printing, for which I would with pleasure remit him his usual charge on his naming the necessary sum. May I venture to add that it must be carte size only, as I keep an album especially devoted to photographic novelties?

Would Surbiton be a sufficiently intelligible address to reach Mr. Fry?—I am, dear sir, yours sincerely, HENRY H. HELE.

High Cottage, Teignmouth, Devonshire, November 10, 1863.

Addendum.—Under my second query to Mr. Fry I might have said that it would not be practicable to remove the negatives with the partly printed impressions from the printing-frame, in order to insert the transparencies in front of them, as it would be impossible to replace the three in their exact and proper places by such a procedure.

H. H. H.

[Mr. Fry will, perhaps, kindly answer our correspondent, and so impart the information required to others besides.—ED.]

#### PHOTOGRAPHY AND PERSPECTIVE.

DEAR SIR,—The subject started by Mr. Anthony is a most interesting one, and although I believe him in error as regards the proportional increase in the reflection of the extended hand in the mirror, I think he has done good service in raising the discussion upon the relative pictorial truth of lenses of various length of focus. From my own experience I have reason to believe that those that will show upon the ground-glass an angle of view equal to one-seventh part of a circle will delineate objects in true perspective, provided that they are in other respects properly constructed; beyond this the lateral rays become too oblique, producing angles which natural vision could never see, and bring the points of distance almost into the picture. The so-called panoramic lenses have this objection, and are, as far as the production of pictures in natural perspective goes, a delusion. Panoramic pictures are not thus designed, but in sections, some objects being introduced and so arranged as to hide the beginning and ending of each section. Short-focussed lenses are, undoubtedly, of service in many cases, but they dwarf the objects in the picture. Lenses of too long a focus, on the contrary, make them appear too high; this is caused by the former producing the lateral rays longer and the latter shorter than those in natural vision; thus in both cases the eye refuses to recognize truth in their delineation. Place a camera having a wide-angled lens in front of and about the middle of a long brick wall, for an angle of 25° on each side of the central visual ray, the courses of bricks will appear straight on the ground-glass, but from those points they will appear gradually to converge on each side to the points of distance. Again, make the front elevation of a portico supported by pillars the subject, and in this case the pillars nearest the sides will appear larger than those in the centre, proving that with such lenses perspective truth is out of the question.

In portraiture the same theory holds good. I do not think exaggeration in foreshortening will be produced by lenses of proper focus unless brought too near the sitter, or what is termed strained, in the attempt to obtain the representation of a head of a larger size than the lens is intended to produce. As regards reflections of objects as seen in a looking-glass, the angle of incidence will always be found equal to the angle of reflection, and therefore the reflected object will always appear as far behind as it is before the mirror, and the foreshortened hand will advance its reflection accordingly. It is probable that the demand for short-focussed lenses has been caused, in many cases, from the very limited space often only to be obtained wherein to erect a studio, or from a wish to avoid the increased expense in the building of a larger one, without giving a thought—or, perhaps, having a knowledge—of their peculiar qualities; in outdoor practice, from the desire to get as near to the object as possible, or to obtain more subject-matter in the pictures. But these should all be exceptions, and not the rule, and their use restricted to such cases accordingly. The reader may form a good idea of the effects of angular distortion by experimenting with a toy called the Dubosqueoscope. It consists of a semi-circular mirror, which stands on the table, and a set

of diagrams, which, when looked at in the usual way, appear a confused network of distorted lines, but when properly placed before the mirror they resolve themselves into various objects in proper perspective.

JAMES MARTIN.

114, High Street, Ilfracombe.

## Talk in the Studio.

**EMBEZZLEMENT BY A "DOORMAN."**—Benjamin Carmichael was charged at Guildhall Police Court with embezzling 25s. belonging to his employer. It appeared that Mr. Nippres, a photographer, carrying on business at 87, Farringdon Street, employed the prisoner as what was termed in the trade a "door man;" that was, a man to stand at the door and solicit the public to have their portraits taken. He was to receive for his services 1s. 6d. per day and 2d. per customer commission. He was put to work on Friday last, and, after being on for a little time, the prosecutor sent him to pawn a lens for 30s. which was worth £4. The prisoner, after trying various pawnbrokers, and not being able to get the required amount, took it to Mr. Wood, in Shoreditch, who lent him 25s. on it. The prisoner then sold the ticket, and the lens was taken out of pledge next morning. The prisoner never returned to his employment, and never paid over the 25s. he received for the lens he pledged, nor the money for which he sold the ticket.—The Prisoner, in defence, said that he was not to have wages at the rate of 1s. 6d. per day, but was to be paid 25 per cent. on the customers. He also said that he lost the money, and that was the reason he did not go back to Mr. Nippres, but if time were given him he would repay the money.—After considerable discussion, the prisoner abandoned his line of defence, and pleaded guilty to embezzling the money, so that he might be dealt with under the Criminal Justices Act.—He was sentenced to three months' imprisonment, with hard labour.—*Standard.*

**CHEAP COLLODION FILTER.**—A correspondent of the *Philadelphia Photographer* gives the following:—"Being without a collodion filter, and being economically disposed, I thought I would try and make one out of home material, and succeeded in making one that answers the purpose admirably. Here is the way: Take a half-pound cyanide bottle, with a wide mouth, and good cork to fit; get another one of similar capacity, but with a small neck, which (the neck) ought to be full an inch or more long. Turn this bottle upside down in something to make it stand, and right at the foot of the bottle tie around some wick saturated in alcohol; set it on fire, and when burnt out immerse quickly in cold water, which will cause it to break off around the foot in a complete circle. Take off the lip from the neck in the same manner. By cutting smoothly a hole of the right size in the cork of bottle No. 1 you can fit the neck of bottle No. 2 into it, which should be put in with shellac. Then get a small glass tube, about five inches long, and with the aid of the pincers slant off one of the ends a little; wrap some clean cotton round it, about an inch from the point. This is put into the neck of the bottle to fit tolerably loose. The end of the tube must reach about an inch from the top, so as to leave space between it and the large cork, which is now to be fitted nicely in the broken end, and the thing is as complete as any poor picture-taker need have."

**CURIOUS EFFECT OF GELATINE UPON GLASS.**—A correspondent of the *Philadelphia Photographer*, noticing a paragraph which appeared in our pages a few months ago, describing the exfoliation of glass by the contraction of gelatine on its surface, says:—"In the course of an examination of old English and French periodicals and Transactions of Philosophical Societies, we met a very similar instance to the above, in the *Histoire de l'Académie*, 1708, page 22:—'*Exfoliated Glass.*'—A person having applied on a piece of glass, about six inches square, a paste of Spanish white and glue size, placed the whole in the sun during the great heat of summer. The paste, which was turned towards the sun, having been much heated, rolled itself up, so that in this movement its under side was raised upwards. But, what was more singular, this surface raised with it and carried away a layer of the glass. This layer made on the paste a species of varnish, as of porcelain, the thickness not exceeding one-half a line. It was astonishing that the adherence of the paste on the glass was so strong, and equally so that it should be able to detach from the glass so considerable a sheet. It had been blown, and apparently they had re-

plunged the pipe with which it was blown in the crucible at different times, which had given it several layers, which, however, were not apparent, because they were exactly applied one upon another. It is to Geoffroy that we owe this observation." We were always a little incredulous about this statement until we saw the above item from the *Photographic News*."

**DOES WATER EXPAND ON BECOMING ICE?**—When a bottle of water is frozen, the bottle is usually burst. Hitherto this has been explained by the assertion that the water on solidifying suddenly expands. M. Barthélemy, one of the professors in the Lyceum of Pau, denies this explanation. In a memoir which he has written on the crystallization of water, he alleges that bursting of the bottle is caused by the disengagement of a large quantity of gas—hitherto in solution—by the water at the moment of its solidification. It is alleged, in support of this, that if a bottle of water be placed outside a window in frosty weather, it will be observed that the rupture takes place at the hottest side, viz., that next the window. Some of our correspondents must have made experiments on this point, and we shall be glad to hear what they have got to say to M. Barthélemy's opinion.—*Scientific Opinion.*

**THE FUNGUS THEORY OF DISEASE.**—In a short communication to the *Centralblatt*, Drs. Bergmann and Schmiedeburg describe a crystalline substance, to which they have applied the name "sulphate of sepsin," obtained from putrefying materials, and which they believe represents the proper poison of organic substances undergoing this kind of fermentation. It is obtained, says the *Lancet*, by diffusion through parchment paper, precipitation with corrosive sublimate from an alkaline solution, removal of the mercury by silver, of silver by sulphurated hydrogen, evaporation, and purification of the residue. Large, well-defined, acicular needles are thus obtained, which are deliquescent in the air, and, exposed to heat, melt and carbonise. They possess a powerfully poisonous action. A solution containing scarcely more than one-hundredth of a gramme was injected into the veins of two dogs. Vomiting was immediately induced, and after a short time diarrhoea, which in the course of an hour became bloody. After nine hours the animals were killed, and on examination their stomachs and large intestines were found ecchymosed, and the small intestine congested. Frogs could be killed in the same manner.

**THE "CENSOR" ON POPULAR PORTRAITS.**—The *Censor*, an able journal of satire, which we have before quoted, has the following remarks on one of the uses of photography:—"There is a simple, somewhat pretty face to be found in the photographic shops—those indecent store-houses of Holywell Street pictures of women with bare legs, arms, breasts, bare faces—bare of any meaning but impudence, and even that of a bad quality—of gaunt, angular forms, worn and vicious looks—of patent wrinkles, paste, false hair, and real folly. And this pretty face looks innocent, with a serpentine innocence—beside the raddled and too-known actress and hetera of the day. It has a grain more intelligence than the faces of the Royal Family, side by side of which (such is popularity) it stands; and it owns a prettier name than Albert Ernest Edward, or Albertina, or Alberta. 'This simple, short, and dainties with the tenderness of love like—'itself, 'Mabel May.' And who is Mabel May? Simply the most fashionable and most followed *Lady* of the day. She is to be seen in certain dancing-saloons, wears fifty-guinea dresses, and makes £5,000 a year by her art—not heart. Should she be as lucky as Mrs. Wyndham, some rich fool may marry her. What is most curious is, that photographers are anxious for her portrait, and hundreds of young ladies buy it for their albums. 'It is so simple,' says the grinning shopman. Simple, indeed! Imagine a brother or a future husband looking over 'one's few friends,' and finding therein 'the common spouse of half the town,' as Doctor Armstrong says. The French would make a drama of such an incident."

**A GOOD CEMENT.**—The *Scientific American* says:—"The best cement we know of for general use is made as follows:—Isinglass, 2 drachms; soak 24 hours in 2 ounces of pure water; boil it down half, add 1 ounce of rectified spirit, and while it is hot strain through linen. Next melt one drachm of mastic and ½ drachm of gum ammoniac in 1 ounce of rectified spirit; add the latter solution to the first, and mix thoroughly. This may be used for joining almost anything that is broken, but is too expensive to be used as a substitute for glue where the latter will do as well. In cementing, warm the edges of the articles to be joined, and spread the cement over as thinly as will cover the entire surface. Most people use too much."

## To Correspondents.

**T. G.**—An Eburneum print is practically a transparency on opaline gelatine. It is obtained by camera printing on wet collodion. 2. In printing stereoscopic slides in the camera on wet collodion no transposition in either negative or print is necessary. The operation of camera copying practically turns round each picture on its axis, and effects a similar result to transposition. Of this you can easily satisfy yourself by experiment. The lenses you mention will do very well, we have no doubt. 3. In the case you put there is a choice of two evils: at one end of the room the evening sun will trouble the sitter a little, and at the other it would enter the lens. We should be disposed to decide the question by experiment, trying whether you could more easily keep it by blinds from the sitter or the lens. 4. Hydrochloric acid alone is sufficient to precipitate silver as a chloride from washing waters; but salt alone is not always safe. 5. We believe that the period for protection by registration is expired.

**C. M. writes:**—"I am a chemist and druggist, and having carefully studied the new Pharmacy Act, have not a doubt that you are right in stating that its provisions do not come into operation until after the 31st of December, after which, as the first clause states, 'it shall be unlawful' to neglect the precautions afterwards indicated. The uncertainty felt by some seems to have originated in an error made by a London magistrate, who fancied that the provisions of the Act came into immediate operation, and, when the error was pointed out, justified his position by referring to a clause in the Act without a date. As the matter stands, it was at best but an opinion even regarding this clause, which is clearly governed by the preceding one giving the date. If a decision had been given on the assumption that the Act was in operation, we should have heard more about it." The subject is scarcely worth reiterated discussion, as very few, we imagine, dealing in poisons would fail to obtain the Act, from which they would gain full information. The question does not appear to us to admit of a doubt by any person not having a position to maintain. The 17th Clause, defining some of the conditions under which poisons may be sold, is clearly, as you suggest, together with all other clauses, governed by the 15th Clause, which states that "from and after the 31st day of December, 1868, any person who shall fail to conform with any regulation as to the keeping or selling poisons made in pursuance of this Act," &c., shall be liable to a penalty of five pounds. This is the only penal clause regarding the sale of poisons which the Act contains, and is therefore the clause which defines punishment. The *Standard* points out that Mr. Flower cannot have read the Act very carefully, as he made a mistake in referring to "red precipitate" as a poison included in Schedule A in the Act, whereas it is not mentioned at all. 2. Hyposulphite of ammonia in crystals has not yet become an article of commerce. Mr. Losh is manufacturing it in solution, but we believe that the difficulties in crystallizing it on a large scale have been found insuperable.

**ARCHER CLARKE.**—The date, as well as the name, is an essential item in the publication line of an engraving. The copyright in engravings remains in existence for twenty-eight years from the date of first publication, which should be distinctly stated on the print. We shall examine your specimens, preserved by Mr. Robinson's syrup, with interest.

**ANXIOUS.**—The coarseness of your copy of a card picture, reproduced the same size as original, is not due to the kind of lens used, but to other causes. When you copy an albuminized print you get in your negative not merely an image of the picture, but of every little inequality in its surface, and light being reflected from a thousand such inequalities will give you a coarse, mealy, flat, imperfectly-defined picture. To get a good copy from an albuminized print is always difficult, and this difficulty is increased when you copy the full size. You may, however, use several adjuncts to success. Roll the print well, so as to secure the smoothest possible surface, and take care that it is illuminated with light equally falling upon it from all directions, so that its inequalities may not give cast shadows. Some approve of wetting the print and attaching it to the surface of a piece of plate glass, so as to get as perfect a surface as possible. Your rectilinear lens will answer better for the purpose of copying than your stereo lens. There is no absolute rule for distance between subject and lens. Judgment must be used in relation to the special circumstances. 2. The white precipitate which you say is deposited is doubtless chloride of silver. Such a result should not take place. What sample are you employing? Collodio-chloride pictures on opal glass are best toned before fixing; developed prints on iodized collodion after fixing. 3. The application of glycerine to a prepared wet plate as a preservative does not answer, and will generally produce fog. If glycerine be employed as a preservative it should be prepared as described in our pages by Mr. Blanchard some years ago. In all such preservative processes there is considerable loss of sensitiveness, and some uncertainty of

result. Our correspondents need not apologize or feel hesitation in presenting their difficulties; we have pleasure in answering them to the utmost of our power.

**C. T. U.**—To become a member of any of the London societies it is necessary to be proposed at one of the monthly meetings, and balloted for. We shall have pleasure in proposing you.

**J. E. W.**—The removal of prints mounted with starch is not easy, especially when they are in an album which does not admit of soaking; but the simplest and neatest plan is to cut pieces of thick blotting-paper rather larger than the size of the print, and, after saturating with water, lay upon the face of the print. After soaking in this way, continued for some time, the prints may be gently removed.

**J. B. M.**—It is a difficult thing to give a precise proportion of silver or silver solution to be added to the printing bath, because different samples of paper, having different proportions of salt, reduce the strength of the bath in different degrees. Observation only can afford safe guidance in this respect. As a rule, the replenishing bath should be stronger than the bath in use, because silver is removed in greater proportion than either nitrate of soda or sugar, the latter substances being removed in their due proportion to water, and no more. 2. We have not had any experience in copying horizontal tombstones, but should conceive that a lens which gives straight lines will be necessary. If you could secure sunlight, in the morning or evening, so as to get incised letters in shadow, we should imagine the best result would be obtained.

**THOMAS STOTHARD.**—In asking for some information on mounting you do not state the nature of the information you require; whether it relates to the adhesive materials to be employed, or the mode of using them, or to the mounts, margins, &c. The adhesive materials have been discussed in our pages within the last year or two, and other points in former volumes. If you will state on what points in regard to mounting you desire information we shall have pleasure in assisting you. 2. Sulphate of copper is not a restraining, but a reducing agent; used in the developers, it modifies the action of the iron salt, but its precise operation has not received much attention. 3. Combination printing has been fully described in our pages, and probably will be again. You will find a copious article on the subject in our *YEAR-BOOK* for 1864. It is too comprehensive a subject for treatment in this column.

**SUBSCRIBER FROM THE FIRST.**—We do not know of any powder which could be applied to the lower lip to make it come out darker in the photograph; nor is it probable that if we did, your sitters would willingly adopt its use. On the stage, ladies occasionally use a red salve to colour the lips, which often gives an unnatural effect, and is said to be injurious to health. One cause of lips coming out light is the practice common amongst sitters, especially when they are nervous, of moistening the lip just before exposure. This they should be cautioned against. A touch of colour in finishing the picture will generally reduce the excessive effect of prominence.

**W. E.**—The cards were delayed a few days, but had been posted before your letter was received.

**W. J. A. G.**—An experienced dry-plate man may succeed in getting good results in a dull light; but the chances are against success, and, except under necessity, it is not wise to run the risk. The peculiar markings of which you send us an illustration appear like the result of blisters; but they may have been the result of some defect in the preparation of the plate. The print sent is apparently one from a subject not very well lighted: slower development and a little more bromide would probably have been useful. If you send a negative we may possibly help you more effectually. 2. Thanks: we will record your promise. True: tho "stuff" to which you refer is neither worth reading nor notice. You should, if possible, get to the exhibition in Conduit Street. We have no doubt that examples of many of the pictures exhibited may be purchased.

**H. C.**—Thanks; we shall have pleasure in receiving your proposed notes of your landscape experiences.

**C. H. FREE** writes to express his approval of a Relief Fund, and urges imitation of the course of "Gum Gallic Amateur." Thanks.

**S. B. BARNARD.**—Thanks for your interesting letter and admirable cabinets, which are excellent in photography, as well as interesting in subject. The portrait of "Oliver Cromwell" affords a singular illustration of the persistence of types, and are full of interest. Your suggestion for a mixed album for cards and cabinets is a good one, and we will try to give it effect in the right quarters. We quite agree with your views on the question of touching, both as to its scope and legitimacy. We shall refer to your letter again.

**H. H. H.**—Herr Grasshoff's work on Colouring is only published in German: the publisher is Louis Gerschell, Berlin.

Several Correspondents in our next.

### THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

A second visit to the Exhibition of Photographs in the Society's rooms in Conduit Street confirms the favourable impression we first received, and we feel an additional satisfaction we had scarcely anticipated in noting the order, symmetry, and general good effect of the hanging, a result which at six o'clock on the evening of exhibition we had not believed possible, seeing that important contributions had not at that hour ceased to arrive. By the hearty and judicious labours, however, of the hanging committee and volunteer friends, the pictures were all hung before the public arrived, and no good pictures got really bad places.

Another fact struck our attention, which is worth noting, namely, that the mode of mounting and framing, as well as the style of portraiture, of M. Salomon had produced a revolution in the practice of portraitists. Instead of the universal white mount with a margin of a few inches wide, we have now many pictures framed close up, some with gold frames, some with gold and black. In many cases this is an improvement; but it chiefly interested us because it indicated a disposition on the part of photographers to get out of the groove in this respect, and exercise individual taste, which we regard as a healthy symptom. Indeed, we regard the tendency to what may, in some degree, be regarded as imitation of M. Salomon as satisfactory, not simply for the unquestionably fine results already presented, but for the promise they give of further excellence in probably various styles, when the influence of suggestion has passed, and equally fine pictures, with more distinctive individualism, shall be produced.

It is not our intention to enter into minute or detailed criticism of the pictures displayed, as the short duration of the Exhibition renders such notice comparatively useless. When an exhibition is open for a prolonged period, and the pictures can be examined after a criticism has been read, comment and observation may often be suggestive and instructive; but as the Exhibition will be closed before these remarks can reach the reader, but little lesson could be conveyed by extended notice. In reference to the portraits by M. Salomon, which constituted a chief feature of attraction, we may remark that they scarcely did him as much justice as those in a former exhibition. Those we sent last year from our own examples of his work were a fair but selected average; those sent this year were, with one or two exceptions, a number of old specimens, sent off at the last moment because they chanced to be ready. But, with these drawbacks, they arrested general attention, and won universal admiration.

Of the dozen persons who exhibited portraits in the same style, all succeeded more or less, and in much higher degree than might have been anticipated. Perhaps most completely approximating to those of the master of this especial school are the contributions of Mr. Blanchard, who contributes a

dozen exceedingly good examples, full of force, delicacy, and modelling, and having fine chiaroscuro. Messrs. Robinson and Cherrill only exhibit two portraits: one of M. Salomon, and one of Mr. Hain Friswell, a well-known *littérateur*. The latter we have heard pronounced the finest portrait in the room; it is singularly solid and well-modelled, delicate and rich, and the expression is rarely life-like and satisfactory. Mr. Netterville Briggs stands very high indeed: his pictures are a little larger than the mass of examples of this style, and in excellence leave little to be desired. Mr. Mayland, of Cambridge, contributes half-a-dozen examples of this style, all fine; but one of which—a gentleman engaged in painting—is of surpassing excellence. Mr. Slingsby, of Lincoln, has some very capital examples, both in single figures and groups; a lady in a black velvet dress being singularly luminous, as well as rich in effect. Mr. Burgess, whose eburneum pictures are well known, exhibits portraits based on the style to which we have been referring, but with distinct characteristics, one large head of himself resembling a reproduction from an old master. His standing portrait of Mr. F. Sutton, of Norwich, was very excellent. Of the especial qualities of the examples by Mr. Fry we have before spoken; but we may again refer to the portrait of an elderly gentleman as especially good, tranquil in feeling, and round and rich in effect. Messrs. Fradelle and Leach exhibited whole-plates in the same style. These are not framed close up, but have buff mounts, which are not ineffective; many of the pictures are very fine in taste and execution. Mr. Leake has a fine frame close by those just mentioned, which are exceedingly effective, but somewhat more worked upon than the majority of the Salomonesque pictures here exhibited, which, for the most part, exhibited very little touching indeed, some of the best being quite untouched. Some similar portraits by Mr. Dunmore possess very good qualities, and are very effective. Mr. Ashdown has some examples in the same style. Mr. Gillo, who contributes largely, has some very spirited pictures, in some respects resembling the style under notice.

Some fine examples of other forms of portraiture are exhibited. Mr. H. C. Heath, amongst other good examples, sends some especially fine portraits of babies, charmingly arranged, happy in expression, and fine in execution. A frame by Messrs. Lucas and Box displays fine taste and skilful execution. A group of three children with natural background, by Messrs. Robinson and Cherrill, is admirable in grouping; the background is an admirable landscape, and the picture most effective. Mr. Duncan Cooke exhibited some good portraits. Mr. Henry Herring's vignettes are very delicate and round. Mr. R. Gillo exhibited some very pretty and artistic cards, and some good cabinets, amongst which were examples of transferred collodion prints. Some very fine cards and cabinets, displaying much taste, were exhibited by Mr. Godbold. Mr. Hewitt's cards and whole-

plate pictures were good. Mr. Bowen's portraits were spoiled by a noisy mount. The cabinets with natural backgrounds, by Mr. N. Briggs, were exceedingly perfect. A variety of styles of portraiture, all displaying very fine taste, were exhibited by Dr. Wallich. Mr. Downe's portraits were delicate, forcible, and well arranged. Mr. B. J. Edwards exhibited some portraits possessing excellent qualities in a rare degree; they were singularly fine in texture, solid, well modelled, delicate, and artistic in feeling. Mr. Bateman, of Canterbury, has some very admirable vignettes, at once delicate and forcible. Mr. J. H. Redin, the Governor of Carlisle Gaol, has a frame of capital portraits fixed with hyposulphite of ammonia; nothing could be finer than the tone and quality; time alone will, of course, be the true test of the superior value of the fixing agent. Messrs. Bullock Brothers also exhibited some good portraits. In the absence of a catalogue it is easy to neglect the mention of some meritorious pictures, but we have mentioned the chief examples of plain portraiture which came under our attention.

The pictorial compositions and art studies in this exhibition are, for the most part, of unusual excellence. Occupying a place of honour, Mr. Robinson's "Returning Home" formed a constant centre of interest to visitors. We have before fully described this picture, and need not enter into further criticism. Mr. Rejlander has a splendid collection, both on the walls and in a portfolio. Few artists, either in photography or painting, have ever exceeded him in giving expression to a thought in the treatment of a single figure, and here are dozens of examples illustrating that photography is wonderfully plastic in the hands of a true artist. Perhaps nothing in the exhibition exceeds in beauty and artistic feeling a little study by Mr. Hubbard, representing a young girl looking out of the window upon a street scene, admirably made out, yet perfectly atmospheric. It is a small picture, about five inches by four inches, and is obtained by double printing, the result being charming. Some other artistic pictures of the same size are exhibited by Mr. Hubbard, and a twelve by ten study, which is full of cleverness. It represents the interior of a cottage with large, old-fashioned fire-place, and various articles of furniture spread around. An old woman sits peeling potatoes, and forms the centre of interest in the picture. The perfect harmony and keeping of the picture, the quietness with which every accessory keeps its place, the admirable blending of the real objects with the painted background, all form a most effective picture, which half the visitors pronounced unhesitatingly a copy of a painting. Mrs. Cameron sent some good examples of her peculiar style, amongst which were some fine examples of artistic feeling, with less slovenliness of execution than we have before pointed out. Mr. C. Twyman's picture, "Be asy, now!" is another of the examples of the plastic power of photography in which this exhibition abounds, and is one of the cleverest pictures in the exhibition. Mr. Crawshaw sends several studies, in which the photography is very excellent indeed: we prefer "What can he be doing?" as a picture. Mr. Brewer's "life studies" are fine vigorous heads with fine expression. Mr. H. R. Rump had some fine large character portraits, which were very effective. Mr. E. W. Dallas, whose name used to be familiar to photographers a dozen years ago, sent a single study, entitled "Samuel," which had many fine qualities. Amongst portrait studies, a fine rugged head, entitled "On the look out," by Mr. Ashdown, may be mentioned. Belonging to this branch of photography, also, may be mentioned some pretty cattle studies by Mr. Archer Clarke, some horseback pictures by Mr. Avey, and some small pictures of animals by Mr. Jewell, and some others, all very excellent.

We had hoped to complete our brief notice of the exhibition, which must possess the character more of a chronicle of facts, than a criticism, this week; but we find that specialities, processes, coloured pictures, and apparatus must be deferred until our next.

## CHEMICAL ACTION OF LIGHT.

WE print on another page an account of a series of exceedingly interesting experiments on the Chemical Action of Light, presented by Professor Tyndall to the Royal Society. To men of no profession can research of this kind present so much interest as to photographers. Upon the chemical action of light is based every possibility in their pursuit; and although its practical operation in their art is at present limited within a comparatively narrow range, and has reference to a small number of substances only, yet every step which widens the field of research, and every discovery which extends the domain of knowledge in this especial direction, are of value to the photographer, if not in presenting materials for immediate application, at least for enlarging the possibilities of his art.

The interesting researches of Professor Tyndall as to the action of light on certain vapours and liquids may have no immediate effect upon the practice of photography, but it is impossible to say at what point in his discoveries a practical application may become obvious. Let us illustrate by a speculation upon the possibilities attending his recent discoveries. In his paper before the Royal Society he states that actinic light decomposes the vapour of nitrite and nitrate of amyl. Amyl is a radical analogous to ethyl and methyl, the hydrated oxide of amyl being known as fusel oil, as the hydrated oxide of ethyl is known as ethylic, or common alcohol, and the hydrated oxide of methyl is known as methylic alcohol. Fusel oil is known to be a common impurity in ordinary alcohol, and its presence in collodion has long been regarded as injurious, and conducive to fog, without any knowledge of the reason why it should produce mischief. Prof. Tyndall's experiments suggest a series of possibilities. When fusel oil is in collodion, and comes into contact with nitric acid, either free in the bath or liberated by action of free iodine in the collodion, a trace of nitrate of amyl may be formed, and this body, being present in the film when exposed to the action of light, and possibly decomposed, would, under some circumstances, yield, as a product of decomposition, valerianic acid, a substance answering to acetic acid, as the product of the oxidation of common alcohol, or formic acid in methylic alcohol. Or, possibly, in the decomposition, intermediate bodies analogous to acetone or aldehyde, might be formed, with a well-known tendency to produce fog when present in a collodion film. Such a series of possibilities exist, and might furnish a clue to the fogging action of fusel oil when present in collodion, which, arguing from ordinary analogies, ought not to be more inimical to success than the ordinary alcohol employed in the manufacture of collodion.

## DOES WATER EXPAND ON FREEZING?

WE gave in our last an extract from *Scientific Opinion*, in which M. Barthelemy denied the commonly-received opinion that water expands on freezing. The subject, although not strictly photographic, is one which will interest our readers sufficiently to justify a few more words on the question, which tend to negative the statement of the French savant. We append a letter from one of our readers who is a most shrewd and intelligent observer, in which he describes a fact which could not be accounted for on M. Barthelemy's theory. Our correspondent says:—

"A short extract in your last impression on the above subject calls to my mind a curious circumstance that came under my notice two winters ago. My operator, at night, filled a stoppered bottle with water, and in the morning the stopper was driven out, and projecting from the mouth of the bottle was a rod of ice about two inches long, perfectly smooth and transparent; the whole contents of the bottle was solid ice. I considered the case sufficiently curious to keep the bottle for some days to show some friends. The bottle was unbroken. What explanation could M. Barthelemy offer to this?—Yours, respectfully, A. L. HENDERSON."

A letter from Mr. D. Forbes, F.R.S., in *Scientific Opinion*, also refutes M. Barthelemy. Mr. Forbes says:—

"The behaviour of water under these circumstances is so intimately connected with the study of many important natural phenomena, that from a very early period it became the subject of rigid scientific investigation, the result arrived at being that water, if cooled, contracts until it acquires a temperature of 40° (4° C.), when it attains its maximum density, but that afterwards it expands to the freezing point.

"The fact of ice swimming upon water would in itself indicate that an expansion had taken place; but the experiments of Hope, Hallstrom, Despretz, and others, appeared to have settled this question beyond even a shadow of a doubt, and to render any further evidence quite superfluous."

"Now as to the question of the gases. To dispel any doubts on this head also, the following experiment was made yesterday:—A quantity of pure distilled water, in a flask, was boiled for some time until every trace of gas had been evolved, and then cooled down to near the freezing point. A bottle completely filled up with this gas-free water, at this low temperature, was hermetically closed, and the water inside converted into ice (by using a frigorific mixture of sulphate of soda with hydrochloric acid): the bottle was at once split to pieces by the expansion of the water, which, of course, could not have taken place had M. Barthelemy's new theory been correct."

## VISITS TO NOTEWORTHY STUDIOS.

### MR. SAWYER'S STUDIO AT NORWICH.

In the course of our recent visit to Norwich during the meetings of the British Association, we visited the studio of Mr. J. R. Sawyer, which possesses some especial points of interest, as yielding very good work with a very unusual kind of lighting. As Mr. Sawyer was engaged in taking the portraits of the principal members of the Association for publication, and his studio and reception room were, when we called, thronged with *savans*, ready to sit, our examination of the arrangements was necessarily hasty, and our description must be brief.

Passing through a handsome shop, devoted to the sale of optical instruments and other wares with which we have no concern, we will pass on, and, neglecting the reception room for the present, ascend to the studio, which is at the top of the building, and extends nearly over the whole of its area. It is 33 feet in length by 24 feet in breadth, the portion in use being a square space of 24 feet; there is no side light whatever, all the light entering through a glazed ridge roof, 18 feet high at the ridge, and 12 feet high at the eaves. The only light entering the studio is through this lofty skylight, which extends all over the studio; but the light so admitted is not generally permitted to reach the sitter directly. A series of narrow vertical blinds, arranged somewhat on the principle identified with Mr. McLachlan's name, cut off the direct light from reaching the sitter. A considerable flood of soft diffused light seems to fill the room, and the direct illumination of the sitter is effected by means of ingeniously contrived reflecting screens. These consist of light frames, some 6 or 8 feet long by 3 feet wide, covered with white calico. These are placed in different parts of the room, at various angles, as circumstances may render necessary. When we inspected the studio, the screens in use were leaning against a wall at an angle of about 30° at the side and a little in front of the sitter, whose face would receive a strong reflected light from the screens so placed.

At first sight nothing would appear more opposed to the recognized conditions of perfect lighting. The general rule is to have as much direct light as can be used, and as little diffused light as possible; to have, in fact, no light in the studio except that which directly illumines the subject to form the picture. Here we have the studio filled with soft, diffused light, and some portion of the direct light, which

enters the room, but does not reach the sitter, received by reflecting screens and thrown on him and on the accessories at second hand. Nevertheless, such a mode of lighting having been thoroughly mastered, Mr. Sawyer assured us he preferred it to any other, as it gave him more varied control over the light, and permitted more varied effects than could be readily produced by a direct light, which would be much less completely under control. Any modification of the angle, of the position, or of the number of reflecting screens, he stated, gave a modified effect in the light and shade and in the quality of the modelling, whilst the amount of light was quite sufficient for rapid working, the exposures averaging from eight to ten seconds on a day with light clouds, using Dallmeyer's and Voightlander's card lenses.

The work produced in the studio was very good, generally tending to vigour and brilliancy. In such of the portraits of members of the Association as we have seen, no indication of lack of direct light is perceptible, and amongst the specimens in the reception-room were many examples of very excellent and artistic work. The lesson we deduce is, that this is the most convenient and efficient form of lighting, but that a skilful man will produce good work under almost any conditions when he has become familiar with them. Mr. T. R. Williams works in a studio with a top light only, but which, by skilful arrangement of blinds, he converts practically into a high side-light. Whilst Mons. Adam-Salomon's best pictures are produced in a studio with a high side-light, facing north, he at times works from choice in a studio facing the south, without any clear glass to admit direct light whatever; and nothing can exceed the beauty of the pictures produced in this studio. Such facts may afford encouragement to those who must obtain their light as they can, and not as they would; but it will not induce any one as a matter of choice to select the conditions involving the most trouble.

In the reception-room we found many evidences of artistic taste. One fine portrait of a lady attracted our attention from its admirable reproduction of the position in the well-known painting of Titian's daughter. Some fine examples of the carbon process were hung around; and Mr. Sawyer's enlargements are some of the finest we have seen.

A startling estimate of the enormously large number of card photographs which must have been produced throughout the country is suggested by the figures Mr. Sawyer gave us. Very many flourishing photographic establishments now in existence sprung up, we know, during and in consequence of the card mania, and only imperfect statistics could be gleaned from such. Mr. Sawyer has been engaged as a professional photographer in Norwich for fifteen years: it is of course only during the last eight years that any serious accumulation of negatives can have taken place; nevertheless, he has stored and registered 25,000 negatives, each containing two different positions—practically, 50,000 negatives in one provincial establishment, making an average of 6,000 negatives a year during the period which has elapsed since cards were introduced. The average number of card prints issued from his establishment, Mr. Sawyer states to be about 50,000 per annum.

## ON A NEW SERIES OF CHEMICAL REACTIONS PRODUCED BY LIGHT.

BY JOHN TYNDALL, LL.D., F.R.S., ETC.\*

I ASK permission of the Royal Society to draw the attention of chemists to a form or method of experiment which, though obvious, is, I am informed, unknown, and which, I doubt not, will in their hands become a new experimental power. It consists in subjecting the vapours of volatile liquids to the action of concentrated sunlight, or to the concentrated beam of the electric light.

\* Communicated to the Royal Society.

## ACTION OF THE ELECTRIC LIGHT.

A glass tube 2·8 feet long, and of 2·5 inches internal diameter, frequently employed in my researches on radiant heat, was supported horizontally. At one end of it was placed an electric lamp, the height and position of both being so arranged that the axis of the glass tube and that of the parallel beam issuing from the lamp were coincident. The tube in the first experiments was closed by plates of rock salt, and subsequently by plates of glass.

As on former occasions, for the sake of distinction, I will call this tube *the experimental tube*.

The experimental tube was connected with an air-pump, and also with a series of drying and other tubes used for the purification of the air.

A number of test-tubes (I suppose I have used fifty of them in all) were converted into Woulfe's flasks. Each of them was stopped by a cork, through which passed two glass tubes; one of these tubes (*a*) ended immediately below the cork, while the other (*b*) descended to the bottom of the flask, being drawn out at its lower end to an orifice about 0·03 of an inch in diameter. It was found necessary to coat the cork carefully with cement.

The little flask thus formed was partially filled with the liquid whose vapour was to be examined; it was then introduced into the path of the purified current of air.

The experimental tube being exhausted, and the cock which cut off the supply of purified air being cautiously turned on, the air entered the flask through the tube *b*, and escaped by the small orifice at the lower end of *b* into the liquid. Through this it bubbled, loading itself with vapour, after which the mixed air and vapour, passing from the flask by the tube *a*, entered the experimental tube, where they were subjected to the action of light.

The power of the electric beam to reveal the existence of anything within the experimental tube, or the impurities of the tube itself, is extraordinary. When the experiment is made in a darkened room, a tube which in ordinary daylight appears absolutely clean is often shown, by the present mode of examination, to be exceedingly filthy.

The following are some of the results obtained with this arrangement:—

*Nitrite of Amyl* (boiling point  $91^{\circ}$  to  $96^{\circ}$  C.).—The vapour of this liquid was, in the first instance, permitted to enter the experimental tube while the beam from the electric lamp was passing through it. Curious clouds were observed to form near the place of entry, which were afterwards whirled through the tube.

The tube being again exhausted, the mixed air and vapour were allowed to enter it in the dark. The slightly convergent beam of the electric light was then sent through the tube from end to end. For a moment the tube was *optically empty*; nothing whatever was seen within it; but before a second had elapsed a shower of liquid spherules was precipitated on the beam, thus generating a cloud within the tube. This cloud became denser as the light continued to act, showing at some places a vivid iridescence.

The beam of the electric lamp was now converged so as to form within the tube, between its end and the focus, a cone of rays about eight inches long. The tube was cleansed, and again filled in darkness. When the light was sent through it, the precipitation upon the beam was so rapid and intense that the cone, which a moment before was invisible, flashed suddenly forth like a solid luminous spear.

The effect was the same when the air and vapour were allowed to enter the tube in diffuse daylight. The cloud, however, which shone with such extraordinary radiance under the electric beam, was invisible in the ordinary light of the laboratory.

The quantity of mixed air and vapour within the experimental tube could, of course, be regulated at pleasure. The rapidity of the action diminished with the attenuation of the vapour. When, for example, the mercurial column associated with the experimental tube was depressed only five inches, the action was not nearly so rapid as when the

tube was full. In such cases, however, it was exceedingly interesting to observe, after some seconds of waiting, a thin streamer of delicate bluish-white cloud slowly forming along the axis of the tube, and finally swelling so as to fill it.

When dry oxygen was employed to carry in the vapour, the effect was the same as that obtained with air.

When dry hydrogen was used as a vehicle, the effect was also the same.

The effect, therefore, is not due to any interaction between the vapour of the nitrite and its vehicle.

This was further demonstrated by the deportment of the vapour itself. When it was permitted to enter the experimental tube unmixed with air or any other gas, the effect was substantially the same. Hence the seat of the observed action is the vapour itself.

With reference to the air and the glass of the experimental tube, the beam employed in these experiments was perfectly cold. It had been sifted by passing it through a solution of alum, and through the thick double-convex lens of the lamp. When the unsifted beam of the lamp was employed, the effect was still the same; the obscure calorific rays did not appear to interfere with the result.

I have taken no means to determine strictly the character of the action here described, my object being simply to point out to chemists a method of experiment which reveals a new and beautiful series of reactions; to them I leave the examination of the products of decomposition. The molecule of the nitrite of amyl is shaken asunder by certain specific waves of the electric beam, forming nitric oxide and other products, of which the *nitrate* of amyl is probably one. The brown fumes of nitrous acid were seen to mingle with the cloud within the experimental tube.

The nitrate of amyl, being less volatile than the nitrite, could not maintain itself in the condition of vapour, but would be precipitated in liquid spherules along the track of the beam.

In the anterior portions of the tube a sifting action of the vapour occurs, which diminishes the chemical action in the posterior portions. In some experiments the precipitated cloud only extended half-way down the tube. When, under these circumstances, the lamp was shifted so as to send the beam through the other end of the tube, precipitation occurred there also.

## ACTION OF SUNLIGHT.

The solar light also effects the decomposition of the nitrite-of-amyl vapour. On the 10th of October I partially darkened a small room in the Royal Institution into which the sun shone, permitting the light to enter through an open portion of the window-shutter. In the track of the beam was placed a large plano-convex lens which formed a fine convergent cone in the dust of the room behind it. The experimental tube was filled in the laboratory, covered with a black cloth, and carried into the partially darkened room. On thrusting one end of the tube into the cone of rays behind the lens, precipitation within the cone was copious and immediate. The vapour at the distant end of the tube was in part shielded by that in front, and was also more feebly acted on through the divergence of the rays. On reversing the tube, a second and similar cone was precipitated.

(To be continued.)

## ON PRODUCING OPEN-AIR EFFECTS IN THE STUDIO.

BY CHARLES E. PEARCE.\*

When I promised, at the June meeting of the present year, to read a paper on the subject of double printing, I had hoped to have worked out a method which would enable us to introduce, with facility, backgrounds from nature into card and cabinet pictures—not merely a method by which,

\* Read at a meeting of the South London Photographic Society, November 12, 1868.

after a great deal of vexation and a number of spoiled prints. one or two presentable examples might be obtained, but a practical method, to be introduced into the ordinary way of business. I have not been able to fulfil my intention at present. However, the subject of the paper this evening has somewhat grown from the preliminary preparations which were necessary to carry out the former idea.

To convey the impression of open-air scenes it is necessary to have the foreground arranged with natural objects; the ground must look like ground; the grass and shrubs must be real, or the deception will be at once apparent. And here, at the outset, is a difficulty which would require a number of "dodges" to overcome.

I dare say most photographers are familiar with the appearance of the studio when, in some moment of enthusiasm, they have essayed to produce an open-air scene, and have called in the assistance of natural objects. Everything of a vegetable nature within reach is pressed into service. Stones, straw, and I have even heard of cinders, are made available, and in five or six minutes the studio presents an appearance of something between a stable and a pigsty; and, if these "accessories" are suffered to remain until next day, the appearance of the whole, with its drooping grass and leaves, is thoroughly wretched. The room has to be cleansed before a fresh sitter can be introduced, and the photographer is tempted to make a vow that he will have nothing henceforth to do with natural properties, until a fresh resolution seizes him, and the same scene is re-enacted.

I felt, on commencing these pictures, that it was absolutely necessary to have some control over the foregrounds; that they should be ready at a moment's notice; that they should be portable, and present somewhat of an orderly appearance. These desiderata, to a certain extent, I have obtained, and have no difficulty in arranging foregrounds with the same grass and bushes that I used during the summer months.

I first tried the plan of a wooden tray, about six feet long by two feet broad, containing mould in which weeds and grass were planted. This I soon gave up; it was unwieldy and awkward to use, and, although quite large enough to be continually in the way, was not large enough to produce any effect without the assistance of other objects.

The next idea was to form a permanent ground which would be always ready, with plenty of room to place the sitter and to build up the foreground in parts; and that is the plan I now adopt, and which I find most convenient. The ground may be formed of canvas or carpet (of course, quite plain). I myself use a material termed "wincey," which I found was suitable and cheap. Over this is strewed a little hay, and it is on this account that a fluffy material is best, because the hay adheres to it, and is prevented from littering the other parts of the room. The grass is kept available by planting tufts in wooden boxes. The boxes are about nine or ten inches square, and the sides about an inch and a quarter high. The grass is simply dug out in patches, with the mould adhering to the roots, placed in the boxes; and the blades falling over the sides entirely conceal the framework. Any number of these boxes can be made; some I have contain common weeds, such as groundsel, nettles, docks, &c., which are very effective, and the whole being easily moved about, the arrangement can be varied without any trouble.

A weed, a sample of which I have brought to-night, I have found very useful. The leaves and stalks are of a very hard nature, and, when dried, retain their shape perfectly; the flower, which is something like that of groundsel, goes to seed on drying, but retains its shape for a considerable period, and the whole photographs remarkably well. This I turned to account in the manufacture of bushes, by tying the stalks together in bundles, and then nailing these bundles in layers to pieces of wood, arranging them so as to make the loose part of one bundle cover the nailed part of another. The wood having a foot to enable it to stand up-

right, the bush is complete. I do not apprehend there would be any difficulty in procuring weeds of a similar character—sorrel possibly might be useful in this way; but, at all events, weeds of a soft, succulent nature are unsuitable, and not fitted for drying.

Another picturesque object will be found in the stump of a tree; it need not be very large, and if it has many roots attached to it, so much the better. The long, dried, feathery grass can be had cheap, and will be found very useful.

Some might be disposed to say, Why go to the trouble of making artificial bushes when living plants can be obtained. But I think the necessity of concealing the flower, pots will be found an inconvenience, to say nothing of the risk of damage to which they are constantly exposed; for instance (I speak from experience), a lady's dress catching in part of the plant, and turning it, together with the mould, on to the floor. However, if any be disposed to living plants in pots, the box tree, arbor vitæ, and American aloe may be suggested as being suitable; and, if placed behind some of the artificial bushes, will have a good effect.

With regard to introducing water into the picture, I have endeavoured to produce the effects with sheets of polished tin; with what result these pictures will show. I should be glad if any member, who has seen real water introduced into pictures of this kind, would point out the defects and the difference between the real and the imitation. The tin has at least the merit of being exceedingly convenient to use. The shape of the water can be altered at will, and a few imitation flags, or a stone placed so as to show the reflections, will assist in giving the appearance of water.

With regard to the backgrounds. That every photographer should paint his own I regard as a *sine quâ non*, and it will be found desirable to have it as large as the room will permit, so as to prevent the necessity of using exactly the same portion for each picture. The chief point to be observed in the background is the agreeable distribution of light and shade, so as to be in harmony with the rest of the picture; and, while giving force to the figure, at the same time producing an effect of atmosphere. Of course, each man must judge for himself the kind of background best suited to his method of lighting. As to the amount of scenery represented, the less there is the better. I have found the indication of a clump of trees to be quite sufficient. One important point to be observed is to have the sitter a considerable distance in advance, so as to throw the background well out of focus, and also to separate it from the figure.

Concerning the vexed question of the horizon: whether it should be high or low, I do not pretend to decide; but, for my own part, I am inclined to give the preference to a position about one-third or a little more from the bottom of the picture. In most cases, if it be merely suggested, and no distinct line made out, it will be all that is necessary.

In conclusion, I would say that I do not offer these pictures as specimens of photography, but simply as the result of an endeavour to extricate oneself from the groove into which photographers appear to have fallen; and however imperfect these attempts may be, the pleasure I have derived and the instruction I have gained, perhaps unconsciously, have more than rewarded me for the trouble.

There is one quality which particularly recommends this class of picture, and that is the infinite variety one may obtain with a few materials—an advantage which every photographer who pins his faith to chairs and tables must have sighed for in vain. It not only takes away the machine-like character which too many photographs, excellent in other respects, have, and gives an individuality to each picture, but it stimulates the invention of the photographer, which must necessarily benefit him.

I have only to say that if we endeavoured to originate, and not be content with slavishly copying each other, we should feel more interest in our work, and instead of sitting down and saying complacently, "The public will have this and no other," we should try to educate the taste of the public,

who are not so blind as some of our brethren would have us believe; and we should find ourselves repaid, not only in the additional instruction we should gain, but in a much more material sense.

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.  
CHAPTER XLII.

As this is my penultimate chapter, I take the opportunity of introducing an example of portraiture, that I may say a few final words on that important subject to the photographer.

The illustration is engraved from a picture by Desanges,

one of the most graceful portrait painters we have, but who, perhaps, will be better known to the reader as the painter of the Victoria Gallery, illustrating the principal actions for which the Victoria cross was awarded, and which for some years formed one of the chief attractions of the Crystal Palace. In this picture will be found nearly every quality that goes to the making of a good portrait—breadth, simplicity, and unity; balance, contrast, and variety. It is dignified and graceful, refined in feeling and expression, and the figure is set before the spectator for itself alone, and without any distracting embellishments which, without adding to the interest of a portrait, often suggest departure from truth. Our illustration is a reduction, by Mr. Fruwirth, of a wood engraving in the *Art Journal*.

Photographic portraiture has not, in a broad sense, yet arrived sufficiently far on the road to perfection to make its

professors as a body very proud of their art, but during the last two or three years it has made great strides. Several causes have combined to help it to advance more rapidly of late than in former years. The exhibition of M. Adam-Salomon's pictures last year at the French Exhibition, and their introduction to the great body of English photographers by the Editor of the *News*, gave an enormous impulse to the production of good work; even those who most believed in the beauty of their own work saw that

in photographic portraiture there was something beyond; they saw a certainty that the end of the art had not been reached, and these pictures gave the promise of a possibility of something still more glorious being achieved in portraiture by their art. Some were, no doubt, sorry for this, as they felt they must give up the hope of ever approaching the works of the great master; while others, more reliant and hopeful, buckled on their armour, and fought honestly to win some honour in the same path. Whether many will

ever equal the original works is problematical; but the present result is not doubtful—better work has been done. That this is so was almost ludicrously shown at the Exhibition of the Photographic Society recently held, the walls having been covered by portraits of every degree of merit, from the lowest to the highest, which had evidently been inspired by the works of M. Salomon. Deprecating, as I do, this servile copying of any man's work, to which English photographers, for lack of originality in themselves, are much too prone, it must be patent to all impartial minds that an advance has been made in photographic portraiture all over the country which could scarcely have been anticipated or believed. Photographers have shown that they have the capacity to imitate a good thing; let them advance another and yet more difficult step: those who follow are always behind; let them rise above mere imitation, and produce original works. There is one fault visible in most of these "Salomoniac" pictures from which even the originals are not quite free, and against which it is perhaps as well to warn the student. In the endeavour to arrive at technical excellence and fine chiaroscuro, expression seems to have been almost forgotten, and the portraits suffer from the neglect.

Another cause of the improvement in the art has been the depression in the *business*. Many who were not fitted for it have had to return to their former employments. It is, perhaps, a cruel thing to say, but the art is all the stronger because the weak ones have been killed off. The public, who would take any rubbish a few years ago, is now more discriminating, and will not accept bad pictures, however cheaply (I would rather say low in price, for bad things are not cheap) soot and whitewash abortions may be offered by despairing "artists" who have mistaken their vocations. But one of the chief causes for this cheering advance in the quality of the pictures produced at the present time—if I may say so without being thought to refer to my own writing—is the sound and practical art knowledge that has been given to photographers of late years by the PHOTOGRAPHIC NEWS, and which is so opposed to the mystic and "high-falutin" substitute for common sense with which the art had been previously surrounded.

Before the advent of these several causes of improvement, the art, except in the hands of a few, was very like that described by the Vicar of Wakefield, when he tells us of the painting of his great family picture. As ridicule is sometimes as good a teacher as sober sense, I am tempted to extract the passage.

"My wife and daughters, happening to return a visit at neighbour Flamborough's, found that family had lately got their pictures drawn by a limner who travelled the country and took likenesses for fifteen shillings a head. As this family and ours had long a sort of rivalry in point of taste, our spirit took the alarm at this stolen march upon us, and, notwithstanding all I could say—and I said much—it was resolved that we should have our pictures done too. Having, therefore, engaged the limner, our next deliberation was to show the superiority of our taste in the attitudes. As for our neighbour's family, there were seven of them, and they were drawn with seven oranges—a thing quite out of taste, no variety in life, no composition in the world. We desired to have something in a brighter style; and, after many debates, at length came to a unanimous resolution of being drawn together in one large historical family-piece. This would be cheaper, since one frame would serve for all, and it would be infinitely more genteel; for all the families of any taste were now drawn in the same manner. As we did not immediately recollect an historical subject to hit us, we were contented each with being drawn as independent historical figures. My wife desired to be represented as Venus, and the painter was requested not to be too frugal of his diamonds in her stomacher and hair; her two little ones were to be as Cupids by her side; while I, in my gown and band, was to present her with my books on the Whistonian controversy. Olivia would be drawn as an Amazon, sitting upon a bank of flowers, dressed in a green Joseph richly

laced with gold, and a whip in her hand; Sophia was to be a shepherdess, with as many sheep as the painter could put in for nothing; and Moses was to be dressed out with a hat and white feather."

Everybody remembers—for it has become proverbial—the fate of this grand historical portrait picture: how it was too big to allow of its being got through any of the doors of the house, and how it was obliged to remain in the kitchen. The description of it is but a very slight exaggeration of the absurd anaæronisms perpetrated in the last century, a subject on which I touched in Chapter 26. And do not we now, in the nineteenth century, when everything is matter-of-fact, see in photography, which should not lie, the most absurd, the most grotesque blunders possible? Columns, curtains, pedestals, profile pianos, pilasters, sham windows, wooden fireplaces,—do not these words call up visions of artistic abominations, horrible to the now more cultivated eye? It has been the reproach of photography that its results fade. The fault I find with it is, that they are too permanent; and early, and to me awful, prints are continually rising up in all their ghastliness to shame their makers.

What photographer takes up an old album in a friend's house without a sort of fear of opening it, and being reproached by his own handiwork? But he may take heart of grace; the very disgust he feels at looking at his early productions shows that he is not only a better photographer and a better artist now than he was then, but that he is on the way to still greater success.

## Proceedings of Societies.

### SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in the City of London College on the evening of Thursday, November 12th, the Rev. F. F. STATHAM, M.A., in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were elected members of the Society: Messrs. F. East, C. Annand, and J. Quarm.

The CHAIRMAN then announced that the presentation prints were ready for distribution, and also reminded members that the subscriptions for the current year were due. He also announced that the annual dinner of the Society would be held on the evening of Saturday, the 12th of December, at the same place and hour as last year; due notice of details would be given by circulars addressed to the members.

A frame of Mr. Henderson's very fine enamels were exhibited, and a conversation thereon followed, in the course of which Mr. Henderson stated, in answer to a question, that the cost of a large specimen, in the Chairman's hand, would be about 15s., with 30 per cent. discount off.

Mr. C. PEARCE then read a paper "On Producing Open Air Effects in the Studio" (see p. 556). The paper was illustrated by some very excellent examples of card portraiture by Mr. Pearce; and Mr. Taylor passed round some examples of cards with landscape backgrounds by Mr. Parry, of Preston.

The CHAIRMAN, in offering to Mr. Pearce a vote of thanks, spoke of the interest he felt in seeing photographers endeavouring to get out of the common-place groove, and aim at more specific pictorial effect in portraiture.

An animated but desultory conversation followed, in which the Chairman, Mr. Bockett, Mr. Simpson, Mr. Pearce, and others took part.

Mr. SEBASTIAN DAVIS, referring to the landscape backgrounds, remarked that he did not think the horizon line should be placed too high, as it detracted much from the effect of the figure.

Mr. PEARCE said it would, of course, be opposite the eye of the spectator; or, in photography, opposite the lens or eye of the camera.

Mr. DAVIES said, of course, and for that reason the latitude the photographer had in fixing the height of his camera gave him some latitude in respect to the horizon line.

Mr. HART suggested that when a background contained open air effects it was important to avoid the strongly marked

light and shade on the face, which indicated that the figure was really taken in a studio. Especially the portraits should not have one side of the face in deep shadow.

Mr. PEARCE said, undoubtedly portraits with landscape backgrounds should be well exposed; but at the same time, he thought a slight sacrifice of literal truth might, without serious impropriety, be made to pictorial effect. It was done by artists constantly, as might be seen on consulting any collection of engravings.

Mr. DAVIS thought that much would depend on circumstances. Even in the open air strong effects of light and shade would often be observed. In Mr. Robinson's "Returning Home" the face was, in some degree, in shadow, but the character of the light and sky seemed to justify it.

Mr. HART said the hat in that case over-shadowed the face.

Mr. SIMPSON thought that whilst circumstances might often produce a face in the open air with strongly marked light and shade, yet, as a general rule, observation of Mr. Hart's suggestion was most important. It was certainly incongruous to see a figure in an open plain, yet distinctly lighted with the side-light of a studio. As a rule, open air lighting had the effect of top-lighting.

After some further conversation the subject was dismissed.

Mr. Taylor exhibited Messrs. Geymot and Alker's *Jumelle Photographique*, an opera-glass camera, with a changing box to hold fifty dry plates, about one and a half inches square. This box was very ingeniously contrived, being circular, with fifty grooves radiating from the centre like the spokes of a wheel. Each groove could be brought in succession opposite an orifice, from whence it was dropped, when required, into the groove in the camera for exposure. The attachment between the changing box and camera was provided with an automatic arrangement, by which both apertures were closed by the act of detachment.

Mr. TAYLOR said that some little attention having recently been called to miniature cameras, he thought that this might interest members. He did not introduce it as a new thing, for it had been described early in 1867.

After some conversation,

Mr. HOWARD exhibited a very charming series of landscapes, the results of his summer rambles. He called attention, as a feature of interest, to the fact that these pictures were taken two on one plate,  $7\frac{1}{4}$  by  $5\frac{1}{4}$  in size, the two halves exposed in succession, thus giving the prints about  $3\frac{1}{2}$  by  $2\frac{1}{2}$ . He found the plan very convenient with his camera intended for  $7\frac{1}{4}$  plates. Some of the collodio-albumen plates had one-half exposed five minutes, and the other half only a few seconds, so that a little judgment and skill in development had been necessary; but he had found no serious difficulty.

After some conversation and much admiration of the charming little views, the subject was dropped.

The CHAIRMAN mentioned that in the *Mirror* for 1826 he had recently noticed a photographic experiment mentioned. A bottle was filled with some lime-water, to which a little nitrate of silver was added, and the bottle was covered with paper in which some device was cut out, and then submitted to the action of light. It was interesting as one of the pioneer experiments in the art.

Some conversation as to the consideration of certain questions in the Question-Box took place, and it was resolved that should no paper be provided, Mr. Davis should introduce the first question at the next meeting, which was as to the cause of pinholes in dry plates. The subjects of other questions were apportioned to other members, who were requested to give them a little consideration, and introduce them when occasion occurred.

The proceedings then terminated.

#### AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL meeting of the above Society was held on Tuesday, the 17th inst., at 12, York Place, Portman Square, JAMES GLAISHER, Esq., F.R.S., in the chair.

The minutes of the last meeting having been read and confirmed, the following members and subscribers were elected:—Captain Grimston, Captain Arbuckle, R.M., W. H. Saville, Esq., R. E. Chidley, Esq., Mrs. Leslie, J. B. Hodgkin, Esq., Robert Brown, Esq., F.R.C.S.E., Rev. T. Hedley, Arthur Lascelles, Esq., F. S. Schivale, Esq., E. Hoasman, Esq., Ed. Roper, Esq.

The Secretary then laid before the meeting the pictures for

the current year, which greatly exceed in number those of any previous occasion; it was, however, found impossible to come to a decision relative to the prizes that day, and the meeting was therefore adjourned A. J. MELHUISE, Hon. Sec.

### Correspondence.

#### LUX GRAPHICUS ON THE WING.

HIS FLIGHT TO AND FROM THE EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

DEAR MR. EDITOR,—On Tuesday night last I took the liberty of looking into the rooms of the Architectural Society, to see the photographs, and listen to the gossip of the visitors at the conversazione of the Photographic Society. To hear the complimentary remarks and the exclamations of pleasure was as delightful to my ear as the first song of the lark in spring.

The assemblage—not brilliant, but genial, pleasant, and happy—was as refreshing to the eye as the first glimpse of the vernal flowers; and the pictures hung upon the walls and screens, and laid upon the tables, were, in more senses than one, a feast to the mind almost without alloy. For my own part, I felt so joyful, I could not help fluttering my wings, shaking my feathers, and flitting about from one place to another, chirping, chattering, and pecking lovingly about this pretty thing, and at that old friend, till long after my usual time of going to roost. And when I did at last tear myself away and fly home, I could not help exclaiming, Well, there never was a pleasanter evening nor a nicer exhibition in the whole history of the Society! But I could not sleep; I put my head under my wing, shook my feathers, and tried to settle into the most comfortable and cosy positions, but it was no use. The pretty landscapes and pleasing portraits I had seen shone brighter and brighter before me; I was compelled to mentally review them; and here follows the result of my incubations. My first thoughts were to work the pleasures of the evening by a kind of rule-of-three process, by considering the value of the landscapes and portraits exhibited, to arrive at the worth of the exhibition, but not so much in a money point of view, as in the merits of the works, and their probable influences on the workers.

Taking the landscape portion of the exhibition, as first in the order into which I had mentally catalogued the pictures, it was an easy and delightful thing to skim over such a vast extent of this world's surface that evening. To journey to and from the glens of Scotland, the dales of England and Wales, the lakes of Ireland, the mountains of the Tyrol, to Abyssinia and the famous heights of Magdala, was but the work of a few minutes, thanks to the purveyors of that mental banquet. But to do full justice to the exhibitors I must endeavour to enumerate their principal works, and comment thereon with the utmost impartiality. Most unquestionably the gems of the landscape portion of the exhibition were eight exquisite little pictures by Mr. Russell Mannors Gordon, affording unmistakable proof of what the gum-gallico dry process is capable of yielding in his hands. It is almost, if not quite, equal to the wet process for detail and delicacy. This is particularly noticeable in the view of Carnarvon Castle. Indeed, Mr. Bedford's picture of the same subject—which, I presume, is by the wet process—on the other side of the screen, contrasts rather unfavourably with it. Mr. Gordon's selection of his point of sight, and general treatment of that subject alone, are unmistakable proofs of his refined taste and feeling for the art capabilities of landscape photography. The wet-collodion pictures by Mr. Gordon are also beautiful examples of the art. His cottages with sheep browsing in the foreground, which is an instantaneous picture, is remarkable for its beauty and arrangement. These pictures are beautifully printed, and possess a tone which harmonizes charmingly with the subjects. Amongst the other landscape photographers Mr. England and Mr. Bedford stand unrivalled in their peculiar branches. The views in the Tyrol, lately taken by Mr. England, are so excellent that they cannot but add to that gentleman's high reputation.

Mr. Bedford's views are also quite equal, if not superior, to his previously exhibited works. Some pretty views of the Lakes of Killarney by Mr. Archibald Irvine were well worthy of notice. Mr. F. Beasley, Junr., exhibited some very excellent examples of the Fothergill process; some printed in silver, and others in carbon, from the same negatives. I think the carbon

prints were superior in colour, but the silver prints possess most detail and depth. Views of Wimbledon and other places by Mr. Vernon Heath were also good examples of that gentleman's photography. Some beautiful cloud effects by Messrs. Robinson and Cherrill, of Tunbridge Wells, and Mr. Fox, of Brighton, attracted considerable attention, and elicited great praise. The large composition picture, "Returning Home," by Mr. Robinson, was greatly admired by nearly everyone that looked at it. One or two ill-natured or ignorant remarks were made about that picture, but I candidly think it is the very best picture that Mr. Robinson has produced. The sunshine on the one side of the picture, and the rain storm sweeping over the other, are both cleverly and artistically managed. I am sorry I cannot say the same of the group of children which hung near the latter. The group, though perfect in its photographic details and tone, is too suggestive of scissors and paste to be a good picture, in my estimation.

Mr. Wardley's large Taupenot pictures were very excellent. The very interesting pictures of Abyssinia by the 10th Company of Engineers were very attractive. Groups of the captives—political, religious, and artisan, with their families—and the officers of the Expedition formed interesting pictures. The views of Magdala, Theodore's house, the mushroom fortifications, and other flimsy defences, as revealed by the truth-telling camera, seemed to lessen considerably the glory of the capture of Magdala.

Having dismissed the landscape portion of the exhibition without mentioning all the many excellent contributions thereto, I next turned my thoughts again to the contributions of portraits. Two examples of that branch of photography were nearly all of first-rate excellence, a large number of them being *à la Salomon*, M. Adam-Salomon himself contributing no less than fifteen. With one or two remarkable exceptions, these pictures were not equal to those exhibited last year, and a general feeling prevailed that they were neither his later works, nor the best of his former; still, they were a very effective display, and attracted great and deserved attention. As I have, on a former occasion, expressed my opinion on the great excellence of M. Salomon's works, I shall not comment further thereon at present, but proceed to notice those which most nearly approached them in photographic and artistic essentials. Undoubtedly Mr. Valentine Blanchard's contributions, both in number and quality, come nearer to M. Salomon's works than any other contributor's. Mr. Blanchard exhibited ten portraits *à la Salomon*, some of which are quite equal to the French artist's best works, without the elaborate working-up which the latter exhibit. Mr. Blanchard has not been at all times fortunate in his sitters, which is very much to be regretted, for we all know how much a beautiful subject helps a good photograph. Hitbarto, Mr. Blanchard has been an exhibitor chiefly as a landscape and figure-study photographer. Now that he has taken more kindly to portraiture, and exhibits such capabilities for its successful practice, I hope he will find it sufficiently remunerative to induce him to be a steady and persevering disciple of M. Salomon. Messrs. Robinson and Cherrill also exhibited two beautiful and Salomon-like portraits: one of M. Salomon himself, and one of Mr. Hain Friswell; the latter, I think, is decidedly the best. Mr. Mayland, of Cambridge, sent six very excellent portraits in Salomon's style, all very good but one; a gentleman in a velvet coat was particularly successful.

The pictures exhibited by Mr. Briggs, of Leamington, though extremely forcible and beautiful, were not exactly an imitation of the style of M. Salomon.

Mr. Leake, of Cornhill, had a frame containing six very capital portraits in the style of the eminent French photographer, but a little over-done in after-touching—too much elaborated. In this respect he far outdid his great prototype. Messrs. Fradello and Leach also exhibited a number of whole-plate pictures *à la Salomon*, which were very good indeed. Messrs. Slingsby, Burgess, Ashdown, Dunmore, and S. Fry, were also exhibitors of the same style of portraits, ten by eight size; but it is a pity the latter did himself the injustice of exhibiting so many, for there was only one—an old gentleman with a grey beard—that was really worthy of him. Never did any man's joke recoil more forcibly on himself than that of Mr. Fry's. The faces of some of his female portraits—one in particular—were, in my estimation, as flat, white, and shadowless as a piece of knob of sal-ammoniac itself; but I must say that the portrait of the gentleman above referred to was all that could be desired as an artistic photograph.

Amongst the cabinet pictures exhibited by English photographers, I think those by Mr. Hubbard were decidedly the finest. One entitled "The Toilet," and another of a lady seated at a window, which might be named "A Sultry Day in Town," are charmingly artistic photographs. A composition picture by the same artist was also very skilfully treated; indeed, it was mistaken by many to be a copy of a picture, and might easily have been taken for a copy of a painting by T. Faed. Mr. Briggs, Mr. Godbold (of Hastings), Mr. Gillo, Messrs. Lucas and Box, also exhibited some beautiful cabinet pictures.

Cartes-de-visite in their ordinary form were somewhat scarce, but Dr. Wallich, Mr. Charles Heath, Mr. Bateman, and others, made a good show of vignettes.

Mrs. Cameron exhibited some large pictures in her peculiar style; but my own opinion and that of others was, that she is improving.

Mr. Ernest Edwards exhibited a large collection of carbon pictures, in black and other colours; some mounted on chromo-tinted paper, and some excellent enlargements in carbon. The Autotype Company exhibited a fine copy of Lord Belhaven, which I noticed some time ago; also a very valuable and beautiful collection of copies from drawings by old masters, all bound together, making a handsome and very interesting collection.

Mr. Rejlander had a large collection of his art photographs on view, all of which were clever, some facetious and many very beautiful conceptions.

A frame of coloured enamels by Mr. Bailey, and some in black-and-white by Mr. Henderson and Mr. Barnes, also attracted considerable notice.

The cburneumtypes by Mr. Burgess, a coloured collodio-chloride portrait on ivory by Mr. J. Edwards, and other collodio-chloride and opalotype pictures, were very much admired. The cabinet vignettes by Reutlinger, and the cabinet pictures by Wendoroth, were both in request at the table, on account of their beauty and interest.

I must not forget to mention a very interesting series of twenty-four stereoscopic pictures by Mr. Alfieri, illustrative of "The Potter's Art."

Mr. Jabez Hughes and Mr. Meagher were both exhibitors of very excellent and useful apparatus—cameras, camera-stands, and rolling presses.

Now I think such an exhibition as I have but partially described cannot fail to have produced a pleasing and beneficial effect on the minds of all who saw it, and ought, on the whole, to have given infinite pleasure and satisfaction to both exhibitors and visitors. Yet I think I heard one or two growls of discontent about the hanging from some one whose pictures or whose friend's pictures were not on the line; but I think I may safely say there never was a case of hanging yet that was not objected to by one individual at least. Even the hangers of the Royal Academy do not escape censure, and they are supposed to have far more skill, taste, and experience in hanging than the volunteer hangers of the late photographic exhibition. I think, however, that the hangers performed their duties both conscientiously and creditably, especially when it is considered in how very short a time the work had to be done. Any one who felt aggrieved, and expressed himself churlishly on that point, must surely have been in that unenviable state which the French very adroitly designate *Etre marqué au B.*

After these reflections I felt too drowsy to reflect any more, and was barely awake enough to subscribe myself—Yours very truly,  
LUX GRAPHICUS.

November 10th, 1868.

#### ALBUMINIZED PAPER AND PRINTERS.

SIR,—In reply to Mr. Bovey, I would ask you to publish the following, after which I shall not again trouble you upon this subject, as it is not worth while to continue a discussion which, however useful it might be in the abstract, or however interesting in its practical application, seems to be somewhat distasteful to your correspondent.

I will confine my attention to the more practical part of Mr. Bovey's communication.

The "three questions" which Mr. Bovey put to me to answer have nothing whatever to do with the matter on hand, and the very fact of Mr. Bovey putting them in the manner which he has adopted, shows how completely he has mistaken both my object and my meaning. I will, however, consider them.

First. It is not of the slightest consequence to me how much albumen each sheet of paper absorbs; that is a question which belongs entirely to the makers of albuminized paper. All that I want to know in respect of quantities is, speaking roughly, how much silver it will take to sensitize a quire of a certain sample of paper.

Second. It is no consequence to me what amount of silver goes to the albumen, and what to the salt, so that I know, speaking roughly, how much silver it will take to sensitize a quire of a certain sample of paper.

Thirdly. If photographers knew how much silver each quire of paper removed from their sensitizing bath, they could easily ensure uniformity in their solutions which would be sufficient for all practical purposes; they do so now, but if some information were given them as to the amount of silver used, it would be easier.

Mr. Bovey will observe here that I have never laid any stress upon the importance of knowing the strength of salting solution, &c. I have only said that a little information on this subject would be useful; and so I hold it would.

The important part of the matter is yet to come; what has gone before has been only preliminary. I hold that it would be a great advantage to photographers generally if they knew what intensity of negative would produce the best result with each sample of paper sent them; as it is, with every sample of paper, it has to be made a matter of experiment. I do not, and never did, ask for the "uniformity" which Mr. Bovey wishes to speak of; nor is the sense of my paper such ridiculous nonsense as Mr. Bovey tries to make out. Here is the point, in Mr. Bovey's own words: "Hence the Saxe paper\* yields an image of lesser vigour than can be secured with the Rivo sample." Now, the information I want is, what must be the comparative intensities of two negatives, the one to print best on one paper, and the other on the other paper? I am perfectly aware that there is no standard at present by which the comparative densities or intensities of negatives can be compared; but the adoption of such a standard was the very point which I ventured to suggest at the North London meeting. I said it would be a good thing if such a standard were adopted. If such were the case, the more different kinds of paper we had the better, so that each might be uniform with itself, and each having some definite relation to the other. Yours truly,

NELSON K. CHERILL.

### THE LATE SOLAR ECLIPSE.

SIR,—I see a letter in your Journal from Dr. Vogel, giving an account of his photographic operations during the eclipse of the sun at Aden. He states, incidentally, that Dr. Weiss, of Vienna, first called attention to this eclipse. Dr. Vogel, probably, saw only the *Astronomische Nachrichten*; but Dr. Weiss was not the first to notice it. A letter of mine to the Secretary of the Royal Astronomical Society is in the January number of their Notices, and you will find more information than Dr. Weiss gives (before his publication) in the number for March of the Notices. My paper was ready on the 1st February, and I had communicated both with the Astronomer-Royal and the Director of the Imperial Observatory at Paris before the reading of my paper, which was necessarily deferred, owing to the Annual Meeting of the Astronomical Society in February.

I am happy to say I, too, have six photographs, done by a Serjeant and two Sappers of the Royal Engineers under my superintendence, and I have myself examined the spectra, both of the great horn described by M. Vogel, and of the corona. The polarization of their light was examined by Captain Branfill, of the G. T. Survey.

When our photographs were taken (at Guntoor) the height of that horn was 90,000 English miles, or more; and my photographs show clearly its extraordinary structure.

I trust that you will reclaim the honour of having first drawn attention to the most remarkable eclipse in history for an Englishman. The Astronomer-Royal, and Mr. Stone, Chief Assistant of the Royal Observatory, and, probably, any working Fellow of the Astronomical Society, can confirm all I have brought forward.—I am, yours faithfully,

J. E. TENNANT, Major R.E.,  
In Charge Eclipse Expedition of the  
Government of India.

Calcutta, October 16th, 1868.

\* Mr. Bovey is mistaken when he says we use his Saxe paper; I did not refer to it.

[It affords us much satisfaction to reclaim for our own countryman the honour of priority in calling attention to the late eclipse, the more so that we recently lamented the absence of perfect success in our photographic operations. This at least balances honours between the two expeditions.—Ed.]

### PHOTOGRAPHER'S RELIEF FUND.

DEAR SIR,—I think your correspondent in last week's Journal, although very liberal in offering to subscribe one, two, or more pounds to the proposed Relief Fund, would wish to make it far too exclusive. It should be for those who have met with misfortune, or require assistance, and deserve it; whether or not they had carried on the business of a photographer only, or in conjunction with another, should make but little difference. The more generally a fund of this sort is distributed the more liberally will the world subscribe.

Another of your correspondents suggests a society on the same principles as the Odd Fellows. I should like to know what they are. We have lots of Odd Fellows amongst us, and it might suit us to do as they do; but what are their rules and regulations?—I remain, yours truly,

Southsea, November 16th, 1868. GUM GALIC AMATEUR.

[The Odd Fellows form a Benefit Society pure and simple, the relation between relief and payment being carefully calculated by an actuary. It forms an organization much too complex, we fear, for the limited number of photographers who would be likely to join it, and would require more time and labour than any individual or committee could give it at present. Besides, those amongst photographers who desire to belong to a benefit society can, if they choose, join the Odd Fellows, or similar body, which admits all trades or professions. So far as we can see, it is to the formation of a Benevolent Fund that attention should be directed at present. We have received a few offers of donations and annual subscriptions in response to our recent appeal; but we expect to receive many more.—Ed.]

### PRINTING FORMULÆ.

DEAR SIR,—In an article on "Our Printing Room," in last week's News, Mr. Nelson K. Cherrill gives an account of the methods he employs in preparing, using, and keeping in order the nitrate printing bath. This is a matter to which I have for many years given a very careful attention myself, and on which I have, in times gone by, written in your valuable paper; and having arrived at a conclusion differing considerably from Mr. Cherrill, I beg you to allow me to lay before your readers the points of dissidence, and the reasons therefor.

Mr. Cherrill's bath is thus prepared:—

Nitrate silver	...	...	...	40 grains
Nitrate soda	...	...	...	20 "
Water	...	...	...	1 ounce
Sugar	...	...	...	a little.

Now, sir, if there be any one thing on which practical photographers insist more than any other, it is on knowing what their materials are. Mr. Cherrill admits this when expressing his anxiety to know the strength of his albumen paper; but with the bath he uses he would not apply in any way such knowledge, if he could obtain it. Starting to-day with (say) 100 ounces of this sensitizing bath, you float 20 sheets of paper, and then add 10 grains of silver—in all 200—to keep up the strength. I say, and from practical experience, that you are now at sea completely as to the strength of your bath; any computation as to its strength becomes mere guesswork, and, as Mr. Cherrill himself says, "the relation between the character of the negative and the quality of the paper becomes upset." Of course it does; and as you are completely in the dark as to the strength of the bath, it requires time and experiments before it can be set right.

All this I have gone through with extreme care years ago, and therefore gave up entirely the cause of all this trouble—the nitrate of soda—and came to a good, honest, uncontaminated bath of silver of 70 grains to the ounce, and have been freed from no end of troubles.

I observe certain of our valued friends who write to these pages seem to vie with one another in a rather "high falutin" style; quote freely from the poets, some sacred, some profane, and, generally, indulge in a good deal of imaginary, doubtless

very appropriate, but, as it sometimes strikes me, rather too far fetched. Now, I should like, without anything of that kind, just to show why I abandoned nitrate of soda, and why I found a good many others did.

First. For the reason given above, that you cannot estimate correctly the strength of your bath, as the argentometer cannot be used when other matters are in solution along with the silver.

Secondly. Because the nitrate of soda, being a deliquescent salt, in damp weather larger pictures were not sharp; the expansion and contraction of a 24 by 19 sheet with nitrate of soda sometimes amounted to five-eighths of an inch. We tried putting it out in every conceivable stage of dryness and dampness without avail; as the atmosphere changed, so did the paper.

Thirdly. Because such is the solvent action of nitrate of soda, a good deal of which is washed off after printing in an unaltered state, upon the residuary chloride of silver, that it was found very difficult—almost impossible—to get it to settle down, and the loss of silver was very great in this way, as even when clear, this liquor was, in fact, chloride of silver dissolved in a solution of nitrate of soda. We found, on abandoning nitrate of soda, this source of serious loss disappear at once.

Fourthly. I abandoned nitrate of soda because it was found to be a complete delusion, and entirely worthless for printing purposes. No mortal man could select, from their superiority, prints so done out of a batch, nor could the producer, unless they were intentionally kept in view.

I had, for a length of time, in order to get at the real truth of the matter, a great number of prints done each way, and would try to pick them out when finished; but it was entirely guesswork. I feel sure Mr. Cherrill will perceive that I have no other object in view than the elucidation of truth. The subject is a peculiarly interesting one, and on that ground I must beg both yourself and Mr. Cherrill to pardon my interferences.

SAMUEL FRY.

#### PORTRAITS ON APPROVAL.

SIR,—I do not endorse the two letters, one by Mr. Downes, the other by Pas-trop, on the subject of taking portraits on approval. I have adopted the plan from the first of my going into the black art, and find it answers perfectly. The public like it, and it gives greater satisfaction to both parties. I get very few returned to me; but if the first sitting is not preferred, I give a second. I find it secures more trade, as the general public like to know what they are going to get for their money. My plan is to make a charge, for the first specimen, of 2s. 6d. (it is paid cheerfully), send the specimen home requesting an answer if more are required in a week's time. I in general get the remaining order in a day or two; if an order for half-a-dozen, my price for which is 5s., the remainder are sent home and the other half-crown paid, and a receipt given. With this plan I get a very good trade without any advertising or puff of any description.—Yours, &c.,

A COUNTRYMAN.

#### Talk in the Studio.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.—The complete success of the exhibition of photographs in Conduit Street is well illustrated by the large number of visitors which have been present. We learn from the attendant of the gallery that not less than five thousand persons have visited the exhibition during the week that it remained open. Two or three considerations are deducible from this: first, that already acknowledged, namely, that the exhibition is a very excellent one, and possesses sufficient interest to secure many visitors; next, that there is no decadence in the public interest in photography as an art; and, hence, that the commercial prospects of photography are not altogether dreary.

PLAIN PAPER PRINTS FROM ALBUMINIZED PAPER.—A correspondent calls our attention to the fact that the plan of printing on the back of albuminized paper is not new, but was proposed many years ago by Mr. Hughes, who mentions it in his *Manual*. We did not mention it as a novelty, but as something old and useful which was not sufficiently generally known, as was evidenced by the frequent enquiries which reached us asking for a simple plain paper process. We have

much pleasure in accrediting the idea to Mr. Hughes, whose prior proposal had escaped our attention.

BRILLIANT PRINTS AND ALBUMINIZED PAPER.—We received from Mr. Bovey, too late for noting in connection with his letter in our last, three albuminized prints intended to illustrate his position that the quality and brilliancy of the print depend much upon the printer, independent of the quality of the paper; and that with the same paper and the same negative, brilliant or flat prints may be produced at will. The three prints are from a good but somewhat soft 10 by 8 negative, and are labelled Nos. 1, 2, and 3. No. 1 is printed on *Saxe* paper, and is somewhat weak and flat; No. 2 is on *Rive* paper, and is vigorous and brilliant; No. 3 is on the *Saxe* paper again, but with a somewhat modified treatment, and is as rich and brilliant as No. 2 on the *Rive* paper, and of as rich and warm a tone. Mr. Bovey sends us another letter this week, in which, referring to Mr. Cherrill's preference for the acetate bath expressed last week, he mentions that it has not always proved certain and trustworthy in Mr. Cherrill's hands, as some months ago it failed, and Mr. Bovey's instructions were adopted to get rid of the difficulty. The failure of a process through accident or error would scarcely furnish an argument of general application, and as a discussion ceases to be instructive when it begins to hinge on individual experiences and involves anything of personal considerations, we think the controversy on albuminized paper had better now terminate.

SENSITIVENESS OF GUM GUAIACUM TO LIGHT.—A correspondent says:—"An alcoholic solution of this gum, spread upon paper, prints green, and as rapidly as bichromate of potash. If, after exposure, the picture is placed in a dilute solution of chloride of gold, it becomes of a brilliant blue, quite equal to cobalt in colour. I know no way of fixing the picture. Salts of gold or silver added to the solution of gum causes a blue precipitate."

#### To Correspondents.

HENRY WILLIAMS.—A charcoal stove will not be injurious in a studio if it have a proper chimney. 2. Good transparencies may be produced either on dry plates with contact printing, or on wet collodion by camera printing. Our advice as to which was best to employ would be governed by the querist's experience and opportunities. Dry plates, to those skilled in their manipulation, have the advantage of permitting night work. The difference in the quality of the results is, as a rule, that those on dry plates are often most vigorous, and have the warmest tones; those on wet plates generally the most delicacy. 3. For producing transparencies on wet collodion, a well-exposed and not over-intensified negative is best.

H. DIXON.—The glaze on the card you enclose is obtained by the process which has been termed "enamelling," in which a coating of gelatine is attached to the print by means of a coating of gelatine, the fine surface being that of the plate glass upon which the collodion and gelatine are poured as a step in the process. The method was first described in the *PHOTOGRAPHIC NEWS* about eight years ago by Dr. Liesegang, and general attention was revived to it in 1864 and 1865, in which years you will find various communications on the subject in the *News*. On pages 447 and 448 of our Eighth Volume (September 16, 1864), you will find detailed instructions. The print has been returned.

J. H. M.—For the economical printing of photographic reductions of maps we do not think you can use any better process than that of photo-zincography as practised at Southampton, or the analogous process of photo-lithography. The series of articles minutely describing the operations, by Lieut. Waterhouse, which have been given in our present Volume, and an article in our *YEAR-BOOK* for 1867, by Mr. Butler, give the fullest practical information on the subject. We do not know of any one who is practising this process for the public, nor do we know prices.

A. B.—The simplest mode of forming the double chloride of gold and sodium, with the two separate salts, is to mix them in their atomic proportions in a concentrated solution, and then evaporate to dryness; in the course of this evaporation all excess of hydrochloric acid is driven off; the two chlorides combined as a neutral double salt are left. The atomic weight of chloride of gold is 303.5, and that of chloride of sodium 58.5.

LONDONSTONE.—If you prefer a studio with sloping front-light, that designed in your rough sketch seems to be a very good one; but our own predilections are in favour of the ordinary oblong ridge-roof with north aspect. 2. The No. 4D is not suitable for card pictures.

A YOUTH OF FIFTEEN.—Your failure may proceed from a variety

of causes, of which we may suggest some. The appearance of the card numbered 2 suggests under-exposure. It may be that you simply give too little exposure of the deteriorated light of winter; it may be that your bath is getting exhausted and weak; or it may be that your collodion is old and insensitive. If you have not considerably increased your exposures since summer, do so at once; if your bath has been much used, try a new one; if your collodion is old, try a new sample. In any case, much longer exposure in the camera would have improved No. 2; under-exposure begets the tendency to push development, and that induces fog, as it has probably done in your case, which may account for the fog manifestly present in the negative of No. 2. Try again, and let us know the result.

E. JUBA.—For ordinary dry-plate work it is not well to use salts of cadmium entirely in preparing the collodion, unless you are going to keep the collodion some time, as when the collodion so prepared is used new it is apt to be glutinous. In order to prepare any commercial sample of collodion for dry-plate work, the addition of an extra proportion of bromide to the iodizer will generally answer well. Take the collodion you mention, and add to the proportion of iodizer necessary for each ounce of collodion about  $\frac{1}{2}$  grain of iodide of cadmium. The papers have been forwarded. We have heard of balsam of tolu having been used as a preservative, but we do not remember details.

T. W. J.—We are not personally familiar with Gray's solution, but presume, from the statement of our correspondent, that it is known amongst house painters. We have used nothing ourselves for cleaning varnished plates which has answered better than a hot, strong solution of common washing soda, which quickly removes the film, after which, friction with woollen cloth and dilute nitric acid is employed; but at best such plates are uncertain. 2. For a strong developer of the double sulphate of iron and ammonia use 50 grains of the salt in an ounce of water and 30 minims of acetic acid. 3. We have no personal knowledge of the lens in question; it is, we believe, pretty good, but not equal to those of the best English makers.

C. T. N.—The annual subscription to the North London Society is 10s. 6d. That amount paid now will entitle you to the presentation prints for the current year, to which we recently referred. The year terminated in March.

J. T.—There are two carbon processes by which half-tone can be produced—Swan's and Poncey's—but both are patented, and the details of the latter are kept secret as well. The sensitive agent in the latter is bitumen, in the former bichromate of potash and gelatine. There is no other carbon process of a practical character, that we know of, by which half-tone can be produced. Fargier's process will render half-tone, but it is scarcely practicable on a commercial scale. For subjects without half-tone there are processes available. Let us know what you require, and we can possibly help you.

GULIELMUS.—You have not sufficiently carefully noted the instructions to which you refer, in which it is stated that 15 grains of carbonate of soda are to be dissolved in water, and part of this added to a bath. When you add carbonate of soda to a solution of nitrate of silver, of course it will effervesce, and will gradually precipitate the whole of the silver as carbonate of silver, leaving nitrate of soda in solution. The yellow precipitate you describe is carbonate of silver. It will gradually redissolve on adding nitric acid; but you will have irrevocably a large amount of nitrate of soda in your bath. In future, when you attempt to neutralize a bath, remember that a very few grains of carbonate of soda can be required. Make a 10-grain solution of the carbonate, and add a few drops at a time; then shake the bottle containing the nitrate solution, and, if it remain clear, add a little more. Cease adding the soda solution as soon as the nitrate solution shows a permanent turbidity, for then all acid is neutralized, and a slight precipitation has commenced. It is quite possible to proceed systematically to rectify a bath and secure certainty of perfect conditions, but you must follow instructions minutely, and not add, at random, 3 drachms of carbonate of soda, when instructions say take part of 15 grains.

JAMES MAYCOCK.—The chief source of crappiness in the film is water in the collodion, too early immersion in the bath, and sometimes dampness from breathing on the plate, or other causes. There is at this season of the year a common risk of immersing the film too soon, as the evaporation of the ether is much less rapid. 2. Sometimes we have known fog arise from excess of alcohol in the developer; but in the circumstances you describe it is probable that the change from gelatino-developer required other changes to prevent fog, as gelatino is a powerful restraining agent. We shall be glad to see the examples you mention. We only know the correspondent you mention by the initials given. It is not necessary that correspondents seeking aid should give their full name.

G. R. GILL.—We will insert your letter in our next. Try floating the paper for a shorter time, so as to leave a little of the salt in the paper unconverted into silver salt; or add a trace of chloride of sodium to the developer.

IGNORAMUS.—Mr. Carey Lea's formula for a solution for cleaning the hands is bichromate of potash 1 part, hydrochloric acid 2 parts, and water 20 parts, and not, as you state it, water 20 ounces. It is clear that when the word parts is used you may make up the preparation in any quantity you like. If you take ounces, you will have 1 ounce of the first, 2 ounces of the second, and 20 ounces of the third. If this quantity, which gives you upwards of a pint, be too much, you can take drachms, which will give you nearly 3 ounces. 2. There is no difference between liquid and solid weight, if parts by weight are stated. The relation between weight and measure in dealing with chemicals may be stated as follows:—A grain in weight is equivalent to a minim by measure; hence a drachm contains 60 grains of a solid or 60 minims of a liquid. An ounce of a solid contains 480 grains, and an ounce of a liquid contains 480 minims.

W. HERBERT.—The photograph has some good qualities. It is a little too red in tone, and the vignette is a little too formal.

OXONIENSIS.—For landscapes solely, nothing can be better than the lens you mark A. Mr. England used for his views in the Tyrol a large variety of lenses, generally travelling with about twenty different lenses, in order to use precisely the length of focus and character of instrument which each subject requires. He uses those chiefly of the first maker you name. We hope he will be induced to record the facts you refer to. 2. Your suggestion as to the cause of the bitterness to which you refer is doubtless correct. The only "elique" we know of consists of three or four disappointed persons, the *disjecta membra* of established journals and societies. Thanks for your kind expressions. The YEAR-BOOK will be ready by the end of the year. We are obliged to defer it until then in order to secure all information necessary for such an annual.

THOMAS STOTHARD.—From the general description of your plan of mounting, we do not see any reason for imperfection in the result, if the manipulation be performed neatly. We will, however, consider your letter carefully, and possibly comment upon it in a future number. 2. You cannot have a good card lens with which a distance of only ten feet would be necessary between lens and sitter; the focus must, in such case, be necessarily too short to do justice to a standing figure. The stereoscopic lens of No. 1 will be as near as any we know.

ONE OF THE EIGHT, referring to a letter on the Photographers' Relief Fund by Mr. Matthews (in which he pointed out that in the town from which he wrote a large number of photographers also practised other professions), charges Mr. Matthews with injuring the profession by low prices. It must be seen at once that questions concerning individuals cannot be discussed in our pages. The broad question of what class of persons should be relieved may be discussed in our pages, but not what individuals. The question of low prices may be discussed and condemned, but not the individuals who charge low prices.

E. HASSELL.—Mr. Trubner, of Paternoster Row, is the London agent for the "Silver Sunbeam."

G. ROBERT FITT.—The splitting of the film in collodio-chloride we have generally found due to the use of a too horny and contractile collodion, and the same cause tends to the production of irregular and patchy toning, the aqueous solutions not readily permeating the repellent film. Keeping for some time, with excess of free nitrate, has a tendency to produce the conditions which cause the film to split. The sulphocyanide tints are pleasant. The lighting relieved by reflecting screens is very effective. Thanks.

W. J. A. G.—Mr. England this year chiefly used the wet process, because he did not find the dry process work to his satisfaction when the plates were prepared by an assistant. The card you enclose is very good indeed. You will be fortunate in obtaining an introduction to and information from the amateur you name; he is a very courteous gentleman, and one of the ablest photographers we know. If you will send us an addressed envelope we have a communication for you respecting your Liverpool plates.

T. GULLIVER.—Many thanks. We will write shortly.

H. KELSALL.—Many thanks.

A. W. HOSMER.—We duly received your offer. Thanks.

W. H. PULLEN.—Received. Thanks.

Several Correspondents in our next.

## FOGGING OF DEVELOPED PRINTS.—NEW REMEDY.

WE have recently been engaged in some experiments for the prevention of fog, or the general browning of the paper during the process of printing by development, and, so far as we can at present judge, the remedy we propose promises the highest success. The fogging of paper prints during development is by no means uncommon. On another page we print a letter which describes this difficulty in a form not unfrequent, we believe, with beginners in this mode of printing; the example accompanying the letter being one of a class which often reaches us, with anxious enquiries for a remedy. The print, instead of possessing pure lights and deep shadows of brown or black, possesses dull-grey whites and weak-brown shades, whilst by transmitted light the whole presents a mottled-brown effect. The silver salt, in short, instead of being reduced in the exact ratio of the action of light in forming the image, is reduced in some degree throughout the whole of the paper, and a dirty, foggy, imperfect picture is the result.

Before proceeding to speak of our experiments, we mention two or three of the most common causes to which this defect may be referred. One of the most frequent is the action of diffused light. It is difficult to bring the novice who has been accustomed to the ordinary process of printing fully out, in which the action on the paper of a feeble light is not regarded, to believe that in printing by development, light should be as carefully excluded from the prepared paper as from an excited collodion plate. And hence a little white light being permitted to reach the paper at some stage of the operations, degraded whites or general reduction is the result. It is probable that the correspondent to whose letter we have referred, who is an experienced and ingenious photographer, would scarcely neglect proper precautions in this respect, and, indeed, an example of good results, obtained by the same formula as the failure, suggests that no white light had been permitted to enter the dark room in its production.

But there are two or three causes to which the defect in question may be due. In the first place, the formula employed, whilst it is one which will doubtless give great sensitiveness, is one which will also very readily give fog the moment any of the conditions necessary to success cease to be present in the precise form. His paper is prepared with a salting solution containing about 17 grains of iodide of potassium, and under 6 grains of bromide of potassium in an ounce of water, and excited on a 60-grain nitrate bath. There is no acid in either the salting or exciting bath. Compare this with a formula recently given in our pages, described as giving very rapid and excellent results. In the latter formula we find the salting

bath contained about  $4\frac{1}{2}$  grains of iodide of potassium and 18 grains of chloride of potassium, together with 7 or 8 drops of lemon-juice and 9 grains of tapioca, in an ounce of water; whilst the silver bath, which is a little weaker than our correspondent's, also contains about 5 grains of citric acid to each ounce. In the latter formula everything tends to lessen the chances of fog or abnormal reduction—the decreased quantity of iodide, the large proportion of chloride, and the free use of citric acid. The comparison of the two formulae will be so suggestive to all working in this direction that we need not enter into lengthened comment on the matter.

Another cause of this fog, or abnormal reduction, arises from the paper being kept after it is excited. It is always desirable that paper should be exposed and developed as soon after exciting as possible. Most printers are familiar with the fact that in any kind of excited paper which is long kept there is a tendency to decomposition in the compound formed between silver and the size of the paper, and if this decomposition be only incipient, it will inevitably be completed in the process of development.

Another cause of discoloured lights, and a general dirty yellow, mottled effect being produced throughout the print, is imperfect fixation. Either from carelessness, or with a view to improve the tone, some photographers place the developed print in the hypo at once, either with very little washing, or none at all. If the hypo be weak or old, the paper, saturated with nitrate of silver and gallic acid, causes a decomposition in the hypo, which sulphurizes the print, or, worse still, leaves it with undissolved hyposulphite of silver in the body of the paper, which, decomposing, produces the dirty yellow, mottled effect familiar to some who have failed in enlarging by development printing.

The remedy for some of the defects we have mentioned is obvious enough: it is simply to avoid the causes we have indicated as operative in producing the defects. There is a remedy for the fog caused by neutral and excessively sensitive conditions, which, in relation to development printing, has never, we believe, been suggested, but which, from recent experiments, we have reason to think will be very effectual, and will especially meet the case of the correspondent whose letter appears on another page. His especial difficulty is that the same conditions which at times give him perfect prints, at other times—without, so far as he knows, any change in causes—yield only fogged prints. We have repeated the experiment, and have been able to produce at will, without any change in the materials used, either clean prints, or prints utterly fogged, and have traced the cause and remedy.

The cleanness or fogging depends on the presence or absence of an unconverted haloid salt in the paper. If the paper be floated sufficiently long on the silver bath to convert the whole of the iodide or bromide into silver salts, the

tendency will be towards fog; and where excess of iodide and little bromide or chloride is used, the complete conversion is much the most readily effected. If the floating be short, and especially if a full proportion of bromide be present, a portion of it is not converted into a silver salt, and its presence during development operates as a powerful preventive of fog in the print.

We have tried adding a trace of bromide or chloride to the gallic acid used for development, and find it a most effectual preventive of fog; but if used in excess, it will very seriously retard development, and will also tend to the production of a print wanting in force and richness. It must be used, therefore, with great caution. Our experiments have not been sufficiently extensive to enable us to decide on the best formula or proportions; but that is a matter which will be easily decided by the experimentalist himself, the more so that the exact proportion required will doubtless vary with circumstances. Let it be understood here that the novelty of the remedy consists in the application to development printing on paper of a principle already found of value in dry-plate photography, and first suggested in regard to dry plates, if we remember aright, by the late Mr. Glover. The presence of a free bromide in securing immunity from fog in dry plates is undoubted; and our experiments suggest an equal advantage in its presence, or that of a chloride, during development of paper prints.

#### AMATEUR CRITICISM.

THE letter of a correspondent on another page, protesting against "amateur and anonymous criticism," suggests the necessity of a few brief remarks on the subject generally. Criticism of pictures affects and interests in relative degrees three classes of persons: the exhibitors, whom it may gratify or displease, and, possibly, instruct; that portion of the public who, having the opportunity of seeing the pictures criticised, are led to examine, compare, and exercise their judgment, and who, whether they endorse or condemn the criticism, and whether they are instructed or not by the remarks in the criticism, are benefited by the exercise of the analytical faculty induced; and the general readers, who, having no opportunity of examining the pictures criticised, nevertheless have two sources of interest in the subject; first, in the information they derive as to the character and degree of the progress which is going on in the photographic world at large, with which they have little opportunity of coming into direct contact; and, second, the instruction they derive from a description of faults to be avoided, or of beauties to be aimed at.

It is desirable that each of these classes should be considered in a criticism, and, if possible, satisfied; but it may be affirmed—and the statement should not be regarded as disrespectful or offensive—that the first class mentioned should be the last and least considered by the critic. It is the second and third class, comprising the public at large, for whom a criticism should be especially written. It is desirable for each that the criticism should be discriminating and able; it is imperative for all that it should be honest. All criticism must, it is scarcely necessary to observe, be but the expression of an individual opinion, and must, therefore, necessarily derive part of its value from the authority which attaches to the judgment and honesty of the writer. If it bear a well-known and trusted name, or if it have the editorial sanction of a journal of repute, it possesses more weight, and its instruction is of more value, than can possibly attach to the dictum of an anonymous writer, or that of a journal of no character.

But in a certain sense, and in some degree, all criticism, anonymous or otherwise, written with a fair degree of ability, and not absolutely tedious or intolerably ignorant, possesses its value, especially to the last and largest of the classes we have named. To them, without the means of testing the precise accuracy of the writer's judgment by an examination

of the pictures commented on, the discussion of qualities in pictures possesses the value of iterated instruction. If the writer attach value to artistic qualities—his criticism dwelling, as he passes picture after picture under review, on various forms of pictorial beauty, praising this for its perfect composition, that for its expression, another for the rare feeling of space and atmosphere, and a fourth for the massive grandeur of its light and shade; or blaming others for awkward lines, spottiness, hardness, and want of transparency, or general feebleness—the mere reading of his criticism, if it be written with any ability, is instructive, as it impresses the student with an increased interest in qualities to be sought, and defects to be avoided. If the critic have a technical mind he will dwell on definition, cleanness, fine tones, pure lights, &c., as virtues; or on slovenliness, fog, stains, bad definition, distortion, &c., as abominations. This in its degree may be instructive; and in all this the instruction will be in some measure irrespective of the precise aptness of the writer's judgment, or the exactitude of the relation of his remarks to pictures which the reader cannot see or compare.

In thus examining the function of criticism, let us refer to the letter of the correspondent above mentioned, who protests against "amateur and anonymous criticism;" and in doing this we must again digress a moment to refer to the varied degrees of editorial responsibility in relation to communications which appear in a journal. This responsibility possesses three degrees. For editorial articles the conductor of a journal is absolutely responsible; whether he is dealing with facts or principles, theory or practice, he is solely answerable for the good faith and capacity involved in such articles. For the character of articles bearing the name of the writer he is responsible in a less degree, the facts and arguments resting generally on the authority of the contributor, the editor being chiefly concerned to avoid the appearance of violations of known facts, and of unimportant or offensive matter. For a third class of contributions, which at times forms a feature of considerable interest in photographic journals, the editor is still less responsible: we refer to letters addressed to the editor, which appear under the general head of "correspondence." For the facts, opinions, or ability embodied in such letters the editor is avowedly not responsible. He is simply concerned to see that they are not unfair, that they do not violate good taste, and, if they contain statements of fact affecting injuriously the interests or feelings of individuals, that they should be substantiated by the name of the writer.

Having briefly stated these conditions, we return to the letter of "Lux in Tenebras." In reply to his suggestion of a doubt as to the propriety of giving insertion to the amateur criticism of an anonymous correspondent, we might briefly answer that we did so because we believed it would be interesting to a large number of our readers; but it is worth while to make a few further remarks. Besides the interest of comments on pictures illustrating progress from a different and, possibly, opposite point of view to our own, we should state that the gentleman who chooses to be known to photographers as "Lux Graphicus" possesses in many respects eminent qualifications for presenting an interesting sketch of such an exhibition. He is an old photographer, and a still older art-student, as well as a shrewd observer, possessing facile and graceful expression; and we know that his letters are read with interest, and in most points we cordially coincide with his views. That we need not do so in all we have already shown, and we may at once frankly admit that in some of the points to which "Lux in Tenebras" refers our judgment is distinctly opposed to that of "Lux Graphicus."

In the first case cited, that of a group by Messrs. Robinson and Cherrill, mentioned by the latter correspondent as "too suggestive of scissers and paste," it appears to us that a knowledge that such a picture must of necessity have been produced by combination printing has unconsciously suggested the criticism, for it strikes us as in all respects

singularly free, in its art qualities, from the most distant suggestion of such a mode of production, and as being in reality one of the noblest works of its class we have seen. The landscape background is a perfect picture in itself, full of light, space, and atmosphere. Three fine children, and manifestly charming portraits, admirably grouped, and composing most harmoniously with the landscape, occupy the foreground, and complete a picture full of life and interest. We see not only no mechanical joins, but no suggestion of piecemeal work; and a pervading sense of unity and harmony, which indicates that the artist conceived the work in its wholeness, mechanical exigencies being entirely subservient to the conception.

We might in like manner take exception to the sweeping remarks on Mr. Fry's pictures, in which, as our correspondent suggests, the temptation to make a joke perhaps gave rise to exaggeration. Mr. Fry's contribution contained pictures of varied qualities, some illustrating the extremest contrasts, others the greatest softness possible without dinginess. It is probable that these gradations in style were specifically intended as experimental effects, something in the fashion in which the Laureate some time ago gave the literary world his experiments, in the *Cornhill Magazine*, in varied metres.

The remarks of "Lux Graphicus" on Mr. Blanchard's pictures, to which our protesting correspondent takes some exception, we, on the contrary, thoroughly endorse; nothing could well be finer than the majority of his contributions.

As to the question on the amount of retouching on M. Salomon's pictures, it is not worth while to revive the discussion. That some of them have a good deal of retouching no one, we believe, denies; and it is not worth while to dispute about the term "elaborate." That the finest of them are not retouched in any degree worth mentioning, if at all, all who have had the best means of enquiry and examination are thoroughly satisfied.

That different opinions must prevail on all questions of art criticism, even as to perception of matters of fact, is a manifest necessity, for it should always be remembered that "the eye only sees that it brings with it the power to see."

### POSING, PHRENOLOGICALLY AND PSYCHOLOGICALLY CONSIDERED.

BY JOHN BEATTIE.

This paper may, at first sight, seem somewhat out of place in the *Photographic News*, and my way of treating it faulty, yet I think the subject worthy of a little thought.

Whatever theory of mind we adopt, whether that of special creation, that of evolution, or development, this much is true—there is, and must be, more than the mere momenta or assumed forces bound up in the molecules forming the first principles of organic life. In spite of the brilliant talent now employed, and, to a great extent, successfully so, to prove that in matter there slumber forces adequate to the production of the higher organisms, and, therefore, of man, to the incisive mind the reasoning employed seems inconclusive. I say it matters not whether the completed organism is the educt from, or product of, a germ. We cannot conceive of a part being the effect of a pre-existing part, and that in its turn the cause of other parts, the completed product being man. We cannot conceive, I say, such a result possible from all the apparently subtle and combined phenomena of matter; nor is it necessary to go out of the organism for the formative force, for that would be what Mr. Lewis would call a theological idea. Philosophers have a great objection to a creative intelligence. There seems to me to be clearly set forth this principle, that the active forces revealed to us, and called physical forces, are the result of disturbance in subtle substances that defy all analysis; when they are at rest, we have no intimation of their existence; yet these are subject to, and pliant in, the

hands of a higher force, which I call *spiritual*; they are not transmutable, the one substance active, the other passive; the one moral, the other material; one conscious, the other unconscious.

The spiritual organic being, therefore, that permeates and circulates through every part of the physical organism is the conscious man. And as the spiritual organism unfolds itself, whether by evolution or otherwise, so does the physical organism. There will not be one secret or sleeping force in the spiritual germ that will not awake and clothe itself in material covering in *form and arrangement* exactly in harmony with all the tendencies of the inner and conscious being. That this is so, all who care to think will admit; it is but the formative law in action. Base affections are always clothed with vicious forms: see the principles in the various animals. Here I must refrain from details.

The complicated phenomena of perception clearly proves that all appearances are but the outgrowth of mind. We have nearly all physical eyes, but to what a limited extent do most of us see! It was said, "He that hath ears to ear, let him ear;" and it might likewise have been said, "He that hath eyes to see, let him see." How difficult it is to see the immense depth of this philosophy! To see into things is the function of the spiritual eye; to see that external forms are outbirths of internal qualities or affections; to see that the whole outward anatomy or mechanism of man is a perfect index to the true or spiritual man; to see that not only are the sum total of exquisite mouldings in the human face, but the whole osseous and muscular structure of the body, indicative of character, from the strong to the weak, from the intelligent to the imbecile, and from the pure to the sensual and base. In a word, before we can give character in portraiture, we must understand those fine appearances upon which such character depends. All this will depend upon our faculty of seeing; and our faculty for seeing depends upon our true spiritual idiosyncrasy.

There can be seen so much of the artist in every work he produces. For instance, one artist may have a keen perception of colour and beauty of form, but a feebler perception of moral and religious beauty; another may have both. Portraits of some of our eminent men by such artists would differ much. Take, for instance, Mr. Bright, with his brilliant intellect, his lofty moral nature, and his impetuous emotions. The former artist would look at his fine physique, place him with the chin prominent, exhibiting the heavy jaw, and, to some extent, the fish-shaped mouth, with a long, though sensitive top lip, and, throwing back the splendid intellectual part, giving secondary effect to the keen eye, thus bringing out in the portrait, with undue prominence, the lowest qualities of his nature. The latter of the two would study the head carefully, and so place it that the lower parts of this face, representing the emotional part of his nature, should be in due abeyance, and the parts representing the noblest part of the man brought most forward; thus not only a likeness, but a portrait in the highest sense, would be the result.

To illustrate my idea further, I could send you, from my own city, portraits of men who, if you once met, you would see by their fine, symmetrical heads and faces, that they were men of many and noble parts. But look at their photographs. True, you will know them, not because they are portraits, for were you to judge of the man by the picture, every fine point is so ignorantly concealed by the pose of the head that you would surely take the photographer for a fool.

I fear I am going to ask you for too much space, but I must have a few words more upon the pose of the figure from the same standpoint.

How often do we see the limbs of a male figure like props to keep the figure up, instead of parts under the control of a graceful mind! Again, in the lady figure there are parts, when badly draped, and unduly prominent, indicate gross vulgarity of taste on the part of the artist. Suppose a lady with the strongest balance of face under the eyes, the upper

lip long, the nose somewhat of a pug, luxuriant hair, with rather a good figure, richly attired in wedding costume, placed as I saw one the other day, sitting with full front face, head well back, the stomach all exposed, one arm on a table, the other thrown away on the skirt of the dress, the face saying—Now look at me!—the effect to the cultured eye one so common-place that you could only conceive it to be the work of a "commercial," and not an artistic, photographer.

I must refrain from further illustrations, and simply say, that as photographic portraiture has passed through all the lower phases of development, its professors must, to succeed, be men versed in all the relations mind holds to matter and form; they must see clearly that form is a product of mind, and not the converse, and thus be able to give prominence to all the fine points of form and figure, the result being, in all cases, true portraits, in both a mental and physical sense. Look at the sublime ruggedness of Carlisle's head, the picturesqueness of Longfellow's and Tennyson's, the fine symmetry of Mill's, the angularity of Gladstone's. In all cases the soul and form are harmonious.

### RAPID DEVELOPMENT PRINTING PROCESS.

USED FOR MULTIPLYING MAPS IN THE BELGIAN WAR OFFICE.

BY J. W. WATERHOUSE.

I SEE a query, in this week's News, from a correspondent, J. H. M., who asks for an economical method of printing photographic reductions of maps. He may possibly find the following process more convenient to practise than photolithography, while it is much more economical than the ordinary silver printing processes, and has the advantage of being worked with great rapidity. It is extensively used in the Belgian War Office, and answers the purpose exceedingly well, the prints produced being very clean, and of a good black colour. The details are as follows:—

Thin Steinbach Saxe paper is salted by floating it for one minute on a solution composed of—

Chloride of ammonium	...	...	2 parts
Citrate of soda	...	...	2 "
Water	...	...	100 "

Sufficient citric acid should be added to make the solution just acid. The paper is then dried, and may be kept for use.

To sensitize it, float for three minutes on a bath containing four or five per cent. of nitrate of silver rendered acid with citric acid. This operation and the drying must be performed in a perfectly non-actinic light, as the paper is very sensitive.

The exposure under the negative varies from a few seconds to one or two minutes, according to circumstances.

When the prints are ready, they are developed as follows:—

Prepare stock solutions of—

A.—Acetate of lead	...	...	1 part
Water	...	...	100 parts
B.—Gallic acid	...	...	1 part
Alcohol	...	...	8 parts

To 4,000 parts of water, 50 parts of solution A and 8 parts of solution B are added (if the weather is warm, or the prints have been over-exposed, a little acetic acid may be added with advantage), and the mixture is filtered into a large dish. The prints are immersed one by one, and constantly moved about, to ensure the even action of the solution. The detail gradually strengthens, and, after about a quarter of an hour, appears of a good black colour. They are then removed to a bath of hyposulphite of soda at 30 per cent., and remain in it with constant movement for ten minutes or a quarter of an hour, and are then well washed with several changes of water. No toning is necessary, but, if required, the prints can be toned in the ordinary way;

but in that case they must be well washed after removed from the gallic acid bath.

I may also draw your correspondent's attention to two other processes which give very good results, and are, at the same time, economical and rapid, with the extra advantage of producing *permanent* prints.

The first of these is the original carbon process of adding some indiana ink or other fine black pigment to a mixture of bichromate of potash and gelatine, and coating paper with it. After exposure to light, the prints are washed in tepid water till the unaltered gelatine is removed. This process is very simple, and gives very good results for copies of maps or line work.

The second is somewhat similar, and consists in coating thick Saxe or Rive paper with the mixture of gelatine and bichromate of potash recommended for photozincography, exposing to light in the same way; but, instead of inking with soft transfer ink, the prints are inked, after exposure, with hard printer's ink, to which a small quantity of dryers may be added. The prints are then washed with warm water in the same way as photozincographic transfers, and dried. The advantage of the last method is, that the progress of printing can be seen, which is not the case in the first process, though, with a little experience, the duration of the exposure is readily guessed. It is, however, chiefly applicable in cases where the small number of prints required will not justify the extra trouble of transferring to stone or zinc. When successful, the prints are very clean, and infinitely sharper than photolithographs. I have also seen some very passable prints in half-tones produced by this process on rough drawing-paper.

40, Hamilton Terrace, N.W., November 21st, 1868.

### EXPERIMENTS, INTENTIONAL AND OTHERWISE.

BY ED. SEELEY.

#### PERMANGANATE IN THE BATH PRECIPITATING IODIDE.

When permanganate of potash is used to clear a silver bath of organic matter, it appears to precipitate the iodide as well. Perhaps it would do so perfectly if excess were used.

#### "ANOTHER GUY!"

I have used both glycerine and treacle to preserve negatives in a moist condition. With glycerine there is a tendency to slight fog, but none at all with treacle. Once, when at work in the dark-room, I was startled by a loud explosion, and found a bottle had been blown to minute pieces. To my astonishment, I found it was one I had used a week or ten days previously for dilute golden syrup (about two-thirds water). The bottle had been left nearly half full, and, I suppose, fermented. It might have been awkward. "From my example warning take!"

#### SUN-PRINTING IN THE SHADE.

As sunshine is rather scarce now, a plan which will enable unlucky photographers who have harsh negatives to get the same softness in the shade as they could in the sun may be to some extent useful. It is very simple, consisting only in placing next the paper a pad of cloth, dried more or less according to the degree of softness required. My attention was drawn to it some time since by finding some very flat, poor prints among a batch otherwise very satisfactory. This continued for a few days. Naturally, as Mr. Bovey says, I blamed the paper, for I *knew* (not guessed) that the chemicals were right. But careful observation showed that good and bad prints were sometimes produced from the same sheet. So the paper was out of the question.

I then found that the printers, finding some of the cloth pads used in printing were damp (after wet weather), had dried them. So we put out several pictures with pads dried in different degrees. They came in softened in corresponding ratio. One was brought in with this remark, "Please, sir, this won't go any darker; it hasn't gone on at all the last hour or so!" In this case both paper and pad had been put in quite dry and warm. The lights were printed through,

while the deepest shades were hardly more than middle tints, and the whole horribly mealy.

For still further proof a picture was printed with a dried pad behind one half, and an ordinary one behind the other. The proof was complete!

Though this plan may with care be sometimes useful in producing passable prints from negatives otherwise too harsh, it must be remembered that not only is it very easy to spoil them quite, but that, at the best, the softness is of the character of mealiness to some extent. So, when circumstances admit of a better plan, do not use this. It is not, however, to recommend its use that I mention this, but because I think it explains a frequent cause of failure.

Many writers advise drying the paper *thoroughly*; and in dry weather the pads will also get rather dry; then the printing is bad, and both paper and toning bath are blamed, when perhaps neither are in fault.

Possibly it may help to throw light on other subjects, as: the difference in the time required in printing on paper, and with collodio-chloride on glass; and also why organic matter is necessary with collodio-chloride and with negative dry processes.

Since making the above experiments, the subject has been slightly referred to in the *News* as a cause of failure.

#### FOG v. MIST.

Some time since nitrate of baryta was recommended as an occasional cure for foggy baths. I tried it with an old one, at first with apparently little advantage; so, as excess was said to do no harm beyond increasing density, I gave it a good dose. "A perfect cure," I thought, while the negative was under the iron; but when I looked through it the density was unmistakable; it was all like ground glass; and when the film was removed, a white ghost of the picture remained on the glass! A little reflection explained it. A mixture of nit. baryta and sulph. iron instantly gives sulph. baryta. So much for taking advice without thinking!

### PHOTOGRAPHY IN UPPER EGYPT.

BY DR. VOGEL.

WE are now arrived at Denderah, fifty miles from Cairo, the second station on our photographic journey. The roof of the temple of Hathor is our lodging, the quarter for night being established in a chamber without roof—I could almost say without walls. The temple beneath is a horrible chaos, once a wonderful piece of work covered with sculpture, paintings, and gold. It is now destroyed by the tooth of time, half-buried by dust, offering a shelter to masses of flittermice, extinguishing with their wings the candle of the harmless traveller, grazing his face, and infecting the vaults by their stench. Every now and then a lizard is gliding along the blackened walls, uttering, in the evening hours, a peculiar smacking noise, and called, therefore, the Egyptian nightingale. For variety's sake, a scorpion joins them, and we cannot therefore be astonished that the Arabians are afraid of these horrible rooms during night, and assert that abode within them after the day is past brings death.

Our adventures in this place began with a misfortune: when the Arabians transported our effects on the roof of the temple, one of them fell in one of the apertures which afford the only light to the inner rooms of the temple. It was in the night; we therefore descended with lanterns, and found him with his arm twice broken; but, happily, alive. One of the company, Dr. Fritsche, instantly applied a provisional bandage, and the following day we transported him to the hospital of Kennec. Nor were we ourselves spared the evils which generally reach all who travel in Egypt. One victim is covered by pustules (Egyptian boils), which prevent him from sitting and lying; another suffers of a cramp in the stomach; whilst a third suffers from ophthalmia. I myself have been spared the sufferings, but, in compensation for this, I have undergone several photographic troubles, which make working very difficult. Our provision of twenty

quarts of distilled water from Berlin had been almost entirely spent at Aden. At Cairo we had procured a new stock at the rate of tenpence for a litre.

The very exterior of this *aqua purissima* discouraged us, a slight milky-tint arousing the suspicion that it had been distilled on the same apparatus which had been employed for distilling etheric oils, without any previous rinsing. Much more suspicious, however, was its behaviour in presence of silver salt. In a very short time a bath prepared with this water became brown; after every plate it became more insensible. Sunning was of no use; after having been placed in direct Egyptian sunlight, which is very intense, for twenty-four hours, the brown colour had been changed into a blue one.

Equally fatal was the influence of this water on an old bath which I had intensified by a solution of silver in the before-mentioned water. At 18° K. (72° F.), crystals of iodide of silver were precipitated in masses, and from this moment it became insensitive, and afforded plates with pinholes. Filtering and cooling (ice cannot be purchased here) was of some use; but as soon as the heat increased the same (fuld) fault again arose, and from eleven o'clock the bath could not be used the whole day. At last I took refuge in use of the old bath at Aden, put aside because it gave spotty plates. The organic substances in it were destroyed by permanganate of potash, and now the bath works admirably. After this happy cure I very successfully treated the second bath with the same permanganate, and I may warmly recommend this remedy to every photographer.

The fabulously dryness threatened our materials, constructed of too fresh a wood. First of all our tripod-stand became full of fissures; afterwards the framework of my camera inclined to part.\* The first was tolerably repaired, the other smeared out with wax. In order to secure the other camera we kept it wet day and night.

Our photographic operations often began by retouching the originals, being often obliged to scrape the dirt from the walls in order to make visible the hieroglyphics. Other difficulties—as, for instance, the gases produced by the dirt of the flittermice, which caused many evils, especially with long exposures; the north wind perpetually blowing, which often made exposures in open air impossible.

Mr. Bedford is known to be a very excellent landscape photographer, and his productions highly appreciated. I felt a little disappointed when I first saw his Egyptian pictures immediately before my departure. These prints were not equal to his other productions. Now I am no more astonished at this circumstance.

In spite of all these difficulties, we have been pretty successful, securing at Denderah alone about fifty negatives, a result by which we may be satisfied. We are now working in the inner of the temple, making visible the dark corners by *sunlight*, reflected to them by mirrors; magnesium light is only to be made use of if the flame can be situated quite near the object. If the light be removed further than 25' it is of no effect. On such occasions we have often burnt six grammes of magnesium wire without success. On the short distances of Sakara the magnesium light was much more useful.

Most of the reliefs and walls were taken with Steinheil's aplanatic lens, which works admirably, in consequence of its flat field and great aperture.

But now I must conclude. It is late in the evening, and my "fanous" (lantern) is nearly extinguished. Our Arabian guard, two men armed with guns with matchlocks, is just arriving in order to protect us. The rumour, however, goes, that these fellows alone would not have courage enough to sleep on the temple, so much are they afraid of the Afrit (ghost) residing in the temple. When Dr. Dumichen, the Egyptologist, had taken quarter in the Temple of Edfu, the inhabitants of the village made complaints to the "schech" (mayor) that he had driven out

\* The camera was a very excellent one, by an English maker, constructed after the idea of Mr. Wharton Simpson.

the Afrit, who was now haunting the village. The schech endeavoured to induce Dr. Dumichen to leave his quarter in the temple. But Dumichen did not go. Now the inhabitants made complaints to the "mudir" (sheriff), who decided that whoever would be tormented by the Afrit should come to him; he would give him a hundred lashes. From this moment nobody ever complained of the Afrit.

With blows you get farther than with love; and for my own part, especially, as I do not know enough of the Arabian tongue, I was forced to purchase a whip of hippopotamus skin. This instrument and the revolver form a very important part of my travelling equipage.

*Denderah, September 26th, 1868.*

PICTORIAL EFFECT IN PHOTOGRAPHY;  
BEING LESSONS IN  
COMPOSITION AND CHIAROSCURO FOR PHOTOGRAPHERS.  
BY H. P. ROBINSON.

CHAPTER XLIII., AND LAST.

"I trust these lessons will have served to dissipate the idea that to acquire art to a useful and gratifying extent, a genius is needed; that they have proved a knowledge of it to be the result of education; and that art may be possessed by all in a valuable degree, if it can only be attained by few in a remarkable degree."—J. D. HARDING.

My task is done. Beginning with the simplest elements of composition, but avoiding all learned preliminary disquisitions on the theory, quality, or moral signification of geometrical forms, with which some writers occasionally risk confusing their readers at the commencement of works of this kind, but which are not useful, I think, to the photographer, I have led the student through the mazes of this often complicated subject, using the simplest language I could command, and often preferring to state a great principle more than once rather than it should not be made perfectly plain to the reader, preferring plain, unvarnished statements to the wonderful flights of fancy by which art has been sometimes made to look so formidable to the photographer. I have endeavoured to keep the subject clear of those "awe-inspiring mysteries" with which those who have nothing practical to teach have endeavoured to surround it. There is often as much art in knowing where to stop as in proceeding in a proper manner; and I have especially endeavoured to avoid teaching too much—that is, leading the photographer further into the depths of the subject than his art can follow; as I said in my first chapter, I have endeavoured to show how the body is constructed, leaving the soul to others. Babies thrive better on milk than on curacao, and I have been writing for the youngest student in art. One of the easiest modes of escaping from the difficulties of analysis and the perils of explanation is to go off into fits of wonder, and talk mysteriously of mystery. The fear of being thought shallow has not deterred me from being clear; I have not tried to appear profound because I was unable to fathom my own ideas; and I have avoided, as much as possible, technical language, which is often the refuge of obscurity, and the pompous sham which is often required to be taken for depth.

Sir Joshua Reynolds, in his last discourse, says, "I am convinced that one short essay, written by a painter, will contribute more to advance the theory of our art than a thousand such volumes as we sometimes see; the purpose of which appears to be rather to display the refinement of the author's own conceptions of impossible practice than to convey useful knowledge or instruction of any kind whatever. An artist knows what is and what is not within the province of his art to perform, and is not likely to be forever teasing the poor student with the beauties of mixed passions, or to perplex him with an imaginary union of excellences incompatible with each other." It was with this sentence in my mind that I commenced this series of papers. Without much previous practice in writing a sustained series of papers, I relied on my knowledge of the subject for success—knowledge of the few simple but immutable

laws of art which I had learnt as a painter, and found of immense value in my practice as a photographer. Thus much for the matter. For the manner I must claim indulgence. I have written as I should have spoken to a pupil, not for the purpose of displaying eloquence, but with the intention of teaching art. What I have written I have practised; and what I have practised I have written. In these articles, to quote Sir Joshua again, "I have, in no part of them, lent my assistance to foster new-hatched, unfledged opinions, or endeavoured to support paradoxes, however tempting may have been their novelty, or however ingenious I might, for a minute, fancy them to be; nor shall I, I hope, anywhere be found to have imposed on the minds of young students declamations for argument, a smooth period for a sound precept. I have pursued a plain and honest method, and I have taken up the art simply as I found it exemplified in the practice of the most approved painters."

So much of myself and my intentions. Now, again, a few more words to the student, and for the last time. There is something more in art than what I have endeavoured to teach; something more than composition, chiaroscuro, and pictorial effect. Composition may be called the skeleton of a picture, and chiaroscuro the flesh in which that skeleton is clothed; but there is something beyond this. As the living body has a living soul, so has art; something that the French try to express by the term "*Je ne sais quoi*;" that indefinite something about which those who know least write most, because it is indefinite and intangible, and about which the ignorant world take rhapsody for knowledge. Who can penetrate into the dim regions of the unknown, teach the unteachable? Who can describe and reduce to lessons the "know not what?" Yet, without this indefinite, intangible, hidden, unknown soul, a picture is but a scientific performance, and gives no more idea of nature than does a rag doll represent the life. "So, then," it may be said, "art comes by inspiration—comes by second nature." In its highest phases it perhaps does; but nevertheless, it comes by laws that it is possible to note, and which it is possible to teach. Those laws govern the forms which art takes, and a knowledge of these laws prepares the student for the higher inspiration.

It has been said, "The poet's born, not made;" but Ben Jonson, with a higher and wider truth, and on an occasion when the first proposition may have been held to be true in a very eminent degree, in his address "To the memory of my beloved Mr. William Shakespeare," said,—

"For though the poet's matter Nature be,  
His *Art* doth give the fashion. And, that he,  
Who casts to write a living line, must sweat,  
(Such as thine are) and strike the second heat  
Upon the muse's anvil: turn the same,  
(And himself with it) that he thinks to frame;  
Or for the laurel he may gain a scorn,  
For a good poet's made as well as born."

And so it is with the artist. Innate taste is not sufficient to make a painter or a photographer. As a poet has to learn the grammar of the language in which he writes, so must the artist learn the principles on which his work is based. If the student trusts to that vague thing called taste, he trusts to a broken reed; let him rather endeavour to acquire that more certain and profitable culture which comes from study and practice.

In conclusion, I cannot do better than impress upon my reader the absolute necessity, if he wishes to become an artist, of incessant application, not only to study, but to the production of the results of study—pictures. To call yourself an artist before you have produced a picture is but to give yourself an empty name. To be an artist it is necessary to do something more than take an occasional bad landscape or portrait in photography, or to paint a poor background, spoil a photograph with colour, or make crude sketches with the brush. Nothing beyond this can be done without hard work. The greatest compliment Michael Angelo ever paid Raphael—although it is doubtful if he thought so at the time—was, that Raphael did not get so far by his genius as

by his industry. This industry means nothing else than the success an artist seeks in the unwearied improvement of his work. Industry is not so much persevering activity or diligence in general as absorption in the one thing to be accomplished. The mark should be right before the student; the higher the better; ambition is a grand quality, so that it does not degenerate into egotism, and is more productive of good and great work than any other desire of man. Strike high, and do not believe in failure; work incessantly and rightly, and good work will be the result.

## ON A NEW SERIES OF CHEMICAL REACTIONS PRODUCED BY LIGHT.

BY JOHN TYNDALL, LL.D., F.R.S., ETC.\*

### PHYSICAL CONSIDERATIONS.

I sought to determine the particular portion of the white beam which produced the foregoing effects. When, previous to entering the experimental tube, the beam was caused to pass through a red glass, the effect was greatly weakened, but not extinguished. This was also the case with various samples of yellow glass. A blue glass being introduced before the removal of the yellow or the red, on taking the latter away augmented precipitation occurred along the track of the blue beam. Hence, in this case, the more refrangible rays are the most chemically active.

The colour of the liquid nitrite of amyl indicates that this must be the case; it is a feeble but distinct yellow; in other words, the yellow portion of the beam is most freely transmitted. It is not, however, the transmitted portion of any beam which produces chemical action, but the absorbed portion. Blue, as the complementary colour to yellow, is here absorbed, and hence the more energetic action of the blue rays. This reasoning, however, assumes that the same rays are absorbed by the liquid and its vapour.

A solution of the yellow chromate of potash, the colour of which may be made almost, if not altogether, identical with that of the liquid nitrite of amyl, was found far more effective in stopping the chemical rays than either the red or the yellow glass. But of all substances, the nitrite itself is most potent in arresting the rays which act upon its vapour. A layer one-eighth of an inch in thickness, which scarcely perceptibly affected the luminous intensity, sufficed to absorb the entire chemical energy of the concentrated beam of the electric light.

The close relation subsisting between a liquid and its vapour, as regards their action upon radiant heat, has been already amply demonstrated.† As regards the nitrite of amyl, this relation is more specific than in the cases hitherto adduced, for here the special constituent of the beam which provokes the decomposition of the vapour is shown to be arrested by the liquid.

A question of extreme importance in molecular physics here arises: What is the real mechanism of this absorption, and where is its seat?‡

I figure, as others do, a molecule as a group of atoms, held together by their mutual forces, but still capable of motion among themselves. The vapour of the nitrite of amyl is to be regarded as an assemblage of such molecules. The question now before us is this: In the act of absorption, is it the molecules that are effective, or is it their constituent atoms? Is the *vis viva* of the intercepted waves transferred to the molecule as a whole, or to its constituent parts?

The molecule as a whole can only vibrate in virtue of the forces exerted between it and its neighbour molecules. The intensity of these forces, and consequently the rate of vibration, would, in this case, be a function of the distance between the molecules. Now the identical absorption of the liquid and of the vaporous nitrite of amyl indicates an identical

vibrating period on the part of liquid and vapour, and this, to my mind, amounts to an experimental demonstration that the absorption occurs in the main *within* the molecule. For it can hardly be supposed, if the absorption were the act of the molecule as a whole, that it could continue to affect waves of the same period after the substance had passed from the vaporous to the liquid state.

In point of fact, the decomposition of the nitrite of amyl is itself, to some extent, an illustration of this internal molecular absorption; for were the absorption the act of the molecule as a whole, the *relative* motions of its constituent atoms would remain unchanged, and there would be no mechanical cause for their separation. It is probably the synchronism of the vibrations of one portion of the molecule with the incident waves which enables the amplitude of those vibrations to augment until the chain which binds the parts of the molecule together is snapped asunder.

The liquid nitrite of amyl is probably also decomposed by light; but the reaction, if it exists, is incomparably less rapid and distinct than that of the vapour. Nitrite of amyl has been subjected to the concentrated solar rays until it boiled, and it has been permitted to continue boiling for a considerable time, without any distinctly apparent change occurring in the liquid.\*

I anticipate wide, if not entire, generality for the fact that a liquid and its vapour absorb the same rays. A cell of liquid chlorine now preparing for me will, I imagine, deprive light more effectually of its power of causing chlorine and hydrogen to combine than any other filter of the luminous rays. The rays which give chlorine its colour have nothing to do with this combination, those that are absorbed by the chlorine being the really effective rays. A highly sensitive bulb containing chlorine and hydrogen in the exact proportions necessary for the formation of hydrochloric acid was placed at one end of the experimental tube, the beam of the electric lamp being sent through it from the other. The bulb did not explode when the tube was filled with chlorine, while the explosion was violent and immediate when the tube was filled with air. I anticipate for the liquid chlorine an action similar to, but still more energetic than, that exhibited by the gas. If this should prove to be the case, it will favour the view that chlorine itself is *molecular*, and not *monatomic*. Other cases of this kind I hope, at no distant day, to bring before the Royal Society.

### PRODUCTION OF SKY-BLUE BY THE DECOMPOSITION OF NITRITE OF AMYL.

When the quantity of nitrite vapour is considerable, and the light intense, the chemical action is exceedingly rapid, the particles precipitated being so large as to *whiten* the luminous beam. Not so, however, when a well-mixed and highly-attenuated vapour fills the experimental tube. The effect now to be described was obtained in the greatest perfection when the vapour of the nitrite was derived from a residue of the moisture of its liquid, which had been accidentally introduced into the passage through which the dry air flowed into the experimental tube.

In this case the electric beam traversed the tube for several seconds before any action was visible. Decomposition then visibly commenced, and advanced slowly. The particles first precipitated were too small to be distinguished by an eye-glass; and, when the light was very strong, the cloud appeared of a milky-blue. When, on the contrary, the intensity was moderate, the blue was pure and deep. In Brucke's important experiments on the blue of the sky and the morning and evening red, pure mastic is dissolved in alcohol, and then dropped into water well stirred. When the proportion of mastic to alcohol is correct, the resin is precipitated so finely as to elude the highest microscopic power. By reflected light such a medium appears bluish, by transmitted light yellowish, which latter colour, by

\* Continued from p. 556.

† Phil. Trans. 1864.

‡ My attention was very forcibly directed to this subject some years ago by a conversation with my excellent friend Professor Clausius.

\* On the 21st of October Mr. Ernest Chapman mentioned to me in conversation that he once exposed nitrite-of-amyl vapour to the action of light. With what result I do not know.

augmenting the quantity of the precipitate, can be caused to pass into orange or red.

But the development of colour in the attenuated nitrite-of-amyl vapour, though admitting of the same explanation, is doubtless more similar to what takes place in our atmosphere. The blue, moreover, is purer and more sky-like than that obtained from Brucke's turbid medium. There could scarcely be a more impressive illustration of Newton's mode of regarding the generation of the colour of the firmament than that here exhibited; for never, even in the skies of the Alps, have I seen a richer or a purer blue than that attainable by a suitable disposition of the light falling upon the precipitated vapour. May not the aqueous vapour of our atmosphere act in a similar manner? and may we not fairly refer to liquid particles of infinitesimal size the hues observed by Principal Forbes over the safety-valve of a locomotive, and so skilfully connected by him with the colours of the sky?

In exhausting the tube containing the mixed air and nitrite-of-amyl vapour, it was difficult to avoid explosions under the pistons of the air-pump, similar to those which I have already described as occurring with the vapours of bisulphide of carbon and other substances. Though the quantity of vapour present in these cases must have been infinitesimal, its explosion was sufficient to destroy the valves of the pump.

*Iodide of Allyl* (boiling point  $101^{\circ}$  C.).—Among the liquids hitherto subjected to the concentrated electric light, iodide of allyl, in point of rapidity and intensity of action, comes next to the nitrite of amyl. With the iodide of allyl I have employed both oxygen and hydrogen, as well as air, as a vehicle, and found the effect in all cases substantially the same. The cloud column here was exquisitely beautiful, but its forms were different from those of the nitrite of amyl. The whole column revolved round the axis of the decomposing beam; it was nipped at certain places like an hour-glass, and round the two bells of the glass delicate cloud-filaments twisted themselves in spirals. It also folded itself into convolutions resembling those of shells. In certain conditions of the atmosphere in the Alps I have often observed clouds of a special pearly lustre; when hydrogen was made the vehicle of the iodide-of-allyl vapour a similar lustre was most exquisitely shown. With a suitable disposition of the light, the purple hue of iodine-vapour came out very strongly in the tube.

The remark already made as to the bearing of the decomposition of nitrite of amyl by light on the question of molecular absorption applies here also; for were the absorption the work of the molecule as a whole, the iodine would not be dislodged from the allyl with which it is combined. The non-synchronism of iodine with the waves of obscure heat is illustrated by its marvellous transparency to such heat. May not its synchronism with the waves of light in the present instance be the cause of its divorce from the allyl? Further experiments on this point are in preparation.

(To be continued.)

#### MICRO-PHOTOGRAPHY.

BY M. JULES GIRARD.\*

THE pictures which I have the pleasure of presenting to your notice this evening are the result of powerful enlargements of diatoms varying from 800 to 1,200 diameters, diatoms being plants of the most minute description, growing both in fresh and salt water. The beauty and perfection of their details, despite their infinite smallness, render them specially adapted for the production of enlargements of the greatest dimensions. They are composed of cellules of silica, sometimes hollowed out, sometimes in relief, and always possessing the greatest geometrical regularity in their organic structure.

To obtain clear objects suitable for enlargement, it is necessary to establish a relation between the lens and the length

of the camera; and the more powerful the lens, and longer the camera used, the greater will be this relation. There exists, however, a very variable limit, which is incapable of being passed without altering the sharpness of the object, and which is the result of experimental trials between these two combinations.

As the intensity of the light diminishes proportionally to the distance of the object, it is necessary to have recourse to a condenser often composed of several lenses corrected so as to prevent distortion, which gives sufficient illumination to impress the sensitive surface. The focussing must be rigorously exact, as the most inappreciable digression of the microscopic screw is sufficient to injure the sharpness of the object.

If enlargements of extraordinary size are required, a process similar to that used for making ordinary photographic enlargements may be employed. A small negative may first be obtained upon a thin strip of glass, which is afterwards magnified by means of the microscope. This method is a very delicate one, and necessitates very careful focussing with a magnifier, in order that the most minute details may be rendered as sharply as possible. In developing, there is likewise the difficulty of obtaining a suitable degree of intensity for the object: if the process is pushed too far, the light will be unable to penetrate; if the development is insufficient, the negative will lack clearness. Thus the pictures taken direct possess the double advantage of being easy to produce, and more exact copies of the original.

#### ON THE FORMATION OF PEROXIDE OF SILVER BY OZONE.

BY M. F. WOHLER.\*

IF in the electrolysis of acidulated water a strip of silver is employed as the positive pole, the metallic surface soon becomes covered with a black substance; this body is no other than peroxide of silver, which effervesces with ammonia, disengaging nitrogen. It is amorphous, and not crystalline, as in the electrolysis of a salt of silver. This formation is a very interesting one, as it leads to the belief that, in all probability, ozone is produced at the negative pole. The current made use of was sufficiently strong to liberate ozone in employing platinum wires as electrodes, but with silver no trace of ozone was disengaged, and it is to be inferred, therefore, that the latter helps to bring about the oxidation of the silver.

When a film of peroxide of a certain thickness has been formed, bubbles of oxygen become liberated from the strip of silver, and, at the same time, metallic silver in an amorphous state is precipitated at the negative pole, there being, likewise, a small quantity of silver in solution. This is due, probably, to a secondary action produced by the sulphuric acid (used in acidulating the water) which accumulates round the positive pole.

The same phenomena are observed with a strip of silver plunged into a solution of sulphate of soda. With a solution of nitrate of potash no peroxide is formed, but the whole of the liquid becomes filled with finely-precipitated oxide of silver of a light-brown tint. In a solution of ferro-cyanide of potassium the silver becomes covered with a white deposit of ferrocyanide of silver. Finally, in a solution of bichromate, the metal strip is covered with crystalline chromate of silver, free from peroxide.

#### Correspondence.

##### PHOTOGRAPHERS' RELIEF FUND.

MR. EDITOR,—With reference to a photographers' relief fund, the question may be asked, Who is it that is a photographer? And, further, is it intended to select the sheep from the goats? Photographers will, I have no doubt, contribute liberally, at once, if the principles be organized and made

\* Read before the French Photographic Society.

\* *Annalen der Chemie und Pharmacie.*

known. In fact, for my part, I am prepared to pay in £5 at first, and £2 10s. yearly, or as may be agreed upon by the committee; and to make up a fund not less from any person would, I think, be worth the trouble. Not that I ever expect any benefit from such a fund, but still I consider at the old age of some photographers assistance may be required. If it were for nothing more than to show the spoil-trade gentlemen how they stand in the estimation of the profession, a distinction should be made. Let the arrangements be made on similar principles to mechanics' funds and the like, and there will be no doubt of success.—AN OLD DAGUERREOTYPIST.

#### AMATEUR CRITICISM.

SIR,—As I conclude, from the appearance of the letter of "Lux Graphicus," that you occasionally admit into your pages amateur criticism, will you permit me to say a few words on that gentleman's remarks, in which I will endeavour to be as good-natured and as plain-spoken as he.

Firstly, let me ask him what he means by saying that Messrs. Robinson and Cherrill's group of children is too suggestive of scissors and paste to be a good picture? Does he mean that "scissors and paste" are illegitimate aids, and should not be used? If so, he condemns, of course, all combination printing. Well and good; but why does he not say so at once, instead of sneering at an individual picture? If, on the other hand, he admits the legitimacy of combination printing, why sneer at "scissors and paste"? He might as well say the picture was too suggestive of the printing-frame or of the albuminized paper.

If he meant to say that the means by which the picture was produced were too palpable, it becomes a matter of individual judgment, and one ought to know who "Lux Graphicus" is before one can attach much weight to the judgment. I, for one, do not agree with him. I suppose, from its character, that the group in question must have been produced from more than one negative, but I must confess that I cannot detect it; and I examined very closely indeed for joins, or signs of what the onivous call "patchwork." In many respects, indeed, I considered this group as the finest picture in the exhibition, and as full of noble qualities. But this is a mere opinion, of no more value than that of your correspondent, whether he writes under the name of "Lux Graphicus," or that of "Ecce Veritas," as he clearly does in other pages.

Again, this unknown gentleman, commenting upon the works of known gentlemen, says of the portraits of Mr. Fry (or, at least, of some of them) that they are as "flat, white, and shadowless as a knob of sal-ammoniac itself." This, of course, everybody sees, is a piece of exaggeration, indulged in to introduce a feeble joke: the statement is not true. The pictures have too much contrast—at least, some of them have—to please my taste; the aim to secure brilliancy has in some cases been carried too far; but it is worth recording that I heard more than one person—of cultivated taste, too—point to these very pictures as amongst the gems of the room, whilst they styled Mr. Blanchard's—which I, as well as "Lux Graphicus," much admire—as "soft, but lacking brilliancy." As for the latter gentleman's pictures being equal to Adam-Salomon's "best works, without the elaborate touching-up which the latter exhibit," the statement strikes me as absurd. Mr. Blanchard's specimens are very first-class, especially photographically; but if he be the modest and discriminating gentleman he is reputed to be, none would so soon declare that his work still remained far behind the best work of the Frenchman in many points. The remark about the "elaborate working-up" of Salomon's pictures appears to me equally untrue and unfair. When his pictures are worked up there is nothing elaborate about it: it is plain, bold, and palpable, though generally judicious, as many of the specimens clearly showed. The two best—a lady in white, and one with a shepherd's plaid scarf—appeared to have scarcely a touch upon them.

My object in writing was to protest against dogmatic condemnation in amateur and anonymous criticism. I fear that I may have seemed in some degree to have been guilty of the sin against which I protest; if so, it will simply illustrate the evil, and suggest that it is scarcely in keeping with the wisdom you generally manifest, Mr. Editor, in conducting your journal, to admit amateur and anonymous criticism at all.—Your obliged servant,

LUX IN TENEBRAS.

[We do not, by any means, endorse all the opinions of "Lux Graphicus;" but if he were not known to us as a photographer

and artist of long experience, his views on the exhibition would not be placed before our readers. We have a few remarks on Amateur Criticism elsewhere.—Ed.]

#### PROPORTION OF SALT IN ALBUMINIZED PAPER.

DEAR SIR,—In your Studio Talk of last week you expressed an opinion that the discussion on albuminized paper should be closed, I presume, with Mr. Cherrill's reply, inserted in the same number of the NEWS. As a personal favour I beg you will give publicity to the present communication, as the question at issue is one of the greatest importance, not merely to paper albuminizers and dealers, but to the whole community of photographers; for in the event of Mr. Cherrill's erroneous ideas being allowed to pass unchallenged, the class first described will continue to suffer injustice, whilst the last alluded to will fail to perceive that a fair amount of skill only is required to overcome the want of uniformity which, for so many years, has been attributed to "that abominable paper."

It will be remembered that in my last letter I addressed to Mr. Cherrill a series of questions to which I requested distinct replies. The answers returned might be condensed into one short sentence: "We desire bricks; I cannot give you straw, but make bricks, though you employ base stubble." In other words: "I do not care by what method you arrive at conclusions, as long as you impart the information we can and will demand." Mr. Cherrill, however, is not too exacting; he perceives the difficulties, therefore has no objection to a little rough guessing. Surely he must have overlooked the fact that for years past dealers in photographic papers have been supplying their customers with the guess-atable information so ardently desired—silver nit. 60 grains, and so on. And the method adopted is a sound one for those who supply an honest paper. Know that as long as the silver bath is kept up to a certain strength, the paper they provide, when floated thereon, can be made capable of yielding the best results; and as Mr. Cherrill requires no greater amount of accuracy than can be obtained from rough guessing, what can he desire better than the information he might find in every publication devoted to the rudiments of photography, if he is not satisfied with the directions offered by the dealer?

Again, Mr. Cherrill would exact information from the albuminizer concerning the class of negative needed to suit a given paper. Mr. Cherrill is once more at fault. But few paper albuminizers are practical printers; *ergo*, these who are unacquainted with practical printing are not in a position to afford the information; whilst those who are thoroughly up in printing matters know full well that in competent hands a paper can be made to suit any class of negative.

"But how about uniformity?" enquires Mr. Cherrill. I reply, suspect that dealer of ignorance or dishonesty who would hold out the faintest hopes of uniformity being attainable with the papers he supplies, as long as "the old acetate bath" is made to do duty in the way indicated and practised by Mr. Cherrill, who prefers toning his prints "few at a time," and yet asks uniformity. As well expect uniformity in ordinary type printing by bidding the printer add oil to the ink after each dozen of proofs are struck off. The reason why, I have fully explained elsewhere, and need not recapitulate.

I now leave this question to my readers. Promising I shall trouble you no further in this matter, I remain, &c.,

Willesden, November 23rd, 1868.

W. T. BOVEY.

#### ASCERTAINING THE AMOUNT OF SALT IN ALBUMINIZED PAPER.

SIR,—After the reading of Mr. Cherrill's paper on the "Relation of Intensity to Tone," recently, there appears to have arisen some discussion as to the means of ascertaining the amount of salt in any sample of albuminized paper. One gentleman having suggested a method of doing so by chemical means, another observed that it was like "using a steam engine to draw a cork." While duly admitting both the force and originality of the remark, may I be permitted to observe that it is possible by a much more simple instrument, though certainly at times a dangerous one, to draw, if not a cork, at least an inference as to the strength of salt present.

I hope no respected female ancestor of mine (photographically speaking) will accuse me of a desire to impart, unasked, instruction in that simple, yet to many persons, gratifying operation, the art of sucking eggs; but in such case the mode I

adopt is as follows:—Bringing the sheet of paper in a vertical position before me, I simply project the tip of my tongue so as to come in contact with the albuminized surface, and I am thus enabled to form a sufficiently accurate estimate of the amount of salt present for all practical purposes. I need scarcely add that the value of the above method will be greatly enhanced when employed by a person of *cultivated taste*.—I am, sir, yours obediently,  
Bromo.  
London, November 18th, 1868.

#### PAPER TURNING BROWN ON DEVELOPMENT.

DEAR SIR,—I have often received great help through your valuable paper, and knowing how many must have received assistance from time to time through the difficulties of others being cleared up, I send you a confession of my own inability to discover the cause of paper fogging under development with gallic acid. The paper is treated in the same way at all times; yet some prints remain clean and white, whilst others fog, or turned quite through the paper, as if taken upon brown paper. The effect at times is not bad, but very trying when you wish a clean white face. The process is as follows:—

Saxe paper, salted with

Water	...	...	...	...	3½ ounces
Iodide potassium	...	...	...	...	1 drachm
Bromide potassium	...	...	...	...	1 scruple
Silvered with a 60-grain solution.					

Probable causes, temperature, want of acid in the developer under certain conditions.—Believe me, yours obediently,  
G. R. GILL.

381, Kentish Town Road, November 16th, 1868.

[Possibly some of our readers, who may have had experience in enlarging processes by development, can give our correspondent a hint. On another page we add a few remarks on the subject.—Ed.]

#### MR. BOVEY'S METHOD OF TONING.

SIR,—May I be permitted to offer my testimony to the great value of the system of toning published in your columns by your correspondent Mr. Bovey. I am indebted to him for a release from some of the worst of those annoyances which have hitherto accompanied the practice of silver printing, at the same time that I am enabled to obtain good results from negatives which heretofore would have been scarcely worth printing at all. The advantages I find are, among others, the entire absence of bleaching, with its attendant imp, "mealiness," and all the vexations thereto appertaining, particularly in the case of weak and "forced up" negatives, which have always been a source of trouble from this cause; the perfect preservation of the delicate tints just below the highest lights, on the presence of which the beauty of the photograph so much depends (presuming, that is, that they already exist in the negative, which is unfortunately not always the case); also the extreme purity of the whites, and the roundness and depth of the picture generally. The difference in the latter respect between prints treated by the usual process and those from the same negative by Mr. Bovey's plan I have, in many instances, found to be most remarkable. I feel that we owe our thanks to Mr. Bovey, both for the valuable improvement he has originated, and for the liberal and unselfish manner in which he has made it known to the photographic world.—I am, sir, yours obediently,  
CHARLES W. SMARTT.

Stockwell, November 24th, 1868.

#### PORTRAITS UPON GRAVES.

SIR,—With reference to the subject of placing portraits of deceased persons upon their graves, which was mentioned in your columns a few weeks ago, it is, perhaps, worthy of note, that the custom is by no means a new one.

Ten years ago I stayed for some time at a little village named Lungern, in the valley of Sarnen, at the foot of the Brunig Pass in Switzerland. The little churchyard attached to the village contained about a couple of hundred gravestones—or, rather, grave-boards—on the majority of which were painted, in a very crude manner, the supposed likeness of the deceased. Weather and age had been so destructive to the paintings that the most distant date traceable upon them was thirty years back. The custom had probably been introduced by some

native artist, and afterwards kept up by the inhabitants of the village, for in none of the graveyards in the vicinity which I visited did the same practice obtain.—I am, sir, your obedient servant,  
H. BADEN PRITCHARD.

General Photographic Establishment of the War Department,  
Woolwich, November 25th, 1868.

#### PRINTING FORMULÆ.

DEAR SIR,—I have just seen in your paper a letter from Mr. Fry, containing several statements utterly at variance with my experience of printing matters.

I do not wish to enter into any controversy with Mr. Fry, but I merely write to point out that one or two of his remarks are apt to mislead those who are not well-up in printing matters.

According to my experience, it is quite as difficult to determine the strength of a nitrate bath made without nitrate of soda as it is when that salt is present. "Argentometers," as they are called, are quite useless when the solution has been used a few times, and I find it is only by observation and experiment that the right quantity of silver to add to the bath for each grain of paper can be determined. If a sheet of paper is salted with chloride of sodium, as soon as it is floated on the nitrate bath chloride of silver is formed on the surface of the paper, and nitrate of soda in the bath, and then, as Mr. Fry very justly remarks, "the argentometer cannot be used when other matters are in solution along with the silver."

It has never been my experience to find the excessive contraction from the use of nitrate of soda of which Mr. Fry speaks. He must, indeed, have had considerable trouble from his paper under such very trying circumstances as he mentions. I should not have been surprised if the paper had been said to contract or expand one-sixteenth of an inch, or even one-eighth, in a whole sheet; though even that would be more than I have ever seen during printing operations. But when Mr. Fry says that a sheet of paper contracts *five-eighths* of an inch, owing to the use of nitrate of soda in the printing bath, I can only say that such a statement reads so like one of Mr. Fry's very best jokes, that it is enough to make one, like Artemus Ward, "git up nights and laff." But, seriously, I have printed, this year, hundreds of pictures, of large size, and every one of them has been perfectly sharp, though I always use nitrate of soda in the printing bath.

Mr. Fry's statement that it was impossible to select from a batch of prints those in which nitrate of soda had been used, and those in which it had not been used, is, to me, a great argument in favour of the use of the soda salt; for if prints can be done with 40 grains of silver, and soda, equal to those with 70 grains silver to the ounce, it seems to me there must be a saving in using the weaker bath.

I do not think that if plenty of hydrochloric acid is added to the first washings of the prints, any more difficulty will be found in collecting the silver when nitrate of soda is present than when it is absent.—I remain, dear sir, yours truly, ANON.

DEAR SIR,—I have perused Mr. Cherrill's paper in the News on "Our Printing Room," and particularly that portion of it referring to the use of nitrate of soda in the printing bath, &c., where he supposes the bath to be kept up by the addition of 10 grains of silver to each sheet of paper, and occasionally of fresh silver solution.

I have also read Mr. Fry's letter, stating with what extreme care he experimented years ago, when, having strayed from shore without a pilot, after considerable drifting, he lauded himself (or his paper) safely again on the good, honest 70-grain bath.

It appears that both these gentlemen are satisfied with the results from the combination of nitrate of soda with the silver, and, as far as I have experienced for many months, I have preferred it to the strong uncontaminated silver till a few weeks since, when I was in as great a dilemma as Mr. Fry; but not being disposed to give up that which I believed to produce superior results at less cost, I considered the whole matter, and it appeared to me that a certain amount of silver was essential to produce certain results, much more or much less would disturb the balance. I had previously tested, by the ordinary argentometer, silver and soda, separately and combined, previously to working, but it was impossible for me at the expiration of three or four months to determine the relative proportions of each.

I was thus working in the dark, so I obtained from Mr. Hart a volumetric apparatus, and found, upon testing a bath, that instead of there being from 36 to 38 grains of silver, as I supposed (the old argentometer registering 54), it stood thus: silver 28 grains, and consequently nitrate soda, &c., 26. Having thus discovered my position, I set matters right at once by strengthening with silver to what suits my method of working, and at present all goes on well. By occasional testing I believe I shall keep the bath in good and constant order, *ad infinitum*. The trouble is a mere bagatelle, and the expense even less.

Having derived much benefit from the experiences of both these gentlemen, I venture, through the NEWS, to give one of my own, that not only the one may be relieved from his supposition, and the other saved from his driftings (should he again venture out), but that others having a fixed datum upon which to work may be able, at any time, to ascertain for themselves the actual strength of their silver bath.—I remain, yours truly,

FORWARD.

Southsea, November 23rd, 1868.

## Talk in the Studio.

**THE PHOTOGRAPHIC EXHIBITION.**—A contributor to the late exhibition in Conduit Street writes to the effect that although he did not call to remove his pictures until two days after the nominal close of the exhibition, it was somewhat difficult to get them away without rudeness, so constant was the flow of visitors into the room.

**MR. HOWARD'S PICTURES AT THE SOUTH LONDON MEETING.**—Mr. Howard calls our attention to an error of figures in describing his charming little pictures exhibited at the last South London Meeting. The report stated that he took two pictures on a  $7\frac{1}{2}$  by  $5\frac{1}{2}$  plate, but the pictures were described as  $3\frac{1}{2}$  by  $2\frac{1}{2}$ , instead of  $5$  by  $3\frac{1}{2}$ , which is obviously the actual size, and also, as it will be seen, a better proportion than that described by the erroneous figures.

**PLAIN PRINTS ON ALBUMINIZED PAPER.**—A correspondent says:—"I had just written a note intending to ask your opinion on printing on the back of albuminized paper, when I observed your notice of the same in the last NEWS. I have used it so for some time, because I could not obtain plain paper. I have written to different houses in London for plain paper without success. First I placed the back of the albuminized paper on the negative after being floated in the ordinary way, but the print was not vigorous enough; then I floated it on its back, and found it answer very well indeed. I have often used it for very hard negatives, as it gives softer pictures than when printed on the albuminized side. The albumen also is a capital sticking stuff for mounting. I run a thin coating of gum arabic over the albumen, which together sticks better than anything I have tried."

**ABYSSINIAN SCENERY, ETC.**—The *Times* has the following:—"Some photographs now being exhibited at Maclean's, in the Haymarket, suggest a question which we should like to ask the War Office, or whatever may be the proper authority. They are photographs of Abyssinian scenery from sketches taken on the spot by Major Hogg, who served in the Quartermaster-General's Department from Zeolla to Magdala, and they give an admirably accurate idea of places, always interesting, if only from their peculiar picturesqueness, but now specially interesting from their association with historical events of which the nation has so much reason to be proud. The sketch of Magdala, for instance, is singularly faithful. We want to ask why the authorities—whenever they may be—do not follow Major Hogg's example, and give the British public the benefit of the photographs taken in Abyssinia by Major Pritchard's company? No labour was spared in taking them, they are admirably done, and so full of interest that it is a great pity they should "waste their sweetness on the desert air" of a few military offices. Do there exist any reasons of State for not publishing them? Economy can scarcely be the motive, for their sale would, we are sure, far more than defray all the expenses attending publication." Mr. H. B. Pritchard, in answer to this, informed readers of the *Times* that the pictures were exhibited at the Photographic Society's rooms in Conduit Street, and added that it was intended, he believed, to issue from the Royal Engineer establishment at Chatham complete

sets of the prints to the British and South Kensington Museums, and also to the various learned societies, so that the labours of the photographic staff in Abyssinia will be turned to very good account. We may add, that as all military officers can purchase copies, possibly many interested in their possession may be able to procure them through military friends.

**NEW SOURCE OF CITRIC ACID.**—The *Scientific Review* says:—"Professor O. Silvestri, of the University of Catania, has recently discovered an abundant quantity of citric acid in the fruit of *Cyphomandra betacea*, a plant of the family of *Solanæ* (the *Solanum betaceum* of Cavanilles). This plant is found here and there in the gardens of Sicily. It is a native of New Spain or Mexico, whence it has diffused itself into Peru and other parts of South America, where it is called *Tomate de la paz*. It is a ligneous perennial, and attains in Sicily some four yards in height. Its fruit yields to analysis one to one and a-half per cent. of pure citric acid. This acid, which probably exists also in our tomato sauce, has already been discovered by Bertagnini in the potato, and will, doubtless, be found in the fruit of all other plants of the family of *Solanæ*."

**PORTRAIT DISCOVERED.**—A daily contemporary says:—"An interesting discovery has just been made at Paris of a portrait of Marie de Medicis, of the date of 1692, when the Queen was 28 years of age. Her Majesty is represented in the florid style of Rubens, with a large collar of guipure on her neck, half covering a necklace of white pearls, to which is attached a cross in bright steel over a dark silk *moirée* dress, with a band set with precious stones round the waist. The blond hair is crisped and rolled round the head, and surmounted with a small black cap. The treatment of the accessories and the execution of the work leave no doubt that it is the production of the younger Porbus."

**CONSTITUTION OF THE SUN.**—Mr. Balfour Stewart, writing to the *Athenæum*, described a double discovery—that is, a coincident discovery by two persons—of certain important facts in connection with the physical constitution of the sun, and of the possibility of making spectroscopic research into the character of the red prominences without waiting for the occurrence of an eclipse. Mr. Norman Lockyer, assisted by the Royal Society with means, has for some time been engaged in the spectroscopic examination. During the late eclipse M. Janssen, the French observer, settled the questions that had been raised regarding the constitution of the red flames, proving that these were composed of incandescent gas, inasmuch as their spectra consist of bright lines, and the results received afterwards from Capt. Herschel and Major Tennant, our Indian observers, confirmed the truth of these observations. Mr. Lockyer, writing to Mr. Stewart on the 20th of October, says:—"Got a prominence with the new spectroscope; got the positions of three lines; one corresponding to C absolutely, one to F very nearly, one eight or nine degrees of Kirchhoff's scale more refrangible than the most refrangible D line." M. Janssen, writing of the eclipse, says:—"Immediately after the totality two magnificent protuberances made their appearance; one of them, of more than three minutes in height, shone with a splendour which it is difficult to imagine. An analysis of its light showed me directly that it was formed by an immense column of incandescent gas, principally composed of hydrogen. . . . The most important result of these observations is the discovery of a method of which the principle was conceived during the eclipse itself, and which will allow of the study of protuberances and of the regions surrounding the sun at all times, without its being necessary to have recourse to the interposition of an opaque body before the sun's disc. This method is founded upon the spectral properties of the light of the protuberances—light which resolves itself into a small number of very luminous pencils corresponding to the obscure rays of the solar spectrum. The day after the eclipse the method was applied with success. I was enabled to assist at a new eclipse, as it were, which lasted throughout the entire day. The old protuberances were greatly modified—they remained scarcely any trace of the great protuberance, and the distribution of the gaseous matter was very different." Mr. Steward says:—"Here, then, we have a very marked instance of two observers, quite independently of each other, observing the same fact with certain differences. M. Janssen, it will be noticed, declares for hydrogen, but names no lines; he considers the bright lines as coincident with the dark lines of the spectrum. Mr. Lockyer, however, has not obtained this coincidence—in fact, in a further communication received from him, he lays stress on the want of complete coincidence except in one case, without in the meantime attempting

to interpret the cause. Probably his spectroscope is more powerful than that of M. Janssen. But for this point, and doubtless many others, we must wait for the promised detailed communication to the Royal Society. These differences of fact, while they render the problem of great scientific interest, are not the only differences which ought to be borne in mind. Although the priority of observation is due to M. Janssen, yet the possibility of the discovery was suggested by Mr. Lockyer more than two years ago, and to my knowledge he has been working at it since that time; whereas M. Janssen frankly acknowledges that the idea only occurred to him during the eclipse itself."

## To Correspondents.

**STRIKE-A-LIGHT** says:—"I prepared several collodio-bromide plates according to Messrs. Sayce and Brother's plan, one of which I exposed and developed the other day. Finding that the intensity was not sufficient for printing, I intensified (or, rather, did not) with bichloride of mercury, when, to my astonishment, the picture, on drying, vanished altogether." The circumstance described by our correspondent is very curious, and, although we are familiar with the fact, we cannot with certainty explain it. There is a singular difference in the behaviour of images simply consisting (like those of an iron developed wet collodion plate) of reduced silver, and those formed partially from an organic salt of silver—as we believe all dry-plate images are. The latter probably consist of metallic silver and oxide of silver. Certain it is that such images behave very differently to the ordinary iron developed image under the action of chloride of mercury. A pyrogallol developed image on a wet plate frequently bleaches under the action of mercury, but does not acquire intensity. All dry-plate negatives almost are injured by the action of chloride of mercury: they assume a faint bluish white tint by reflected light, whilst the intensity is reduced to a mere phantom, scarcely perceptible, by transmitted light. The best mode of intensifying dry-plates is by the use of silver and pyro; or, if it be desired to change their colour, it is probable that the method of intensifying by permanganate of potash would be found available.

**W. J. A. G.**—The chief defect in No. 1 is in the plate. A trace longer exposure, or a little more patience in development, would have been useful; but the subject is not well lighted. Remember that in landscape photography it is of the first importance that the scene should be so lighted as to produce pictorially a satisfactory amount of light and shade. If it be illuminated with an equally diffused light all round, a tame, flat, unsatisfactory picture must be the result. Either from sunlight or the action of bright clouds, it is desirable to have the subject illuminated from one source, which should be preferably from one side. The same defect characterizes No. 2, which is really a little over-exposed. No. 3 required better lighting, and a little more patience and bromide in development. Look to the shading of the lens from all skylight not forming the picture. No. 4 is chiefly spoiled by defects in the plate. The negative from which the transparency was printed appears to have been a little hard. Nothing but the extreme care and cleanliness will produce clean backgrounds in such a case; great care to avoid dust on the plates, great cleanliness in developing-cups, great care that the solutions do not become turbid, and precision throughout. When you see Mr. Gordon's operations, note the extreme care and cleanliness of every detail. The oxymel process is one of the oldest of the preservative processes, and one which produces very good results. It fell into disuse chiefly because of the somewhat sticky surface of the plates. We have posted a letter to you.

**ASTONISH.**—Mr. Solomon's apparatus for enlarging by means of the magnesium light appears to be very excellent. We believe that Mr. Solomon supplies the paper ready for sensitizing, and instructions for the best mode of working. See an article on printing by development in present number. A saturated solution of gallic acid is generally the best developer for paper prints. Whether acid is necessary with it, or not, depends somewhat on the preparation of the paper.

**J. W.**—A pint of fresh fixing solution containing 4 ounces of hyposulphite of soda will very safely fix half a dozen twelve by ten pictures, whether they be put in altogether, or singly in succession. 2. Old silver stains are more difficult to remove than new ones. Apply tincture of iodine freely to the stain, and then apply strong hypo or cyanide.

**PHOTOS.**—Mr. England's photographs can, we believe, be obtained of Marion and Co.; his own address is St. James's Square, Notting Hill. 2. We do not know of any means whereby you can procure one of M. Salomon's pictures. It is probable that you can procure an example of the style of picture he issues by applying to some one of the gentlemen who have exhibited such

pictures at Conduit Street, whose names you will find mentioned in our recent notice of the exhibition. 3. A bag is placed in the aperture at the bottom of the box, just large enough to contain the bath.

**C. T. NEWBERRY.**—We will duly forward the P.O. order to the treasurer of the North London Society.

**CITRIC ACID.**—There will be no impropriety in your increasing the strength of your developing solution for winter use; but the chief cause of your difficulty is in the useless obstruction of light. A north light always is a diffused light, and when you "putty" your north side for the purpose of diffusing the light, you simply waste a great deal of light, not only by the obstruction, but by the yellow tint it soon acquires. Remove all this from your north side-light at once, and you will find a great reduction in the time of sitting; if that is not sufficient, remove the paint from the north top-light, which will still further reduce the exposure. Let us know the result.

**N. C. EVANOFF.**—Your work generally appears to be very good; it is clean, brilliant, and round. There is just a little too much top-light, which causes some tendency in the shadows under the upper lip, the chin, &c., to be a little blacker than is desirable.

**F. D.**—The plan is a very good one; but, as we have not seen such a studio in use, we cannot say that it is the best. We can see, however, no disadvantage in the form, and should prefer it to a roof of half-cylindrical form recommended by the same writer. Fluted glass is only of service where direct sunlight is concerned. For a south light, it is useful as assisting in diffusing the light; for a north light, we should not use the fluted glass.

**OLD DAGUERREOTYPIST.**—We publish your letter referring to the Relief Fund. You are surely in error, however, in supposing that the best men in photography have secrets to propose. All the men who have done the highest and best work in photography, and who have achieved the highest success, have been the most ready to communicate and describe most fully all their operations.

**G. H. (Manchester).**—You are scarcely specific enough in your question. You do not state whether you wish to transfer to plain paper or the "porcelain" paper; nor do you state which method of transferring you adopt, nor where you fail. The glazed or "porcelain" paper is sold ready prepared to receive the transferred film, but plain paper you must prepare for your own use. We have described as fully as we can both the wet and dry methods of transferring; but if you will state which method you employ, and in what point especially you fail, we will endeavour to help you. We regret that we have not time to enter into private correspondence on points of this kind.

**IGNORAMUS.**—A variety of theoretical reasons for the use of nitrate of soda in the printing bath have been given; but, on the whole, it seems a little uncertain as to what is its precise function. The fact, however, is affirmed by many veritable printers that there is a considerable advantage in its use, and that it permits the use of a weak silver bath without risk of bad prints. Most printers are agreed that an old silver bath gives better prints than a perfectly new one; and as an old bath has acquired an accumulation of nitrate of soda or of ammonia, the addition of such salts to the bath is said to give the advantage of an old bath. The value of the addition is still a subject of discussion, but the balance of evidence seems to be in its favour, and we think we could, if space permitted, give some good reasons why it may be useful.

**THOMAS STOTHARD.**—The YEAR-BOOK for 1869 will be out at the latter end of December. That for 1864 forwarded. We did not find the group of statuary to which you refer in your letter.

**H. DIXON.**—We have made enquiry, and find that the envelope containing the card was posted at a pillar-post in the northern district on Wednesday the 18th. We are sorry you have not received it. The best plan will be to apply to the Postmaster-General by letter, describing the envelope and address, and stating circumstances.

**A. B.**—Upon treating the precipitated sulphide of silver with nitric acid, and warming in a test-tube, the silver will be taken into solution, and can be readily detected by the addition of common salt to a few drops of the liquid. With regard to the sulphur, much of this will commonly be left insoluble, and assume the form of a semi-fused globule; there will, however, always be a small proportion oxidized and dissolved, and this can be recognized in solution by one of the usual tests for sulphates, viz., nitrate of baryta, producing a white precipitate insoluble in dilute nitric acid.

**T. G.**—Thanks.

**A CORRESPONDENT WITHOUT SIGNATURE.**—The letter was duly forwarded.

**D. WINSTANLEY** in our next.

Our final Notice of the Photographic Exhibition, together with several articles in type, are compelled to stand over until our next.

Several Correspondents in our next.

### THE GODDARD RELIEF FUND.

WE feel sure that we shall be pardoned by the generality of our readers for occupying part of our space this week with an official report and a few remarks on a matter which, in a direct manner, concerns only a few of them—the subscribers to the Goddard Relief Fund, less than three hundred in number. Besides these, the subject may possess an incidental interest to those whose attention has of late been fixed on the importance of a general relief fund for photographers; and possibly also to the still smaller number who may have felt any interest in the foolish rumours circulated by a few mischievous persons as to alleged malversation in connection with the fund in question. And, finally, in justification of devoting some space to the matter now, it should be stated that a good proportion of the money was contributed through this Journal in response to an appeal made in its pages; and there is a fitness in publishing the final report of the committee in the same columns.

The story is pretty well known, but we may very briefly restate the leading facts. Mr. J. F. Goddard, originally a lecturer on popular science, became, in 1840, connected with the then newly-discovered art of photography, and by his early experiments materially contributed, if not to make Daguerreotype portraiture a general possibility, at least to improve its quality and practice. After many years of connection with the art, he was left behind in the struggle for profit and honours, and old age found him with enfeebled and precarious health, mental and bodily, and still more enfeebled and precarious means. He was old, infirm, and very poor. His only resources for subsistence were a few pounds subscribed annually by the friends who knew something of his history, and believed in his necessities, if not in his great services to the art.\* Mr. T. R. Williams was the almoner of these few contributions, which averaged, so far as we remember, not more than about £15 a year, which just kept the recipient from actual starvation. We were amongst the limited number of contributors, which we occasionally attempted to extend; and in such efforts we chanced to bring the matter under the attention of Mr. Jabez Hughes, who, with characteristic energy and generosity, at once proposed a general appeal to photographers for means of immediate, if not of permanent, relief. We cordially seconded the idea, which was at once carried out. "A few facts and an appeal" in connection with the discoverer of the use of bromine in collodion were written by Mr. Hughes, and inserted willingly in the journals connected with photography, the editors of which (namely, Dr. Diamond, Mr. Shadbolt, and ourselves) as well as Mr. T. R.

Williams and Mr. Hughes, undertaking to receive subscriptions. Besides these appeals, upwards of two thousand circulars and many hundred of letters, written personally, were issued by Mr. Hughes, and sent all over the world where photographers could be discovered. The response to this appeal was liberal, and upwards of £370 were contributed. We may incidentally mention here, as a matter of historic interest, that in the exuberant desire to present the claim strongly, Mr. Hughes discovered, in the course of the immense correspondence which followed, that he had somewhat exceeded fact in his statement, and various protests accompanied some of the contributions. In America Mr. Goddard's claim to the application of bromine to the Daguerreotype process was altogether ignored, and it was ascertained also, from published documents, that both Sir John Herschel and Mr. Fox Talbot had preceded Mr. Goddard in the use of bromine. That Mr. Goddard was honourably connected with early progress in the art there can be no doubt; and upon this subject it is not necessary to enter into further detail here.

On the receipt of liberal contributions a new question arose. No organization and no responsible body existed for dispensing them. It became something like a necessity, therefore, that those through whom the funds were contributed should form a committee to consider their disposal; and the gentlemen we have named assumed that office, Mr. Hughes, to whom the bulk of the subscriptions were sent, practically becoming treasurer, conjointly with Mr. T. R. Williams, who also, being in most constant contact with Mr. Goddard, became dispenser of the fund. Very early after subscriptions began to be received, Mr. Goddard was relieved from the pressure of immediate want by a portion of the money contributed; but it became apparent, on a little reflection, that no permanent method of relief could be carried out on that system.

In the appeal first made it was proposed to relieve Mr. Goddard from immediate need, and a hope was expressed that his remaining years might be spent "free at least from the anxieties of physical want;" and, as funds began to flow in, it became important to consider how the committee could carry out their implied pledge to care for his remaining years. The purchase of an annuity was the obvious means of meeting the end, and in the two thousand circulars and many hundreds of personal letters to which we have referred, the appeal for funds to purchase an annuity was expressly made, and by far the larger proportion of the amount was contributed under those conditions.

But here a new difficulty arose. Mr. Goddard wished to have the whole of the funds placed unconditionally at his disposal, and a series of schemes for its appropriation were proposed by him in succession, in none of which was any security offered for his future subsistence. His antecedents

\* It is perhaps due to the memory of the late Mr. Claudet, also now gone, to say, that whilst he systematically denied the nature and extent of the claims made for or by Mr. Goddard, he was one of these subscribers, as he was afterwards a liberal contributor to the relief fund.

presented a saddening record of his unfitness to have irresponsible charge of his own welfare, which age had in no wise removed. We pause at this stage, without entering into a history of the troubles of the administrators, and remember the good old maxim, *de mortuis nil nisi bonum*. Suffice it to say here, that it was pointed out to him that the committee felt they had no alternative in the matter. Prudence rendered it desirable that the fund should be invested in an annuity; good faith to the subscribers of more than two-thirds of the amount rendered it imperative. Whilst anxious to obtain the uncontrolled use of the whole sum, he promised oft, and as often evaded, the signing of the official document identifying him with the annuity policy, and without which it could not be completed; and before any definite step was effected, he died.

During the whole of the period in which the fund was in course of collection, during the time which the medical man required for observation before he could give promise of possibly prolonged life, and during which Mr. Goddard delayed from time to time the necessary signature for securing an annuity—a period of something less than three years—he was in the receipt of an income from the fund sufficient to supply moderate wants. He had gratuitous residence, without food, in St. Joseph's Retreat, at Hammersmith, and the amounts he received from the committee averaged, during the period in which he was practically in their charge, about sixteen shillings weekly. The figures before us in the treasurer's account stand thus:—Payments made to Mr. Goddard, £104 18s. 8d.; tailor's and doctor's bills, incurred during these three years, paid for him, £4 12s.; a further sum of £5 paid to Mr. Goddard, but for which, no signature having been obtained, Mr. Williams declines to charge, making altogether £114 10s. 8d. The funeral expenses, which the committee paid, amounted, in round numbers, to about £20; for other disbursements we refer the reader to the balance-sheet.

Our object in this brief analysis is simply to show those of our readers interested in the question, that the declining years of the unfortunate gentleman were relieved from the pressure or fear of actual want, the grim spectre which had stood at his threshold during the years immediately preceding the existence of this fund. At the latter end of 1866, bronchitis—from which, in a chronic form, he had suffered for years—attacked him in an acute form, and he went to Middlesex Hospital, where, after remaining a few weeks, he died in the December of that year. Perhaps one of the most satisfactory assurances of the sufficiency of the relief he continued to receive from the fund collected is derived from the fact that a few pounds—six or seven sovereigns in gold—were found in his pocket after his death by the ward attendant at the hospital, and handed over to Mr. Brothers, who claimed to act as the representative of the deceased gentleman.

After his death the balance of the fund naturally reverted to the subscribers. But now another trouble arose. A gentleman named Mr. G. Brothers, of whom the committee until then had known nothing, produced a will, made at an early period in the history of the subscription, in which Mr. Goddard—acting under the assumption that the funds would be placed in his own hands—had disposed of the prospective contributions. Mr. Brothers, as executor under this will, claimed the balance of the fund. On taking legal advice the committee learned that their own first impression was correct: that they held the money in trust for a special purpose; that this purpose having been as far as possible consummated, the balance belonged to the subscribers, and could not be applied in any other manner. What followed, and the cause of delay in closing their duty, those concerned already know, and we refer any others interested to the report for details. The balance in the ratio of their subscriptions is now in course of distribution to the original donors.

With this brief statement, the history of the Goddard Fund, in our pages, closes. Undertaken in kindness, carried

out in steadfast good faith, not without an amount of labour, difficulty, and anxiety far beyond what could have been anticipated, the committee have, we think, one specific source of satisfaction: that, so far as we know, every subscriber who has communicated with them—and the number has been large—has signified cordial approval of the course they have pursued. And when we speak of the committee, let us do an act of justice by a remark which we are in the best position to make: whilst, as the report states, the committee were in perfect unanimity in all their decisions, and each one accepted any share of duty or responsibility which fell to him, the chief labours were performed by two gentlemen, Mr. Jabez Hughes and Mr. T. R. Williams. In response to the single effort of Mr. Hughes, the greater part of the money was contributed. With the exception of about £100—upwards of £50 of which were contributed through the PHOTOGRAPHIC NEWS, and the remainder through two other journals and Mr. Williams—the total amount was sent to Mr. Hughes in reply to scores of personal applications, hundreds of written letters, and two thousand circulars, addressed by himself to photographers in all parts of the world. The duty—not always pleasant under the circumstances—of administrator was undertaken by Mr. Williams; and to these two gentlemen the subscribers are chiefly indebted for discharging, on their behalf, the arduous task just completed.

One word more. Suggestions well-meant, and rumours ill-meant, have reached the committee, hinting the desirability, or imputing the intention, of employing the balance as a nucleus of a general relief fund. After reading the brief history of the case, the kindly-disposed gentlemen who have suggested the desirability of such a course will perceive that any steps which could have been taken in such a direction would have added too seriously to the complications of a sufficiently troublesome responsibility.

#### THE NEW SECRETARY TO THE PHOTOGRAPHIC SOCIETY.

A SOMEWHAT premature announcement in a contemporary states that Mr. John Spiller, F.C.S., has been appointed secretary to the London Photographic Society. It will interest many of our readers to learn that Dr. Diamond, who has been for some time anxious to retire from the duties of secretary to the Society as soon as a suitable successor could be found, recently tendered his resignation to the Society, and asked the council to take steps to relieve him from the discharge of duties which the state of his health and his numerous other engagements rendered too exacting. His resignation will take effect at the end of the Society's year in February next; at which time he will have completed, we believe, his eleventh year as secretary to the Society and editor of its Journal. Mr. John Spiller has been appointed by the council, on the resignation of Dr. Diamond, as honorary secretary, in which duties he will probably have the assistance of another honorary secretary. Mr. Spiller will also act as editor of the Journal. The appointment is one which cannot fail to give general satisfaction, both from Mr. Spiller's standing as a photographer and a man of science, and from his estimable personal character which wins many friends, and makes no enemies. His ability, activity, and zeal cannot fail to be of great service to the Society. Other changes in the officers of the Society will be announced in due course.

#### A PHOTOGRAPHERS' RELIEF FUND.

As the probability of the establishment of a photographers' relief fund acquires more definite shape among the photographic public, some points regarding the nature of the organization and the limitation of its operation begin to be discussed. The question especially arises, For whose benefit

is such a fund proposed? The answers [which will be given by different persons are illustrated in letters in our present and recent issues, and these are types of others we have already published. One class would limit the aid to those only who could present proper credentials of their sole devotion to photography as a profession; whilst another class would extend the aid to all who needed it who may in any way have been connected with photography.

It is clear from the different views held on the subject that it needs a little discussion. One of our correspondents is under the impression that we raised the question as to whether hangers-on of the profession should be recognized in such a benevolent scheme. He is in error; we simply gave expression, as we at the time stated, to the question as raised by a metropolitan photographer of many years' standing in the profession, who wished that the question should be discussed, but himself rarely expressed his thoughts in writing. No matter, however, by whom the question is raised; if a fund have to be established, the subject should be discussed. At this stage of the inquiry it is not a matter of sentiment, but one of necessary prudence. It is a very plausible affectation of large-hearted generosity for a man to exclaim, "Oh, I would give to all without limitation, necessity alone constituting a fitting claim." But if the professor of this ample liberality were literally without means whereby his liberality might be tested his words would be of little avail. So if a system were established whereby funds could not be obtained, it would be quite useless, however comprehensive its professed charity. From the tenor of some of these letters we have received, the writers would be unwilling to subscribe to a fund which would extend help indiscriminately to all who had been connected with photography, whether it had been their sole profession or not; but they would readily contribute to a fund exclusive in its aims. Here we have a class—possibly a large class—representing a probably large annual subscribing power, who will contribute on conditions; and the question very properly arises, Can these conditions be met?

Although we have raised the question by giving expression to the voice of others, we have expressed no opinion on the subject ourselves. We hold, nevertheless, a very strong conviction on the subject. It is, that narrowness or exclusiveness will be the very worst course as a matter of policy, as well as a matter of benevolence, which can be taken; and we think that due reflection on two or three considerations will satisfy that class who at present are only prepared to subscribe on condition that photographer-mechanics, photographer-barbers, *et hoc genus omne*, shall be excluded from the provisions of the organization. First, let it be remembered that the probable largest contributors to such a fund will be wealthy amateurs, and these will be inspired with no sympathy with the notion of excluding from the fund all but the most precisely-defined professional photographer. The offer of £50, already made, is from an amateur, and no more sure means of cooling the interest of such gentlemen could be devised than the introduction of any spirit of narrowness into such a scheme, and no surer means of evoking warm and extended aid can be conceived than a spirit of catholic, but not reckless, comprehensiveness, in considering the objects of benevolence. As a question of policy, professional photographers have far more to gain than to lose by avoiding exclusiveness.

There is another consideration of policy worth a moment's attention. It is very improbable that many of the class who join photography to another occupation will ever be likely to become dependants on such a fund; for however undignified it may be—and it is, perhaps, a little painful to the dignity of some to see the professions of "chimney-sweep and photographer" conjoined on one sign-board—yet it should be remembered that such persons are rarely unthrifty. We may possibly lose caste in the estimation of some of our readers, when we confess to some degree of sympathy with those who so dwell on the border-land of photography. The attempt to practise photography gene-

rally indicates some degree of taste and ingenuity; and the conjunction of photography with some other business generally suggests a desire to "provide things honest in the sight of all men," and, therefore, such conjunction is, we think, a "failing which leans to virtue's side," always provided there is an aim to do good work and secure fair prices. But, in any case, the alliance of the two businesses generally argues thrift, and the thrifty man is the least likely to become an applicant for benevolence.

A third condition of prudence is, that there is a very large class, consisting of those employed in the manufacture of lenses, cameras, and photographic apparatus and materials generally, who would be just as probably contributors as applicants to such a fund; and that, in short, to attempt to limit its aid to the "photographer" only, according to the narrowest definition, would be probably to limit its contributions to the same class, a course which must of necessity seriously contract the chances of its establishment.

Finally, it might be asked, On what ground should exclusiveness be practised? What occult fitness is possessed by the photographer, according to the present definition, which he whose occupations are associated with photography does not possess? It may be answered—in fact, has been answered—that there are "hangers-on" to photography—men more likely to need the fund than to contribute to it—and that this should be provided against. In a benefit society such considerations would be of importance, but in relation to a benevolent organization such a consideration has no weight whatever. We presume that nine-tenths of the contributors will never contemplate the bare possibility of their own need of aid from such a source. The fitness of a claimant for relief out of the funds of a photographic benevolent fund will, we presume, be duly considered by the administrative officers who may be appointed, and the broader the basis upon which the claims shall be estimated the more in accordance it is likely to be, we believe, with the desires of the most important of the contributors.

The mere discussion of the subject now might be considered premature, if it were not for the fact that some are indisposed to promise to contribute until they know how wide or how narrow a basis is contemplated; and as we are anxious to be able to give the photographic world, in six months, some estimate of the amount in donations and subscriptions which may be anticipated if an organization is formed, we wish to remove any objection which might exist, on the score we have indicated, to make a conditional promise.

## EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

### FINAL NOTICE.

So far as any descriptive memoranda on the prints enable us to judge, the bulk of the contributions were produced by the wet process. The dry processes, however, although not extensively illustrated, present some very admirable examples, and these go far to prove that in the hands of skilful and careful men, almost every process will yield good results. The oldest, the Taupenot, in Mr. Wardley's hands and in those of Mr. F. Howard, gives some marvelously fine landscapes; and the newest, Mr. Gordon's gum process, gives in his hands prints which leave nothing to be desired. Mr. Whiting also exhibits some excellent results obtained by the gum process, and some scarcely less excellent by the tannin process. Mr. W. W. King's prints of tropical plants in Kew Gardens, taken with the tannin process, are very excellent. Mr. Beasley, as usual, excels with the Fothergill process. And these names, so far as we know, comprehended the names of all the dry-plate men who contributed.

The wet-plate workers were legion. Besides the charming Welsh views of Bedford, those in the Tyrol by

England, the exquisitely delicate work of Mr. Gordon, the beautiful little bits of Mr. F. Howard, which tread closely on the heels of those of Mr. Gordon, the admirable landscapes of Mr. Vernon Heath, of Mr. Spode, of Mr. Brownrigg, and others, whose works are well known, and the excellent and interesting Abyssinian photographs taken by the Royal Engineers during the recent war, which we have already noticed, there are very attractive pictures, possessing fine qualities, both artistic and photographic, by men whose names are less familiar to the photographic public. Amongst these, we may mention some singularly delicate landscape bits by Mr. Fernely, of Melton Mowbray. Without lacking any force, there was a delicacy of treatment which resembled that of a clever pencil drawing, and a crispness of definition like that of a steel engraving. Mr. Archer Clarke exhibited some fine landscapes, which were described as having been treated with the golden synp solution recently described in our pages. Also amongst the exhibitors of excellent landscape work were Mr. Crofton Atkins, whose bold mountain and cataract scenery was rendered with much picturesque effect; Mr. A. Irving, who exhibited some charming Killarney views; Mr. Greene, whose views in the Mauritius possessed much interest; Mr. Fox, who exhibited effective sea and cloud pieces; Mr. Heaviside, who exhibited some fine views in the picturesque neighbourhood of Durham; Mr. J. B. Best, who, with others, exhibited good pictures.

Most striking amongst the illustrations of special processes was the portrait of Lord Belhaven, reproduced by Mr. Annan from a painting in the last exhibition of the Academy. It was printed in carbon by the Autotype Company, and resembled a fine mezzotint engraving, which, however, in many respects, it surpassed. The same Company exhibited a portfolio of splendid carbon reproductions from old masters. Edwards and Co. exhibited a large and interesting collection of carbon or pigment pictures, consisting of portraits, enlargements, and examples of different applications and different tints. Mr. W. H. Smith exhibited some very interesting applications of photography to decorative work on wood, in which pictorial subjects, with borders, imitating the grain of ornamental woods, were both produced by photography, the method employed being, we believe, the gelatino-chloride of silver process.

Dr. Mann's ethnological studies from South Africa were strikingly full of character. The enamels of Mr. Henderson we have before mentioned as exceedingly perfect. Mr. Barnes also exhibited some good enamels, plain and coloured; and a gentleman in Hull, who described his work as that of an amateur, exhibited some very good enamels. Mr. Britton's collodio-chloride pictures on opal glass were very attractive. Mr. Alfieri exhibited a frame of excellent work, and full of interest, illustrating the art of pottery by views of the men at work in the various operations of potting. Mr. Jewell's dogs, and Mr. Avery's horseback pictures, received and were well worth attention. With the exception of the carbon reproductions already named, very few illustrations of this branch of photography were exhibited. Mr. Fred. Hollyer exhibited a fine reproduction of a painting by Rosa Bonheur; the Misses Bertollacci exhibited some capital reproductions from engravings of Turner's works, and Mr. Hubbard also exhibited a few good examples of copying. Mr. H. Dixon exhibited one or two of his fine reproductions and some other pictures, chiefly with a view to illustrate the effect of a preservative varnish which will effectually protect the print from the action of external agencies, and so contribute to the permanency of the print.

Of the coloured work we can only briefly indicate the character of the contributions. A very charming portrait, produced by the collodio-chloride process on ivory, and coloured in water colours, was exhibited by Mr. B. J. Edwards; and a water-coloured cabinet picture, exhibited by Mr. Burgess, was very interesting, and

closely resembling the effect of ivory. The bulk of the coloured work consisted of enlargements, some by Mr. Plumridge striking us as amongst the finest we have seen. The oil-coloured work of Mr. Edwin Davis was of very high character. Mr. J. H. Wills exhibited work of various qualities: a vignettted coloured head on a grey board was exceedingly fine. Lock and Whitfield's work in water-colours was, as usual, of the highest excellence. Messrs. Sawyer, of Newcastle-on-Tyne, exhibited two good enlargements, coloured in oil, one of which especially pleased us. Lenthall, Herring, Rees, Cunningham, Monnickendan, Palmer, and some others, exhibited very good coloured enlargements. Some coloured enamels by Mr. Bailey were especially fine and artistic in quality. Mr. Piercy's examples of his patented method of treating photographs were exceedingly excellent, and full of artistic finish.

Raines' panoramic camera, exhibited by Mr. Ross, and some photographs produced by it and by Mr. Ross's doublet, excited much interest. The method of obtaining a panoramic picture is very simple, and is analogous to that which has occasionally been effected by means of a stereoscopic camera: one-half of a view is first taken on one-half of the plate, the camera is then moved so as to bring the next half of the view accurately into position, and the front of the camera holding the lens moved so as to bring the second half of the view on the second half of the plate. The especial feature of this camera is the presence of an endless band, with serrated edges, placed just in front of the plate at the part where the two halves of the view join. This being kept in revolution during the exposure practically vignettes each half into the other, and so prevents any appearance of joining. A panoramic landscape exhibited by Mr. Wardley was produced from two negatives printed in succession on the same paper, and is admirably joined. A small pocket-camera was exhibited by Messrs. Negretti and Zambra. One of the most complete, convenient, and handsome camera-stands we have seen was exhibited by Mr. Hughes. Some admirable examples of folding-cameras, and some capital stands, were exhibited by Mr. Meagher.

Of the apparatus exhibited nothing was more interesting than the examples of the Holmes stereoscope, which Mr. Blanchard has recently called attention to. Mr. Meagher exhibited some handsome examples in polished walnut wood, which excited much attention and admiration.

## ECHOES OF THE MONTH.

BY AN OLD PHOTOGRAPHER.

THE LATE EXHIBITION—SECRETARYSHIP OF THE PHOTOGRAPHIC SOCIETY—THE RELIEF FUND—PORTRAITS ON APPROVAL—THE SOCIETIES.

No photographic event during the month—in fact, none during the year—has possessed half the interest of the exhibition of the Photographic Society held in Conduit Street. A photographic exhibition is always interesting to a photographer, but this possessed a startling interest, from the degree of excellence possessed by the mass of the contributions, being so much in advance of anything which could have been anticipated. Technically, everything was perfect, and there was not a bad photograph exhibited; but, what was of far higher importance, the art qualities were so much in advance, in portraiture especially, of anything previously exhibited, that everyone was taken by surprise. That the great impetus in this direction was given by the attention which has been called to the pictures of M. Salomon seems to be generally admitted; but it is very gratifying to see so many good men willing to learn, and capable of learning; and it is pleasant to note, too, that even in what are, I presume, confessedly imitations, so much individualism is manifested—an individualism which will necessarily become more specific and marked,

and produce diversity of style, with, it is to be hoped, uniformity of excellence.

The exhibition has been so fully noticed that I shall not venture to comment upon any of the pictures. There is one reflection in connection with the subject somewhat apt to be forgotten, which I should like to impress upon the minds of photographers, as being very appropriate at the close of such a satisfactory exhibition. I would suggest how important it is for all interested in the art to strengthen the hands of the Photographic Society. Despite the heavy losses it has sustained through the maintenance of exhibitions in former years, being impressed with the vast importance of such exhibitions in advancing the art, and of their interest and value to photographers, the council, it appears, have resolved to maintain as an annual institution this exhibition inauguration of the winter session. However economically it may be done, it is clear that it involves some serious expenses and a vast amount of labour for somebody; and, although I believe that the Society does already include the mass of the respectable metropolitan photographers, and many in the provinces, I cannot help thinking that a society which undertakes the trouble and expense of opening gratuitously to photographers and the public such an exhibition every year, has a claim upon the support of everyone interested in the art. I have been led to these remarks by having observed in print—truly, in a very insignificant quarter, but still showing there are minds small enough for the kind of thought it embodied—a phrase alluding to the “exhibition in the Photographic Society’s rooms, not the exhibition of the Photographic Society.” As the trouble of arranging, hanging, managing, and opening gratuitously to the public for a week, and all the expenses of doing this, are undertaken and borne by the Photographic Society, I should like to know whose exhibition it is, if not that of the Society. Some of the exhibitors were not members of the Society, it will be said. True, although by far the greater part of them were. But there is nothing affecting the matter in this. At least nine-tenths of the pictures in the exhibition opened every May, in Trafalgar Square, are not by members of the Royal Academy; but who dreams of speaking of the display as other than the Royal Academy Exhibition?

*Apropos* of the Photographic Society, I see an announcement in the *Chemical News* to the effect that Mr. John Spiller has been appointed Secretary of the Photographic Society. It has been known for some time, I believe, that Dr. Diamond was anxious to resign whenever the council could release him from his duties; but I cannot help fancying that an announcement of a new appointment in the middle of the session must be premature.\* In any case, however, I think that everyone will readily admit that Mr. Spiller will be the right man in the right place. A veteran in photography and photographic reputation, although scarcely yet in the prime of life, having attained high recognition in the scientific world as an accomplished chemist, and a man of pre-eminently courteous and conciliatory personal bearing, it would have been difficult, I think, to make a more efficient or a more popular appointment.

Last month, I ventured to hint that the subject of a Photographic Relief Fund had not been discussed in detail, and did not seem to have excited the general interest it deserved. The correspondence in your pages the last few weeks indicates a more general desire on the part of photographers to give attention to the matter. I am sorry, however, to see a spirit of jealous narrowness in some of the letters, and a disposition to exclude from prospective benefits the dwellers in the border-land of photography, or hangers-on to the art. I think that all considerations as to the claims of applicants for relief may very well be left to the consideration of the committee or officers of any organization which may be formed. Your proposed “test-

operation” is, I think, a happy idea. If all who are disposed to aid the formation of such a fund will forward to you intimation of their willingness to contribute, it will be easy to estimate the probable success of the project; and as the promise will be conditional, and depend upon the formation of a trustworthy committee, no one need fear the risk of promising aid to a project which might eventually fall into bad hands.

A recent letter in your pages, by Mr. Downes, raises a question of considerable importance. He protests against taking portraits on approval, a practice which is, he alleges, becoming common, so that a portraitist may have an hour or two of valuable time wasted in producing two or three negatives, proofs may be printed from them, and the sitter, from some whim, after disapproving of them, coolly leave the photographer with his labour for his pains. I should hope that such cases would not, under any circumstances, be common; but it is clear that if the practice of taking portraits on approval were established, they might easily occur. The case of the sitter may seem reasonable enough when he says that he cannot think of paying for portraits which are not like. But what is the practice of other trades in such matters? If a tailor or a shoemaker make a misfit, he will either alter the article or make another. But the customer would be considered as acting unfairly and dishonourably if he declined to allow a second trial, but withdrew his order altogether. Now, if he deal on this wise with the photographer, his conduct becomes as nearly dishonest as it is dishonourable. To engage the time of the portraitist in taking a negative, and then decline either to accept what is done or to sit again, when possibly the defect in the first attempt is due to the sitter himself, is clearly dishonest.

On the other hand, I think that portraitists will, as a rule, find their account in giving re-sits wherever a customer is dissatisfied. Suppose he decline to do so, and the customer, with a bad grace, pays for the smallest number of the prints he can order; it is quite certain that no more copies will be required from that negative. But if, for some real or supposed fault, the first portrait does not please, and a second sitting is given, the customer is propitiated and in a humour to be pleased with the next attempt; and, being pleased, probably gives a large order for prints, and, possibly, continues ordering for some time from the same negative. It is clearly the interest of the photographer to please his customer, even at the cost of a little extra and even unreasonable trouble, especially in these days, when it is not uncommon to order many copies of prints from one negative. Of course, there will always be fidgetty, unreasonable people whom it is impossible to please, but as these cannot be cured they must be endured. I remember an old portraitist who had a curious rule on the subject of re-sits. When customers found fault with a portrait, and asked to sit again, he found in many instances, not that the first was unsatisfactory, but that they wished to have the choice of two effects of dress. He made it a rule, therefore, to consent to a re-sit, on one condition, namely, that the first negative should be destroyed before the second was taken, and that the customer should consent, in any case, to accept the result of the second trial. In the majority of cases this was declined, and the first accepted, showing that there was, in reality, very little objection to the first, seeing that the customer would not take the chance of getting something better, seeing it might also be something worse. In the days when one or two copies were the common orders, such a plan answered; but now it is the photographer’s interest to keep all the negatives he takes, with a view to possible orders from all.

The proper remedy for any misunderstanding between the photographer and his customer I hold to be prepayment. Let a rule be systematically carried out, that the sitter’s name and instructions be at once entered in a book, and his money taken before he sits for his negative, as a

\* See remarks in another page.—Ed.

traveller pays for his railway ticket before commencing his journey, or for his concert ticket before listening to the music.

The photographic societies have all commenced their winter sittings. The London Society had an interesting conversation at the opening of the exhibition in place of a meeting. The North London, in the absence of a paper, had a conversational meeting. At the South Mr. Pearce read a modest and interesting paper on natural backgrounds and open air effects in portraiture, upon which an interesting discussion followed. At the Edinburgh the annual meeting was held for reporting progress and appointing officers. A capital suggestion was made in the "curator's" report, to the effect that every member should present to the society his card portrait with his autograph appended, and so form a gallery of the members. At the Manchester Society the chief business was an interesting magic lantern display.

### Foreign Miscellanea.

At the last meeting of the French Photographic Society M. Pachelo again called attention to the formation of spots upon positive prints, which he attributed to some injurious material in the mounting boards, whereupon M. Girard stated that as the cardboard is manufactured in the same factory as the mounts with gilt edges, it is very possible that the injury complained of arises from finely-divided metallic particles deposited upon the card, as pointed out by him some time since.

At the same meeting, M. Despaquis exhibited several transparent carbon photographs mounted upon glass, and obtained by means of a film of so-called leather collodion (*collodion-cuir*). The material is well adapted to the production of pictures of this description, as favourable results are obtainable even from inferior negatives; a film of the material is merely exposed under a negative, washed in warm water, and then mounted upon glass. The pictures have created so favourable an impression that many of the principal photographers of Paris are experimenting with it—to wit, MM. Disderi, Reutlinger, Lejeune, &c.

MM. Geymet and Alker, in a letter to the *Moniteur de la Photographie*, state that in dull weather they can use the magnesium light for their remodelling process.\* For printing a negative, a pose of forty seconds' exposure will give an image sufficiently good for transferring; and for reproducing designs by means of the camera, an exposure of two minutes is necessary.

Under the title of "Recent Progress in Science," a series of articles have been published in the *Revue des Deux Mondes*, by M. Radau. One of these articles, on Photographic Chemistry, although containing no novelty, is, on account of its simplicity and clearness, worthy of perusal by photographers. Referring to a ray of light which is decomposed by a prism into six principal colours—red, orange, yellow, green, blue, and violet—M. Radau says:—"These rays, which affect the retina of the eye, constitute what is called visible light. They are warm rays, and capable of acting chemically upon certain substances which are called impressionable (sensitive), but they do not produce all the calorific and chemical effects obtained with sunlight. The visible spectrum is prolonged on each side by obscure rays; beyond the red line extends the region of obscure heat; and beyond the violet are the chemical or ultra-violet rays. The latter become visible under certain conditions, when they appear of a light-grey lavender tint; they do not produce heat, but they exert a powerful action upon impressionable substances."

\* This was done by Mr. Joubert a year or two ago.—Ed.

In stating that the theory of photographic phenomena is still enveloped in obscurity, M. Radau proceeds:—

"Nevertheless, one may endeavour to group known observations and effects under several general categories. There are, first of all, the reducing agents. Under the influence of solar rays, oxygen and haloid bodies have a tendency to abandon the metals. Chloride and nitrate of silver become decomposed, and it is the same, generally speaking, with chlorides, bromides, iodides, cyanides of the less oxidisable metals; the oxides, or suroxygenated acids, &c. In these cases light has the effect of destroying the affinities. There are, besides, the combining agents, in which affinities are, on the contrary, brought about by light. Oxygen, chlorine, bromine, &c., have a tendency, under the influence of light, to combine with hydrogen and organic bodies. A mixture of chlorine and hydrogen may be preserved for an indefinite period in obscurity, but if exposed to light it liquefies and gives birth to hydrochloric acid. Bitumen of Judea becomes insoluble under the action of light, because it absorbs oxygen; and a large number of essences and varnishes likewise become oxidised by light; gum-guaiacum assumes a bluish tint on oxidising. In mixing together a substance which tends to become decomposed under the action of light with another inclined to absorb one of the bodies which is separated, more energetic effects are produced. It is in this manner that organic matter facilitates the reduction of salts of silver by absorbing the oxygen disengaged. But what is most remarkable is the fact that if one only of two sensitive substances is exposed to sunlight, and both are afterwards placed in contact, the molecular action developed by the sunlight continues after the withdrawal of the substance from exposure, and, by bringing together the two substances, the same effect is produced as if they had both been subjected to the direct action of solar rays. Thus, for instance, in order to facilitate the reduction of iodide of silver, it is placed in contact with gallic acid after one of these substances has been exposed to sunlight, or even both have been exposed together. The effect produced as regards intensity is nearly always the same. Photographers denominate as *sensitive*, or *impressionable*, any material which receives and preserves the action of light, and give the name of *developer* to any substance capable of developing the image or completing the chemical reaction; but this distinction is of no essential value, inasmuch as the roles played by the two descriptions of bodies may be inverted."

Collodio-chloride paper is now made commercially in Germany, and advertised largely for sale. Each sheet is stated to contain three grammes of nitrate of silver, which is in most part recoverable from residues. The prices asked are somewhat high, being twenty-four shillings per quire of sheets 20½ by 12, or six shillings per gross of papers suitable for printing cartes-de-visite.

At a recent meeting of the Berlin Photographic Society, M. Stolze stated that he had experimented with good result upon a silver bath with permanganate of potash; the bath contained 4,000 cubic centimetres of solution, which was quite unserviceable, giving rise to pinholes and other imperfections. To this it was found necessary to add as much as 200 cubic centimetres of saturated permanganate solution in order to impart to the bath a red tinge. The precipitation and discolouration did not take place so rapidly as M. Stolze had been led to expect, as hours elapsed before the red colour changed to yellow. After a few days a yellowish turbidity of the bath was perceived, although the solution had previously been filtered, and it was not until the liquid had been sunned and treated with a few drops of cyanide of potassium that the difficulty was overcome. M. Stolze recommends the employment of permanganate for restoring silver printing baths to which sugar has been added for the purpose of preserving the whites of the albuminized paper.

M. Johannes Grasshoff publishes in the *Mittheilungen* a few remarks upon backgrounds and effects. He criticises the carpets generally used by photographers, intimating that as

a rule they are too good and showy, and that a quiet pattern, free from glare, should be employed. On this account a worn and bleached material will furnish better results than a span new article, as in the photograph the carpet should not be a prominent object, but very subdued in character. He remarks upon the occasional inconsistency of photographers who sometimes produce standing figures upon deal boards with a grand landscape background, and states that the time is evidently not far distant when the public will be treated with open-air scenery with fine carpeted foregrounds. To render an ordinary floor more suitable for landscape backgrounds, M. Grasshoff suggests the use of a wooden ledge, three or four inches wide, and about one inch thick, placed against the background. The ledge must be placed diagonally, so as to slope downwards to the floor, and painted of a dark colour, and covered thickly with glue, upon which dried moss or other similar materials are made to adhere; the join between the margin of the ledge and the floor should be as imperceptible as possible.

Some discussion has taken place at the last two meetings of the Berlin Photographic Society respecting certain collodion gun-cotton which has been received from New York, possessing a yellowish tint, which it imparts to the collodion. M. Kruger experimented with it, and found that the colour was not due to free acid, and that the material when boiled in alcohol remained unchanged, whereas the ordinary kinds were considerably swollen by the treatment; on adding a little iodide of cadmium to the alcoholic liquid obtained from the American sample, a yellowish colouring of the fluid was perceived, which did not take place in the fluids from the other specimens. M. Kruger's results led him to believe that the American gun-cotton had either been prepared in a liquid in the compounding of which the acids had not been used in the right proportion, or the acids themselves were too weak. M. Kleffel had also examined the gun-cotton, but had come to a different conclusion, believing that the colour was due to the acid mixture having been of too high a temperature. He found that the gun-cotton in question did not produce a transparent collodion, but one of a very friable character, when dry; neither did it dissolve entirely in ether.

At the same Society, a few remarks were made relative to the precipitation of residues. It was stated that chemically pure muriatic acid at once threw down the precipitate and clarified the water, whereas ordinary commercial acid often failed after some days in bringing about the same result. M. Junghans suggested the warming of waste liquids to facilitate precipitation, and Dr. Jacobsen recommended the addition of a solution of glue or gelatine to the same, which seemed to possess the property of combining with the precipitate, and falling down with it.

#### THE GODDARD FUND.—REPORT OF THE COMMITTEE.

[We have been requested to publish the following official Report of the Committee of the Goddard Fund.]

The Committee that undertook the management of this Fund beg to lay the following Report before their fellow-Subscribers:—

It will be remembered that in December, 1863, an appeal was made by Mr. Jabez Hughes to raise a fund to relieve the urgent necessities of Mr. J. F. Goddard, in consideration of services rendered to photography in its early days. This appeal was endorsed by Dr. Diamond, G. Shadbolt, Esq., G. Wharton Simpson, Esq. (the Editors of the Journals in which the appeal was made), and T. R. Williams, Esq., who had personally known Mr. Goddard for many years; and these gentlemen accordingly formed themselves into a Committee. The response to the appeal was the handsome amount of £374 2s. The original intention was immediately to purchase an annuity with the money raised; but as Mr. G. was then in feeble health, it was thought that if his life were likely to be a short one, it would be better to administer the money in

larger amounts than could be realized from a purchased annuity. To estimate how long he might probably live, the advice of a skilful physician was taken, who reported, after examining Mr. G., that though he was suffering from bronchial disease and affection of the heart, there was no immediate danger, and he proposed to make another examination after the lapse of twelve months, so that from the progress of the disease in the interval he could more accurately estimate the probable length of Mr. G.'s life. Mr. Goddard was therefore maintained by means of the fund, and at the end of the year underwent another examination. The report then given was that, though the disease had made progress, yet, the constitution being generally a strong one, it was not improbable that Mr. G. might live several years. It was now felt that the wisest course would be to carry out the original intention, and purchase an annuity with the balance of the money. Accordingly, after careful enquiry, an Annuity Office was selected where the largest annual sum could be obtained for the money, and the necessary papers for signature provided. To this Mr. G. objected. Indeed, he had all along demanded that the whole sum should be given to him to expend in any manner he thought proper. The gentleman who had raised the money felt it impossible to listen to this proposition; they represented to Mr. G. that the money was subscribed, in the words of the appeal, to relieve his necessities, and *preserve his remaining years* from the anxieties of physical want; and that if they parted with the money they had no guarantee that the original purpose would be secured. The truth is, that the Committee, from the information supplied by one of their members who had known him longest, had no confidence in Mr. G.'s judgment and prudence in the employment of the money. They were well grounded in this conviction, not only from this knowledge of his past history, but also by the crude schemes by which he proposed to dispose of the fund; the probability being that at the end of six months not a penny would be left, and that he would be in as great distress as ever. Otherwise, nothing would have been more gratifying than in this manner to have terminated the self-imposed trust. But it was felt that it would be neither real kindness to Mr. G. nor justice to the Subscribers—the greater proportion of whom had contributed with an express understanding that an annuity was contemplated—to have to end the matter in this unsatisfactory manner.

The Committee, who have acted all along with perfect unanimity, urgently pressed on Mr. G. the propriety of accepting the money in the form proposed, and promises were made by Mr. G., from time to time, that he would sign the Annuity Office papers; but these promises were as regularly broken. Meanwhile, he was in the constant receipt of sums of money at least equal to the amount he would have received from the Office, and very much larger than he had been receiving from precarious charity at the time when the appeal for help was made.

During these proceedings it was the source of great pain and trouble to those who dispensed the fund to find their best endeavours thwarted by the recipient of the bounty. In this state of the affairs Mr. G., after a short illness, died. Soon after, a Mr. G. Brothers produced a will, and, as executor, claimed that the balance of the fund should be placed in his hands, he (Mr. G. Brothers) being one of the chief legatees. On consulting a solicitor, the Committee were informed that they had no power to devote the fund to any purpose but that for which it was raised; namely, to relieve the necessities of Mr. Goddard. That object being, as far as possible achieved, the balance at his death reverted to the original Subscribers. On this advice action would immediately have been taken to distribute the money among the donors, but, litigation being threatened, they were advised, legally, that it was desirable to delay final proceedings. Sufficient time having elapsed, the Committee are unwilling to permit further delay in the removal of their responsibility in regard to the balance of funds, and, as nothing prevents the legal advice being carried out, the money will at once be distributed. The remaining balance in hand will permit a return of 12s. 6d. in the £ to the Subscribers, which sum, where their addresses are known, will be immediately remitted.

In making this repayment, it is gratifying to the Committee, and will be to the Subscribers, to know that—despite all the troubles that have arisen—Mr. G. was relieved from the deep penury in which he was found, that he received during his life more than he would have done from an annuity, and that

all expenses incurred in his illness, and in connection with his death and burial, including a memorial over his grave, have been defrayed out of the funds so munificently contributed.

#### STATEMENT OF INCOME AND EXPENSES.

JABEZ HUGHES.

November, 1868.

#### ON A NEW SERIES OF CHEMICAL REACTIONS PRODUCED BY LIGHT.

BY JOHN TYNDALL, LL.D., F.R.S., ETC.\*

*Iodide of Isopropyl.*—The action of light upon the vapour of this description is at first more languid than upon iodide of allyl; indeed, many beautiful reactions may be overlooked in consequence of this languor at the commencement. After some minutes' exposure, however, clouds begin to form, which grow in density and in beauty as the light continues to act. In every experiment hitherto made with this substance, the column of cloud which filled the experimental tube was divided into two distinct parts near the middle of the tube. In one experiment a globe of cloud formed at the centre, from which, right and left, issued an axis which united the globe with the two adjacent cylinders. Both globe and cylinders were animated by a common motion of rotation. As the action continued, paroxysms of motion were manifested; the various parts of the cloud would rush through each other with sudden violence. During these motions beautiful and grotesque cloud-forms were developed. At some places the nebulous mass would become ribbed so as to resemble the graining of wood; a longitudinal motion would at times generate in it a series of curved transverse bands, the retarding influence of the sides of the tube causing an appearance resembling, on a small scale, the dirt-bands of the *Mer de Glace*. In the anterior portion of the tube those sudden commotions were most intense: here buds of cloud would sprout forth, and grow, in a few seconds, into perfect flower-like forms. The most curious appearance that I noticed was that of a cloud resembling a serpent's head: it grew rapidly; a mouth was formed, and from the mouth a cord of cloud resembling a tongue was rapidly discharged. The cloud of iodide of isopropyl had a character of its own, and differed materially from all others that I had seen. A gorgeous mauve colour was developed in the last twelve inches of the tube; the vapour of iodine was present, and it may have been the sky-blue produced by the precipitated particles which, mingling with the purple of the iodine, produced this splendid mauve. As in all other cases here adduced, the effects were proved to be due to the light; they never occurred in darkness.

I should like to guard myself against saying more than the facts warrant regarding the chemical effects produced by light in the following three substances; but the physical appearances are so exceedingly singular that I do not hesitate to describe them.

*Hydrobromic Acid.*—The aqueous solution of this acid was placed in a small Woulfe's flask, and carried into the experimental tube by a current of air.

The tube being filled with the mixture of acid, aqueous vapour, and air, the beam was sent through it, the lens at the same time being so placed as to produce a cone of very intense light. Two minutes elapsed before anything was visible; but at the end of this time a faint bluish cloud appeared to hang itself on the most concentrated portion of the beam.

Soon afterwards a second cloud was formed five inches further down the experimental tube. Both clouds were united by a slender cord of cloud of the same bluish tint as themselves.

As the action of the light continued, the first cloud gradually resolved itself into a series of parallel disks of exquisite delicacy; the disks rotated round an axis perpendicular to their surfaces, and finally they blended together to produce a screw surface with an inclined generatrix. This surface gradually changed into a filmy funnel, from the end of which the "cord" extended to the cloud in advance. This also underwent modification. It resolved itself into a series of strata resembling those of the electric discharge. After a little time, and through changes which it was difficult to follow, both clouds presented the appearance of a series of concentric funnels set one within the other, the interior ones being seen through the spectral walls of the outer ones; those of the distant cloud resembled claret-glasses in shape. As many as six funnels were thus concentrically set together, the two series being united by the delicate cord of cloud already referred to. Other cords and slender tubes were afterwards formed, and they coiled themselves in spirals around and along the funnels.

Rendering the light along the connecting-cord more intense, it diminished in thickness and became whiter; this was a consequence of the enlargement of its particles. The cord finally disappeared, while the funnels melted into two ghost-like films, shaped like parasols. The films were barely visible, being of an exceedingly delicate blue tint; they seemed woven of blue air. To compare them with cobweb or with gauze would be to liken them to something infinitely grosser than themselves.

In a second trial the result was very much the same. A cloud which soon assumed the parasol shape was formed in front, and five inches lower down another cloud was formed, in which the funnels already referred to were considerably sharpened. It was connected as before by a filament with the cloud in front, and it ended in a spear-point which extended twelve inches further down the tube.

After many changes, the film in front assumed the shape of a bell, to the convex surface of which a hollow cylinder about two inches long attached itself. After some time this cylinder broke away from the bell and formed itself into an iridescent ring, which, without apparent connection with anything else, rotated on its axis in the middle of the tube. The inner diameter of this ring was nearly an inch in length, and its outer diameter nearly an inch and a half.

The whole cloud composed of these heterogeneous parts was animated throughout by a motion of rotation. The rapidity of the rotation could be augmented by intensifying the beam. The disks, funnels, strata, and convolutions of the cloud exhibited at times diffraction colours, which changed colour with every motion of the observer's eye.

Moisture appeared to be favourable to the production of these appearances; and it hence became a question how far they were really produced by the light; hydrobromic acid, even from its solution, fumes when it comes into contact with the aqueous vapour of the air; its residence in water does not appear to satisfy its appetite for the liquid. The same effect, as everybody knows, is observed in the solution of hydrochloric acid. Might not, then, those wonderfully shaped clouds be produced by an action of this kind, the presence of the light being an unnecessary accident?

The hydrobromic acid was permitted to enter the experimental tube and remain in diffuse daylight for five minutes. On darkening the room and sending the electric beam

\* Continued from p. 572.

through it, the tube was optically empty. Two minutes' action of the light caused the clouds to appear, and they afterwards went through the same variety of changes as before.

No matter how long the hydrobromic acid was allowed to remain in the tube, no action occurred until the luminous beam was brought into play. The tube filled with the mixture of air, aqueous vapour, and hydrobromic acid was permitted to remain for fifteen minutes in the dark. On sending the beam through the tube it was found optically empty; but two minutes' action of the light developed the clouds as before.

Permitting the beam to pass through a layer of water before entering the experimental tube, no diminution of its chemical energy was observed. Permitting it to pass through a solution of *hydrobromic acid*, of the same thickness, the chemical energy of the beam was wholly destroyed. This shows that the vibrations of the dissolved acid are synchronous with those of the gaseous acid, and is a new proof that the constituent atoms of the molecule, and not the molecule itself, is the seat of absorption.

*Hydrochloric Acid.*—The aqueous solution of this acid was also employed, and treated like the solution of hydrobromic acid. I intend to invoke the aid of an artistic friend in an effort to reproduce the effects observed during the decomposition, if such it be, of hydrochloric acid by light. But artistic skill must, I fear, fail to convey a notion of them. The cloud was of slow growth, requiring fifteen to twenty minutes for its full development. It was then divided into four or five sections, every adjacent two of which were united by a slender axial cord. Each of these sections possessed an exceedingly complex and ornate structure, exhibiting ribs, spears, funnels, leaves, involved scrolls, and iridescent fleure-de-lis. Still the structure of the cloud, from beginning to end, was perfectly symmetrical; it was a cloud of revolution, its corresponding points being at equal distances from the axis of the beam. There are many points of resemblance between the clouds of hydrochloric and hydrobromic acid, and both are perfectly distinct from anything obtainable from the substances previously mentioned; in fact, every liquid appears to have its own special cloud, varying only within narrow limits from a normal type. The formation of the cloud depends rather upon its own inherent forces than upon the environment. It is true that, by warming or chilling the experimental tube at certain points, extraordinary flexures and whirlwinds may be produced; but with a perfectly constant condition of tube, specific differences of cloud structure are revealed, the peculiarity of each substance stamping itself apparently upon the precipitated vapour derived from its decomposition.

When the beam, before entering the experimental tube, was sent through a layer of the aqueous acid, thirteen minutes' exposure produced no action. A layer of water being substituted for the layer of acid, one minute's exposure sufficed to set up the decomposition.

*Hydriodic Acid.*—The aqueous solution of this acid was also employed. On first subjecting it to the action of light no visible effect was produced; but subsequent trials developed a very extraordinary one. A family resemblance pervades the nebulae of hydriodic, hydrobromic, and hydrochloric acids. In all three cases, for example, the action commenced by the formation of two small clouds united by a cord; it was very slow, and the growth of the cloud in density and beauty very gradual. The most vivid green and crimson that I have yet observed were exhibited by this substance in the earlier stages of the action. The development of the cloud was like that of an organism, from a more or less formless mass at the commencement to a structure of marvellous complexity. I have seen nothing so astonishing as the effect obtained, on the 28th of October, with hydriodic acid. The cloud extended for about eighteen inches along the tube, and gradually shifted its position from the end

nearest the lamp to the most distant end. The portion quitted by the cloud proper was filled by an amorphous haze, the decomposition which was progressing lower down being here apparently complete. A spectral cone turned its apex towards the distant end of the tube, and from its circular base filmy drapery seemed to fall. Placed on the base of the cone was an exquisite vase, from the interior of which sprang another vase of similar shape; over the edges of these vases fell the faintest clouds, resembling spectral sheets of liquid. From the centre of the upper vase a straight cord of cloud passed for some distance along the axis of the experimental tube, and at each side of this cord two involved and highly-iridescent vortices were generated. The frontal portion of the cloud, which the cord penetrated, assumed in succession the forms of roses, tulips, and sunflowers. It also passed through the appearance of a series of beautifully-shaped bottles placed one within the other. Once it presented the shape of a fish, with eyes, gills, and feelers. The light was suspended for several minutes, and the tube and its cloud permitted to remain undisturbed in darkness. On re-igniting the lamp the cloud was seen apparently motionless within the tube; much of its colour had gone, but its beauty of form was unimpaired. Many of its parts were calculated to remind one of Gassiot's discharges; but in complexity, and, indeed, in beauty, the discharges would not bear comparison with these arrangements of cloud. A friend to whom I showed the cloud likened it to one of those jelly-like marine organisms which a film barely capable of reflecting the light rendere visible. Indeed no other comparison is so suitable; and not only did the perfect symmetry of the exterior suggest this idea, but the exquisite easing and folding of film within film suggested the internal economy of a highly-complex organism. The *twoness* of the animal form was displayed throughout, and no coil, disk, or speck existed on one side of the axis of the tube that had not its exact counterpart at an equal distance on the other. I looked in wonder at this extraordinary production for nearly two hours.\*

The precise conditions necessary to render the production of the effects observed with hydrobromic, hydrochloric, and hydriodic acids a certainty, have not yet been determined. Air, moreover, is the only vehicle which has been employed here. I hazard no opinion as to the chemical nature of these reactions. The dry acids, moreover, I have not yet examined.

## Correspondence.

### A PHOTOGRAPHERS' RELIEF FUND.

DEAR SIR,—I think that a serious error will be committed if, in forming a Relief Fund, a spirit of exclusiveness be permitted to govern the arrangements. Some of your correspondents seem anxious to draw a rigid line in defining who may be legitimately styled photographers, and so be properly qualified to claim aid from such a fund. And I notice that in a leader you raise the question whether the "hangers-on" to photography may not possibly be induced to continue in that equivocal position, with a view to the aid such a fund would supply. I think that distinctions between photographers *pur sang* and those of a more hybrid character are inadmissible here. The fitness of a claimant, both as to the extent of his necessities and the nature of his claims, will doubtless be considered by the committee in charge of the Fund; and it is scarcely worth while considering how the benefits of such a fund may be best narrowed until, at least, it is in existence.

Although not a professional photographer, nor one who by any stretch of probability would be likely to need the aid of

\* "It is as perfect as if turned in a lathe." "It would prove exceedingly valuable to pattern-designers," were remarks made by my assistants as they watched the experiment. Mr. Ladd, who is intimately acquainted with the phenomena of the electric discharge through rarefied media, remarked that no effect he had ever seen could compete in point of beauty and complexity with the appearance here imperfectly described. I mention this to indicate how the phenomena affected other eyes than mine.

such a fund, I will subscribe a guinea a year.—Your obliged servant,  
P.

November 20th, 1868.

SIR,—The plan of your correspondent who is ready to pay in £5, and thinks to make up a fund not less from any person, would be worth the trouble—would, I think, be a bar to making up a respectable fund. How many employes have £5 to spare? But a small portion, I fear. Let the employes subscribe £2 to £5, according to their means, and the principals not less than £5.

For my part, I have a five-pound note ready.—I am, yours, &c.,  
W. MATHEWS, Another Old Daguerreotypist.

Bury-St.-Edmunds, November 30.

[We conceive that any committee who may undertake the management of such a fund will regard no sum as too small to accept and duly enter into their accounts. In the list of promises already sent to us there are sums ranging from 5s. to £50.—Ed.]

### LUX GRAPHICUS IN DEFENCE.

MY DEAR SIR,—Although the clear and noble defence of your right to conduct your journal on the wise and broad principles you have so lucidly laid down in your article entitled "Amateur Criticism" renders a reply from me almost unnecessary, I will, if you please, answer those questions and remarks which are most directly addressed to me by your correspondent "Lux in Tenebras," and honestly endeavour to throw a little more light on the darkness in which he is evidently enveloped, not reluctant, however, to my real name, but to my reasons for giving the opinions to which he takes exception.

Answering his questions in the order in which he puts them, I assign the following reasons for saying that Messrs. Robinson and Cherrill's group of children was "too suggestive of scissors and paste to be a good picture." Firstly, the figures are too much scattered and detached, in my estimation, to present that appearance of unity and relation which is absolutely necessary in good composition, no matter whether the picture be produced by combination printing or from one negative. Secondly, the boy seated on the right hand side of the picture, and placed against a dark mass of foreground, presented to my eye the appearance of flatness—of being cut out, and laid or pasted on that portion of the picture. Hence the origin of the term I used. It may not have been the softest phrase I could have employed, but, such as it was, it presented itself to my mind while writing the critique, and has the merit, at least, of being outspoken candour. I cordially agree with all that you and your correspondent say concerning the photographic beauties of Messrs. Robinson and Cherrill's picture of the group of children, and had it not been for the defects which I noticed and have described, I would have unhesitatingly pronounced it a noble picture.

The second question which "Lux in Tenebras" puts to me, "Does he mean that scissors and paste are illegitimate aids, &c.?" is best answered by referring him to my comments on Messrs. Robinson and Cherrill's picture of "Returning Home," which picture is produced by similar means, but much more successfully. If "Lux in Tenebras" cannot see as I do, or coincide with my opinions, I do not blame him. He has as much right to hold his own views and give expression to individual judgment as I have. It is such freedom of thought and action that has made photography what it is, both artistically and scientifically considered.

Your other "unknown gentleman" also takes exception to what I said about Mr. Fry's and Mr. Blanchard's pictures, and charges me with "a piece of exaggeration, indulged in to introduce a feeble joke." Granted. The exaggeration was too apparent to escape the notice of the least observant, and the joke was of necessity "feeble," seeing that it was but a dim reflection of a weak original. Jokes are not my "forte points." Nevertheless, what I said of Mr. Fry's pictures was true. With one or two beautiful exceptions they were too white and chalky, possessing a great deal too much contrast. As to their being "the gems of the room" is an idea too absurd to be entertained for a moment. What I said of Mr. Blanchard's works I readily confirm. But, be it understood, that my encomiums

were not unqualified. When alluding to his pictures in my critique I said, "Some of which are quite equal to the French artist's best works," &c. As far as my judgment could guide me I gave, in all cases, a fair and honest criticism, according to my own convictions; neither sparing praise nor condemnation where I thought it was merited. If a critique be made at all, it should be done honestly and fearlessly, without prejudice or bias of any description, and in a spirit of fairness that cannot be imputed to any unworthy motives. Otherwise, if a critique consist of unqualified praise when censure is merited, it would not be criticism, but blind, ignorant, or venal adulation. And as such it should be received, by exhibitors in particular.

In conclusion, I beg to tender my thanks to "Lux in Tenebras" for his outspoken objections to the opinions I advanced. Though he indulges in the practice of what he condemns, he is, at least, fair and honourable in challenging me to fight with my own weapons, which is a much more manly and straightforward course than to use others at random and in the dark, which would be much more likely to strike and injure an innocent friend than wound a supposed enemy.—I am, sir, yours very truly,  
LUX GRAPHICUS.

November 30th, 1868.

### IODIDE OF MERCURY-INTENSIFYING.

SIR,—A few weeks ago you favoured the readers of the News with an article on intensifying with mercury. That article was doubly interesting to me, as I had during the summer used the process for the first time, and I found several discrepancies in my practice fully and satisfactorily explained. One discrepancy, however, I do not understand, and it is that having produced a negative with the olive tint and put it by to dry, I next morning found it perfectly yellow, whilst three or four more negatives produced at the same time retained their colour. In every case I used a final wash of very dilute hydrosulphate of ammonia, as recommended in the Year-Book of 1867, and it is the absence of this chemical in the article referred to that induces me to trouble you with this letter. May I therefore ask you what part the hydrosulphate of ammonia is supposed to take in the final operation of intensifying, and whether it is better that, when the mercury process is employed, the developing solution should not contain gelatine, honey, sugar, or any such organic substances?—I am, sir, your obedient servant,  
AMATEUR.

London, November 26th, 1868.

[It is not customary to apply a solution of hydrosulphate of ammonia when the iodide of mercury intensifying process is used. Some operators apply this solution after bi-chloride of mercury, the object being to produce a film of sulphide of mercury, which is black, or very dark brown, but, as a rule, gives a less delicate negative than the iodide. Where the mercury intensifying process is used, it is not desirable to employ organico-iron developers.—Ed.]

### AMORPHOUS ALBUMINIZED PAPER.

SIR,—In calling your attention to this subject, mentioned in your issue of the 13th inst., I wish to say that I had formerly great difficulty in procuring a continuous supply of this very useful paper, till I got a photographic chemist in this town to procure some from Berlin, where it was made expressly for me. I much regret that so useful a paper should be neglected, as its advantage over the simply salted paper is, that it not only produces a more brilliant print, but, what is of more importance for worked-up pictures, the artist can put one wash of colour over another almost as well as on drawing paper.

If any gentleman would wish to know where I get this matt albumen paper from, I should have great pleasure in informing him.—And remain, yours obediently,  
JOHN W. BURTON.

3, Haymarket, Leicester, November 25th, 1868.

PS.—I forgot to say that using the back of albumen paper is a good makeshift, but the watermarks are a decided drawback.

## Talk in the Studio.

**SOUTH LONDON ANNUAL DINNER.**—The annual dinner of the South London Photographic Society will be held on Saturday, the 12th inst, at the Salutation Tavern, Newgate Street, at five o'clock. Members can procure their tickets at the regular meeting on the evening of the 10th, or of Mr. How, Foster Lane.

**SALE OF POISONS.**—We notice that some of the photographic dealers are issuing circulars calling attention to the fact that the new Sale of Poisons Act will come into operation at the end of this year, and recommending photographers to lay in a stock, which they offer, until the end of the year, on favourable terms, after which time they will cease to supply cyanide of potassium, bichloride of mercury, &c., in accordance with the provisions of the Act.

**ARTISTIC COPYRIGHT.**—At the opening of a new session of the Society of Arts, London, Henry Lennox, in the inaugural address, referred to this subject as follows:—"First, I may allude to the Artistic Copyright Bill, drawn up by the Council, which it is intended to again introduce during the coming session. You are all aware that it was last year introduced by Lord Westbury, but, owing to circumstances which I need not further allude to, it did not pass into law. I believe there is no one belonging to this Society who does not entirely approve of the objects of that bill, which is to supplement the Act of 1862, also the work of this Society, and, by consolidating and amending the laws of artistic copyright generally, to bring this branch of the law into one consistent whole, worthy of the nation, and more in harmony with the laws which regulate this subject in foreign countries. It must also be borne in mind that it is not ourselves only who are concerned in this matter, but also various foreign states, at present thirteen in number, with whom we have conventions for international copyright, and who feel deeply the present defective state of our artistic copyright law."

**STUDIO ACCESSORIES.**—We have received from Mr. D. H. Cussans, of Southport, some photographs of very excellent studio accessories, such as a posing-chair, cabinet, and table. The designs are very good, and free from vulgarity. We understand that they are free from composition or tinsel of any kind, being manufactured in walnut wood, and covered, where necessary, in Utrecht velvet. The manufacture of this kind of studio furniture is a step in the right direction, and should be encouraged by photographers.

**AMATEUR PHOTOGRAPHIC SOCIETY.**—At a recent meeting of this Society, notice of which reaches us just as we go to press, prizes to the amount of about £80 were awarded.

**PIRACY.**—Solomon Alber, a Jew, of 1, Great Prescott Street, Whitechapel, appeared before Mr. Paget to answer 25 summonses taken out against him by Mr. Henry Graves, the printseller and picture dealer of Pall Mall, for pirating copies of the engravings of the "Railway Station," by Frith, "My First Sermon," "My Second Sermon," the "Anxious Mother," and the "Parable of the Lost Piece of Money," of which Mr. Graves possessed the copyright. The defendant was also charged with importing a copy of paintings prepared from the same designs. The penalties amounted to £125. Mr. Graves said the painting and engraving of the "Railway Station" cost him £24,000. He was still in possession of the original, which was not consumed when his gallery was destroyed by fire. After some discussion between the parties the defendant agreed to pay Mr. Graves £70 and all the costs, and to sign an undertaking in writing not to repeat the offence.

**A NOVEL PHOTOGRAPHIC GALLERY.**—General Grant is coming to New York to spend a week or two. We take the liberty of letting out one of his secrets. He intends to get the photograph of every place-hunter that approaches him, and to send all off to Washington, to be filed in a conspicuous place for his information during the entire term of his administration.—*New York Times.*

**NATURAL NEGATIVES.**—A provincial journal says:—"Mr. James Thompson, of Glasgow, has contrived a new method of

producing photographic negatives of geological specimens. He saws from the stones thin slices containing fossil remains or other specimens; these, when polished, are so thin and transparent that they may be used as negatives for photographic printing upon the usual sensitive paper. Beautiful prints are thus obtained, having all the fidelity of nature itself.

**PHOTOGRAPHS TO MEASURE.**—We find amongst the facetiae of a contemporary the following:—"A photographer in Suffolk was recently visited by a young woman, who with sweet simplicity asked, 'How long does it take to get my photograph after leaving my measure?'"

## To Correspondents.

**NO THEORIST** sends a somewhat strongly-worded letter, commenting on the letter of Mr. Fry respecting the use of nitrate of soda in the printing bath, in the course of which he says:—"I have yet to learn that because I cannot give a good theoretical reason for everything I do in photography I am to abandon it. You have often repeated, sir, that practice is a head of theory in photography. If a formula seemed wrong, and yet gave me good pictures, I should stick to it; much more shall I stick to the use of nitrate of soda, the advantage of which I have practically proved for years, seeing that, so far from seeming wrong, I think that a score of good theoretical reasons could be given to show that it ought to be of service in the printing bath." We should have preferred to insert our correspondent's letter in its entirety, as it was sent for publication, but for three reasons: It consists chiefly of assertions and opinions, it is strongly worded, and it is anonymous. Anonymous letters are quite eligible for publication if they contain instruction or reasoning; but anonymously expressed opinions merely, carry no weight with them. If anonymous opinions are unsuitable for publication, they are still less suitable if they are expressed in strong language, addressed against some one who has signed his name to his communication. If a war of opinions were desirable, it would be obviously unfair whilst one writes in his proper person for the other to shelter himself under an anonyne. Take a notorious illustration, familiar to metropolitan photographic circles, of the necessary unfairness and occasional dishonesty of such a case: a person who occasionally writes in another journal, on subjects connected with photography, in his own name, also writes under some other apparently real name, confirming his own statements, and complimenting himself by the application to his first communication of such words as *able* and *honest*; and then generally writes a few anonymous notes, still further supporting the statements made in the article under his own name. Although such a course is seen through, and excites contempt, it deceives some, as it is intended to do. As a general rule, it will be seen that letters of mere opinion possess more value if they bear the writer's name; imperatively they should do so if they make statements or comments affecting the interests or feelings of others. An abstract argument loses nothing by being anonymous, as it should stand or fall by its own force and letters devoted to the discussion of a subject, or devoted to practical matters, need not necessarily bear the name of the writer. Our correspondent thinks he could give a score of good theoretical reasons for the use of nitrate of soda. Why did he not devote part of his letter to their statement, instead of indulging in personal remarks which are smart, but not instructive. We, who have many reasons for approving of the use of nitrate of soda, should have been glad to give them publicity.

**LOOKER-ON.**—We place the answer to "Looker-on" in immediate contact with that of "No Theorist," because he writes on the same subject, and although with opposite views, yet much of our reply to "No Theorist" is applicable to the letter of "Looker-on." He says:—"Whatever photographers may think of Mr. Fry's condemnation of nitrate of soda in the printing bath, I for one agree with him in regarding it as an abomination." He gives no reasons any more than does "No Theorist," but further proceeds to express approval of Mr. Fry's condemnation of the "high-falutin style" of some writers, and to add further condemnatory comments of his own, kindly giving the Editor some advice as to the proper mode of dealing with the articles of professors of the "high-falutin" school, for which we are duly grateful. Personally, we have a strong objection to "high-falutin," and believe that, in a scientific journal, either a stilted or a flippancy style is out of place; brevity, clearness, terseness are required in writings intended to instruct; but when gentlemen have instruction to convey, there is some degree of fairness in permitting them, within reasonable bounds, to do it in their own style and in their own language.

O. P.—With the exception of the manual of instructions issued by Mr. Hughes, and the second part of the "Practical Photography" published by Messrs. Negretti and Zambra, and our own YEAR-BOOKS, we know of no work containing any extended account of the various dry processes. There is no work devoted exclusively to that subject. It would not be piracy to compile such a work if care be taken that the matter is re-written, or, when any other work is made to contribute, that due acknowledgment be made. Let us know if you contemplate such a step.

W. J. A. G.—Photography in winter is always more difficult than in summer; but in clear frosty weather there is generally some good light. It is desirable to maintain a moderately warm temperature, both in the studio and in the dark room; but it is not necessary to keep it as high as 63°, nor would it be easy to do so. Keep it somewhere between 50° and 60°, taking care, if possible, to avoid a lower temperature than 50°. Use a 40-grain silver bath, and a tolerably strong plain iron and acetic acid developer. As a rule, avoid warming bath and developer much beyond the temperature of the room, and, as a rule, not at all. Use as much light as you can admit, and as large apertures in your lenses as the subject will permit, and give full exposures. White reflecting screens are often useful. Read an article in our YEAR-BOOK for 1867 on Photographing in Winter, which is full of valuable hints. The print you enclose is very good, but a little under-exposed. There is every promise of your success by that process if you persevere; but, so far as possible, use the wet process in winter.

FENIAN (Belfast).—The repeated immersion of coated plates in your bath, and leaving them all night, is most probably the cause of your pinholes. The bath has become supersaturated with iodide of silver, one of the most fertile causes of pinholes. Add to your bath an equal bulk of distilled water (this will precipitate a large portion of the iodide), filter, and then add crystals of nitrate of silver in proportion to the water which has been added. The markings you indicate are suggestive of a damp or dirty plate. Craze markings chiefly arise from excess of water in the collodion, which is scarcely likely to be the case with the sample you describe. It may arise from immersing the plate too soon after coating. Let it set well, and keep the plate in motion all the time immediately after immersion. 2. The maker you mention in question 2 will supply you with a good article, we believe. 3. The washing apparatus you describe will, we doubt not, answer very well.

HYP0.—As a rule, publishers prefer to buy prints rather than negatives. We cannot tell you of any one who, as a rule, purchases negatives. Such houses as Marion and Co., or the London Stereoscopic Company, are the best to apply to.

X. Y.—The lenses you name are moderately good; certainly not equal to those of the best English makers. 2. Your question is scarcely sufficiently definite. In speaking of eight or ten feet of skylight you doubtless mean that amount in length, but you do not refer to the width, nor do you state whether there is to be any side-light, nor how much. Write again a little more explicitly, and we will give our best attention to your query.

J. TURNER.—See article in our last on dirty whites in developed prints. 2. Allow the prints to remain in the fixing bath about twenty minutes. It depends on the size of the print and the quantity of solution as to whether you should use it fresh for each print. It may not always be necessary to have it fresh; but with large prints it is a good precaution to use it so. We have published very full information on enlarging from time to time. If you have the volumes, look through them, and you will find information on every point connected with enlarging. Any special difficulties we shall have pleasure in advising you about; but it is difficult in this column to give general information on any topic.

A. PARRY.—We do not know of any place where silk or linen is sold with an especial view to photography; nor do we think that any special fitness is necessary. Ordinary fine linen cambric, or muslin, and fine white silk will serve. Perhaps some of our correspondents who may have worked in this direction will state whether they have found any especial kind desirable, and where it can be procured.

COLLODION.—The rapid rectilinear is better for out-of-door work and general purposes than the D, the latter better for portraiture; but the first is the most generally useful. 2. Our personal confidence is not shaken in England's process, but the experience he has had shows how imperative is extreme care in manipulation. This is the case in all the dry processes to a much greater extent than in the wet. The results of the last exhibition would suggest the superiority of the gum process, and nothing, indeed, could be better in careful hands; but for general trustworthiness we still believe that the collodio-albumei is the safest. Thanks for your suggestion. We aim to consider the interests of all photographers, professional and amateur, alike; but, as a rule, all that interests

professional photographers is also interesting to amateurs. There is no point and no process interesting to amateurs, that we know of, in regard to which we do not give the fullest information.

H. S.—The oxyhydrogen light is more powerful than the oxycaleium light. You will find very full information on the subject in a pamphlet published by Negretti and Zambra, price one shilling.

VENATOR.—We always recommend the wet process in preference to any dry process, where it can conveniently be used; but the gum plates yield such delicate and rapid results that in the hands of a skilled manipulator they may save much trouble in the class of work you name. 2. Clean rain water, purified by means of a little permanganate of potash, is the best substitute for distilled water. Animal charcoal is not quite admissible as a purifier, as some of the phosphates it contains would be dissolved by the water, and would interfere with the results. Your specimens have not reached us at the time we write. It is not necessary to use fresh water for washing each plate, unless a very small quantity is used.

CARL MEINERTH (Newburyport, U.S.).—Thanks for the specimens and your interesting letter. It is always pleasant to us to receive such long friendly and confidential letters from our readers at a distance. We shall notice the cards shortly; they admirably illustrate the effect of printing in varied degrees of deviation from perfect contact, and so securing varied degrees of the softening effect. It is very singular how jealous photographers have ever been of any of their body attempting to secure his ideas by means of a patent, especially in cases where a special method of definitely producing something is devised, in regard to which some indefinite ideas have been floating about.

THOMAS GULLIVER.—Thanks.

J. MARTIN.—Received.

WM. BLAIR (Perth).—Received, with many thanks. The examples of the simplified processes are very admirable. We shall have something to say upon the subject shortly.

A. BROTHERS.—Thanks.

DR. LIESEGANG.—Received. Thanks.

DR. JACOBSEN.—Received. Thanks. We will write shortly.

J. W. SMITH.—We shall have pleasure in proposing you. You will, on election and payment, be entitled to this year's presentation prints.

H. NEALE.—Thanks. In our next.

OXONIENSIS and several Correspondents in our next.

Several Articles in type are necessarily deferred for lack of space.

### Photographs Registered.

- Mr. J. B. GIBSON, Hexham,  
Photograph of Countess of Derwentwater
- Mr. J. COLLINGS, Cardiff,  
Two Photographs of Mr. H. S. Giffard.
- Mr. TOLLERTON, Lincoln,  
Two Photographs of Mr. J. H. Palmer, M.P.
- Mr. GREEN, Coventry,  
Four Photographs of A. S. Hill, Esq., Q.C.
- Mr. W. LAWRENCE, Dublin,  
Five Photographs of Prince Edward of Saxe Weimar.
- Mr. H. J. BROOKS, Abingdon,  
Photograph of G. Lushington, Esq.
- Mr. W. HECTOR, Crediton,  
Photograph of Oakmeur Valley, Devon.
- Mr. DONNAN, Northampton,  
Photograph of Mr. Ward Hunt.
- Mrs. H. R. WILLIAMS, Bath,  
Photograph of Rev. H. F. Lyte.

\* \* All photographs forwarded to the Publisher for registration receive attention at once; but the pressure on our space sometimes compels us to defer the acknowledgment in this column. It should be borne in mind, therefore, that non-acknowledgment at once does not necessarily imply non-receipt or non-registration.

All Communications for the Editor to be addressed to 15 Gough Square, Fleet Street, London, E.C.

## SIMPLIFIED CARBON PRINTING.

WE were favoured a few weeks ago by Mr. Blair, of Perth, with an admirable selection of examples of carbon printing by the simplified methods upon which he has for some time been engaged in experiment, and in which he has attained a degree of success which gives them the highest interest.

The prints consist of two classes, of each of which we have several excellent examples. The first class, amongst which we have both portraits and landscapes, consists of prints produced upon a tissue similar to Mr. Swan's, but with only a single transfer. Instead of the tissue being mounted on a temporary support for the purpose of development, and afterwards again transferred to the paper which serves as its permanent basis, the tissue here, after exposure, is mounted at once, face downwards, on the paper which is intended to form part of the picture, and is developed and finished upon that paper. Various modes of effecting this end have been attempted before; but in the prints before us Mr. Blair has secured an unusual degree of success. Another interesting peculiarity of some of these examples is found in the fact, that in preparing the tissue, a double layer of colour, of two distinct tints, has been used, which gives to the lighter half-tones a peculiarly warm and pleasant glow. The negatives used in producing the carbon prints with a single transfer are of course reversed or transferred negatives.

Still more interesting than these is another series, in which no transfer whatever is used. Two of these are on plain paper, and two on albuminized paper, and in all of them there is a degree of excellence which presents something considerably more than merely good promise. Although obtained direct without transfer, they possess an admirable degree of half-tone. A "Bit of Quarrymill Dam," a landscape with some fine foliage and water, is a very charming picture. "Marshall's Monument, Perth," is an architectural subject produced without transfer on albuminized paper, a pleasing picture with good half-tone, as, indeed, have all the examples. A portrait by the same process which we received from Mr. Blair two or three months ago was not equal in half-tone to these landscapes. Whether this indicates progress in the process, or its greater suitability for landscape work, we cannot say; but we shall look with interest for further indications of the capabilities of the process, as well as for some account of the *modus operandi* employed in producing the excellent results.

On this score any remarks we can offer can only be conjecture, and we may say at once that, so far as we can see, only two methods would have been available: one, the preparation of a very thin coating of pigment, gelatine, and bichromate, thoroughly rubbed into the texture of the paper, which, on developing, presenting various degrees of insolubility,

according to the more or less perfect action of light, would give some degree of half-tone; but not nearly so much, we believe, as Mr. Blair has obtained here. The other method would consist in printing through the prepared paper, probably after washing the back, to remove the yellow tint caused by the bichromate. Possibly Mr. Blair has some new and improved method of effecting these known operations, or possibly he has a method not dreamed of by others. Certain it is that the devotion of years to the carbon process—and few men have remained more constant to a very early love—has, in his hands, produced most excellent results.

## WARMING THE DARK ROOM AND CHEMICALS.

SOME recent enquiries have reached us as to the best mode of keeping the temperature of the dark room and of the chemicals used therein from falling too low during the cold winter months. The best plan much depends on the especial circumstances of each case. For most cases nothing can be better than the heating and ventilating stove described by Mr. Hockin in our last YEAR-BOOK. We may, however, mention a plan of exceeding simplicity and economy which we have recently seen.

It is unnecessary here to enter into any preliminary comment on the injurious effect of extreme cold in retarding photographic operations, or on the importance of keeping all the solutions at one temperature, and that, if possible, not much lower than 50° Fahrenheit. The arrangement to which we refer, which seemed as efficient as simple, was in operation in Mr. Blanchard's dark room, and consisted of a small ring gas burner turned on so as to give a very small flame. As, however, the products of the combustion of gas might be injurious if constantly present in a dark room, Mr. Blanchard had improvised a very simple method of getting rid of them. A large tin funnel was inverted over the burner, and to the small end a piece of tin pipe was attached, and carried out of the window. This arrangement served two purposes: it provided a chimney to carry off the products of combustion, and it concentrated the heat in the neighbourhood where it was required, keeping the nitrate bath, and other solutions all placed near, at a satisfactory temperature. It is probable that a small lamp treated the same way would answer the same purpose.

## AN ART CRITIC ON THE LATE EXHIBITION.

IT is sometimes good to see ourselves as others see us, although we may have a profound conviction that "those others" are wrong, and their views shared by few. We subjoin a criticism on the late exhibition in Conduit Street, given amongst the "Notes and Incidents" of the month in

the last number of the *Gentleman's Magazine*. It runs as follows:—

When the photographic fever was at its height, and every hobby-rider was buying cameras and dirtying his fingers with silver solutions, exhibitions of sun-pictures were of as regular recurrence as those of the painter's productions. But as the fever subsided, the shows lost interest, and were discontinued. Now they have been revived on a modest scale, the London Photographic Society having last year and this invited the artists to send specimens in an informal way, to make a collection for a *conversazione* exhibition. The walls of the Architectural Societies' rooms in Conduit Street were thus richly covered on the 10th of the past month, and an opportunity offered for forming a tolerably fair estimate of the progress that eight or ten years have wrought in the light-painter's art. This is less than might have been expected. The majority of the specimens shown were portraits; landscapes were few, and of no higher merit than many produced a dozen years ago; this branch of photography has remained at a standstill. But the portraits were far in advance of older works; manipulatory details having been mastered, artistic matters have come in for attention; posing, lighting, accessories, and the score of trifles that are necessary to approach perfection, have in turn been studied, and the effects are very marked. Further, a new master of portrait art has arisen, M. Salomon, whose exhibits in this line at the French Exhibition astounded and abashed the photographers. They went half-crazed about him: invaded his studio, brought him to England, studied his methods, puzzled out his secrets—such as they were, mere exercises of a master mind—and in the end have done their very best to imitate him. Half the portraits in the Conduit Street show were Salomonised: some of the imitations were successful, others were almost parodies of the Frenchman's system. The peculiarities of M. Salomon's art are chiefly the introduction of masses of dark drapery, deep backgrounds, with few accessories; and here lies the main secret—the use of brain in every part of the process. He has, too, abolished the white mounting hitherto universal, and surrounds all his pictures with narrow gold borders, placed, if necessary, in larger frames. Every secondary point is made to retire to give prominence to the leading one—the face of the sitter. How this matter has hitherto been neglected by photographers every one knows. When we have noted the effects of this Salomon influence, we have noted the chief novelty of the exhibition. But we ought not to omit mention of the laudable attempts to make ideal pictures which some of the more ambitious artists displayed. These, as usual, were beautifully executed, and very pretty, but they missed their mark, as such productions must always do. A picture that is anything else than a mere portrait must bear the impress of a soul, and there is no soul in a photographic camera.

Precisely so: a true picture must bear the impress of a soul, and there is no soul in a photographic camera. Of course there is not, any more than there is in pencils and palette, or in chisel and mallet. But are no pictures produced by soulless pencils?—no sculpture by soulless chisels?

"But the artist who employs them has a soul which he impresses on his work."

Precisely so, once more. It is the artist whose soul must impress the work, not the artist's tools; and the camera is the artist's tool, when an artist chooses to use it, exactly as are the pencil and chisel: a tool somewhat less controllable, working in materials somewhat less plastic, and therefore making the triumph the greater when it is achieved. The successor of *Sylvanus Urban* repeats the same old story, which has been refuted a thousand times, in which he mistakes the artist's tool for the artist, and apparently fancies that pictures are ground out of a camera like tunes out of a barrel-organ. But if this were so, whence the "use of brain" to which the critic refers as the source of Adam-Salomon's success?

#### COPYRIGHT IN PHOTOGRAPHS IN AMERICA.

ENGLISH photographers have not unfrequently expressed dissatisfaction with the working of the Copyright Act in this country, so far as it relates to photographs. A consideration, however, of our own laws and those of the United States in this respect will probably tend to satisfy our readers that they are highly privileged when compared with their American brethren. We condense from the *Philadelphia Photographer* an account of an important case which has just terminated unsatisfactorily for the photographer, and in the course of which the old, stale fallacies as to the inferior

and mechanical character of photography are revived, and made to do duty for arguments:—"The action was brought by Mr. F. Gutekunst against Messrs. Weise and Co., lithographers, of this city, to recover damages for the violation of the copyright of his photograph of General Grant. Mr. Gutekunst had duly entered his title in the court office as required by law. The next step was to impress upon the face of the photograph that he had made the entry and secured his exclusive title. The Act of Congress requires that this notification shall be upon "the respective copies of every edition," and "upon the face thereof." Instead of scratching this imprint upon one corner of the negative, so that every impression should necessarily present the information of the copyright, the notice was, as usual among the fraternity, printed upon the card-board. The print could, therefore, be floated off from the card-board, and then it would be without the copyright notice, and the card bearing that notice would be ready to receive any other print. Judge Grier decided that, under the Act of Congress, it was for the jury to decide as a matter of fact whether the notification was impressed upon the face of the photograph, and, of course, the decision was necessarily against Mr. Gutekunst."

From this it would seem that to obtain any chance of protection a card picture would require to be defaced by having printed on the picture itself the name of the photographer, the date, and an intimation that the picture has been duly entered according to the Act of Congress.

Our contemporary further points out that even if the proper precaution had been taken, it seems very doubtful whether the United States Copyright law would protect photographers; and he quotes the argument of the counsel for the defendant to explain the difficulty. Photographers will read with a little surprise the remarks of this gentleman, M. Constant Guillou—made, it is true, as an advocate on behalf of his client—when they are informed that he is an able amateur photographer, and was recently president of the Philadelphia Photographic Society. He states that the Act of Congress under which photographic copyright is supposed to be obtained is based upon the following clause in the *Constitution*:—"Sec. viii. Congress shall have power to promote the progress of science and useful arts, by securing for limited times, to authors and inventors, the exclusive right to their respective writings and discoveries." M. Guillou remarks in relation to this as follows:—"A photographer in the usual exercise of his profession, employing the ordinary instruments and known processes, is certainly no 'inventor,' and has no claim for a 'discovery': it is equally clear that he is not an 'author,' and his negative is not 'writing.' Congress has power to grant exclusive privileges only to authors and inventors—to no one else; and as a photographer is not in either of these classes, Congress has no power to pass an Act giving him such privilege. If there was no such power, then the passage of the Act was unwarranted, and the law is null and void."

It is not necessary that we should discuss the question here. Whenever it arises for absolute decision capable champions of photography will doubtless be found amongst our American brethren; but we remark, in passing, that, according to every comprehensive construction of the word a photographer is an "author." Not only does the common use of the word, to indicate a producer, justify the comprehensive application, but its derivation leaves no doubt of its fit use to describe not simply the writer of a book, but also the contriver of a thing, and its especial fitness to describe the producer of a photograph. Our Philadelphia contemporary well adds:—"Is there no *invention* in posing a figure gracefully and manfully, and in lighting it so as to produce a likeness and a work of art? Should he have no credit or protection for this? Where does the skilful photographic artist get his attitudes that attract and please so much? He *invents* them. By whose method does he produce such charming effects of light and shade? By those of his own invention. The sun does all this, says the

learned counsel in his argument, *not the photographer*. May he not say with equal force, that the water saws the fauciful seroll-work from the solid piece, and not the slender blade guided by the hands and the inventive brain of the skilful workman? or that steam weaves the brilliant-coloured threads into beauteous patterns, and not the intricate machine produced from and by man's inventive genius?"

### PRINTS ON APPROVAL.

BY NELSON K. CHERILL.

How can a portrait be more utterly condemned, than by being "not approved of"? It matters not how artistic the pose may be; it matters little how good the *picture* may be; it matters absolutely nothing how good the *photograph* may be; if the *portrait* is not approved of, its condemnation is complete; and if a picture is condemned, who is to blame—the sitter, or the artist? Certainly, in nine hundred and ninety-nine cases out of a thousand, not the sitter. The sitter usually comes and places himself or herself for the time quite at the photographer's command; the sitter will, as a rule, obey orders (if the artist knows how to give them), and if not, the photographer has the simple recourse of objecting to proceed with his work; so that almost invariably failure must be laid, not at the door of the victim, but to the charge of the unskilful executioner.

It is to be confessed that some faces are easier to take than others, and that some persons are more capable of being managed than others, and so often make better pictures, as well as better portraits; but even the most difficult to manage, and the most ugly to look upon, have some phases of action, or expression; which, if not decidedly elegant or pleasing, are at any rate, very much better than any other; and in these cases it becomes the chief part of the photographer's duty, first to find, and then to draw out by conversation and manner, the most excellent characteristics of the model. No man, however great his practice or skill, can always do this at first sight; indeed, with the majority of men, it is a matter of long study to see anything at all, much more to see the whole so perfectly as to accept the good and reject the bad. For this reason, if for no other, photographers should only be too glad to have an opportunity of taking the portraits of their more difficult customers over again a second, or even a third time. And if by this trouble a picture is obtained which is perfect as a work of art, and as a faithful portrait of the sitter, surely it is worth all the labour; and even if never paid for, such work must in reputation more than make up for the loss of time and trouble it has taken to produce it. To take a successful photographic portrait is a much more wonderful thing than many people seem to think. Persons who have known each other, and who have been constantly in each other's society for a long course of years, naturally know infinitely more of each other than those who meet only for a few minutes only once, perhaps, in the course of a lifetime; and yet the photographer is often blamed if, after five minutes' conversation with a person whom he has never before seen, he cannot call up in the portrait he produces the very best expression ever seen, by even the most intimate friends of the sitter. What, then, can the photographer do but try again? He may find with some sitters no cause to be ashamed if the specimens are "not approved."

There is, therefore, I conceive, no reason, so far as the art considerations of photography are concerned, why prints should not be sent "on approval"; but there are, I imagine, the very strongest reasons, on the other hand, why pictures should be sent out in this way. The public has a right to be its own judge as to the excellence of portraits for which it has to pay, and therefore no photographer can complain, with any show of justice, if his pictures are required to pass the ordeal of public approval. There is no photographer in the world, however high he may rank as an artist, who is, on any rate ought to be, above having his

pictures "approved" of; he may refuse to take them again, but he cannot refuse the public the right to judge them.

The case is just this: a man wants his portrait taken; he goes to a photographer, and asks him to take him; he looks at specimens, and decides the general style in which his picture shall be executed. He is taken; the proofs are sent home. Now, if these proofs are not considered good, there are, it seems to me, only three positions left for the photographer to choose. He can first (and, if a wise man, he probably will) say he is very sorry, and if he may have another try he will do better next time, and so on (for half an hour if necessary); or he may, if of an abrupt temperament, at once give his customer "the lie direct," on which, of course, legal action will be taken, and the whole profession be put to disgrace. An intermediate course is also possible, and some will adopt it, by saying, "If you do not like the pictures, I am sorry; as, however, I am the best photographer in the world, and as you are a very plain-looking man, I tell you (*entre nous*) you cannot get anything better; if you will have these, well and good; if not, good morning!"

The wrangling between a photographer and his discontented customer may in a measure be likened to the quarrel between Touchstone and the courtier in respect of the latter gentleman's beard. With a slight adaptation it would read thus:—

*Touch.* . . . . I did dislike the taking of a certain photographer's pictures. He sent me word, if I said his pictures were not well done, he was in the mind they were: this is called the Retort Courtous. If I sent him word again, They were not well done, he would send me word, He took them to please himself: this is called the Quip Modest. If, again, They were not well done, he disabled my judgment: this is called the Reply Churlish. If, again, They were not well done, he would answer, I spake not true: this is called the Reproof Valiant. If, again, They were not well done, he would say, I lied; this is called the Countercheck Quarrelsome; and so to the Lie Circumstantial and the Lie Direct.

*Jaq.*—And how oft did you say his pictures were not well done?

*Touch.*—I durst go no further than the Lie Circumstantial, nor he durst not give me the Lie Direct; and so we measured words, and parted.

*Jaq.*—Can you nominate in order now the degrees of badness in photographs?

*Touch.*—No, by no means; it is a thing past my comprehension.

I do not think, however, that photographers and the public often quarrel about pictures, both parties fighting rather shy of any such proceeding; but there is constantly in the mind of inferior photographers the idea that the public would like to swindle them if it could. They seem to think that when pictures are not approved of, it is from some underhand design of getting a certain number of proofs for nothing; but this will not stand a moment's reasoning; the public is not so fond of having its portrait taken that it will reject pictures unless they are absolutely too bad. There are, indeed, many people who would sooner put up with a bad portrait than have the trouble of sitting again. And if the photographer has his wits about him, he can at all times recover his rejected specimens, on the simple plea that he does not care to be represented by pictures which are not approved of.

We make a regular system now of having a "day-book" specially for specimens, and every one that is sent out is charged at a very high price, and this entry is not cancelled till the pictures are returned, either as ordered, or as not approved of. In the latter case, when the pictures are taken again, the new proofs are also entered in the specimen day-books when sent out, and by this means a most perfect check is given as to the number of pictures out on approval, and the number returned, and so on.

## PHOTOGRAPHIC MARKING INK.

BY H. NEALE.

THE following method of marking or producing designs on linen, &c., which I have long been going to send you, and although, perhaps, known to some of your readers, I cannot remember having seen published, may be of service to many. Proceed thus:—Make a 20-grain solution of ammonia nitrate of silver by the usual method, adding sufficient gum mucilage to make it flow better from the pen. Damp slightly the linen or other fabric with a solution of pyrogallol and citric acids (the ordinary redeveloping solution); let dry; then, with a quill pen and the silver solution, trace the design on the linen. The effect seems magical, as the instant the design is formed—in fact, as fast as the pen goes—the design appears of a rich black colour, and is perfectly permanent, requiring no fixing, and will bear any amount of washing.

The above idea might probably be utilized in block printing on linen, &c., as designs could be produced as quickly as by the ordinary printing press.

## A VISIT TO THE PHOTOGRAPHIC STUDIO OF THE IMPERIAL MILITARY GEOGRAPHICAL INSTITUTE IN VIENNA.

BY ALOIS NIGG.\*

HAVING recently occasion to pay a business visit to my friend M. Frank Fink, the Assistant-Director of the above-named establishment, during the ordinary working hours of the department, it was my good fortune to obtain permission to witness the mode of operating pursued at this deservedly-celebrated photographic studio. This favour I appreciated the more fully from the knowledge that an indulgence of the kind is rarely granted to strangers, on account of the hindrance to work which such a proceeding generally involves.

The establishment is under the careful direction of Lieutenant Johann Schopf, and the excellent work which has been produced therein has acquired for it such a reputation that no laudable commendation is necessary on my part; at the same time, notwithstanding the high character of the studio, I believe that there are some among my colleagues who do not at all envy me the opportunity I have enjoyed; more especially, I would mention, those gentlemen who are not accustomed to the manipulation of large plates, and those, likewise, who, with the most anxious care, tenaciously hold fast to the methods of operating with which they first become familiar; for in this establishment those orthodox rules and regulations which are generally considered indispensable to proper manipulation, and an infringement of which would, to many minds, inevitably bring about the most disastrous consequences, are simply regarded as null and void; and it would seem almost as if even the chemical reagents had been placed under military discipline to obey in all things, and in no way to disregard, the commands or wishes of the operator.

As regards the situation and construction of the different work-rooms, they have all been arranged and built according to the necessary requirements; such, in fact, as could only be the case with a government institute. In an exposed and isolated position upon the roof of the building is constructed the studio, lighted from all four points of the compass. Here the negatives are taken from the original maps and drawings, which are screwed in an upright position to movable frames, placeable against any of the walls of the studio. The top and side-light windows are removable, so that work may be performed, if necessary, in the open daylight, or even sunlight, which streams uninterruptedly upon the object to be reproduced; white reflecting screens may likewise be used on the two opposite sides from those whence the light enters, to prevent the casting of any shadow by the roughness and texture of the paper, an

effect which often occurs when the surface of the object is strongly lighted.

The giant camera stands upon a table capable of being lengthened out or shortened, and provided with iron rollers running upon rails; by this means a picture of any size may be sharply focussed in an incredibly short space of time by a couple of assistants who have had some experience in working together. I am a great stickler at military discipline and working by word of command, but if such satisfactory results were always produced by its means as those shown at this establishment, it is, I think, to be regretted that a certain amount of soldierlike character cannot be infused into every photographic studio. I had the pleasure of personally witnessing the process of copying a map of the same size as the original, which was a drawing composed of four sheets of paper, and the whole operation conducted in such an efficient and original manner that I cannot refrain from giving a detailed description of the same.

A sheet of plate-glass measuring from twenty-five to thirty inches, and roughened all round the margin to the extent of a quarter of an inch by means of a flintstone, was placed upon a frame in the form of a cross, which was supported on a movable socket exactly in the centre. At all four extremities of the cross are clamps, which, being packed together, fasten the plate down, and, at the same time, keep it in the centre of the stand in perfectly horizontal position. By means of an arm fitted underneath the cross, the same may be depressed or elevated at will, so that the glass plate may be turned or tilted in any way without being touched. This description of cross has been used by many photographers for the manipulation of small plates, and I do not allude to it, therefore, as any special novelty: the manner, however, of applying the collodion is, I believe, a perfectly new one.

M. Fink seated himself comfortably to perform this bold operation, pulling sideways towards him the horizontally-swinging plate, and pouring the collodion thereon from a half-pound measure in a thin stream, in the manner indicated by the

lines *a, b, c* in the accompanying sketch. He commenced at the furthest edge of the plate, and allowed the stream of liquid to fall in a parallel line to the same, about two inches distant, tracing a horse-shoe figure backwards and forwards with the collodion. As soon as the latter, by means of a little skilful handling, had been made to spread itself over the plate to the extent of

a hand's-breadth, as shown by *d e*, the operation was repeated in the same manner at a more advanced part of the plate at *e, d, g*, and the collodion so manipulated that it extended to and combined with that previously poured on; in this way the plate was coated until there remained but a margin of about three inches uncovered, as shown at *i h*. Under those corners of the plate which were still dry, vessels were placed for the reception of the superfluous collodion, and the cross-stand was next very slowly and carefully tilted by means of the handle in such a manner that the material flowed evenly over that part of the plate which was yet uncovered. From the commencement of the operation of collodionizing the plate until this moment a period of not less than six minutes had elapsed, and until the material had set sufficiently to allow of the plate being placed in a perfectly upright position at least ten minutes had gone.

The coated plate is now placed in a horizontal sensitizing bath, the collodionized surface uppermost, and allowed to remain therein quietly for a quarter of an hour. It is stated that the plate should never remain immersed in the bath for

\* Photographische Correspondenz.

a longer period than twenty minutes, as otherwise the iodide of silver formed becomes dissolved to too great a degree. During the time required for sensitizing, the object to be reproduced is placed in position, and focussed ready for operating, all of which can be undertaken during the interval.

M. Fink concealed himself behind the black cloth which covers the ground-glass of the camera, and then gave the words of command to his assistants, posted at the frame containing the original drawing or map to be copied, the following orders being called out at different intervals:—"To the right!" "Halt!" "The bottom more forward!" "Halt!" "To the left!" "Halt!" "Again!" "All right!"

I was astonished at the rapidity of the manœuvres, and of the appearance upon the focussing glass of the faultlessly-straight lines and sharply-defined image, depicted of the same size as the original, which, in order to produce such an effect, must have been placed in position with mathematical correctness. The institute possesses for this description of work a three-inch lens of Dallmeyer's, which is almost exclusively used for the purpose, and which fulfils the necessary requirements of equal distribution and sharpness in the highest degree.

The exposure which took place in my presence was, by reason of the unfavourable state of weather, a somewhat long one, lasting five minutes and a quarter; in a good light two minutes only is required; while in the sunshine the duration of the exposure is but half a minute.

The same degree of novelty and originality exhibited by the application of the collodion was displayed in the development and fixing of the plate, these operations being conducted in a manner which was perfectly new to me.

In the middle of a sufficiently large receptacle there had been constructed a raised, somewhat convex, and rounded wooden ball, resembling in appearance the buffer of a railway carriage. The plate was placed crosswise upon this rest, being held at one of the corners, that side of the glass furthest from the operator being depressed somewhat; the developing fluid was then poured from a vessel—which, to my thinking, was scarcely large enough for the purpose—close along the upper margin of the plate, from right to left, and allowed to flow downwards over the surface. I observed the liquid flow slowly towards the lower edge of the plate in disconnected streams, and, more slowly still, by careful tilting to and fro of the negative, finally spread equally over the whole surface, until gradually a clean picture was developed, to the certainly unexpected astonishment of your humble servant. The word "Intensifier!" was uttered, and the assistant immediately handed a vessel containing citrate of iron, with which the same process was gone through as with the developer. "Water!" is called for, supplied, and the plate therewith washed. "Soda!" A hand reaches out the fixing agent. "Water!" Here it is. "Mercury!" One hand takes away the empty vessel, while another supplies the required solution.

The treatment with the bichloride of mercury is the same as that pursued with the iron developer; the same divided streams are allowed to flow heedlessly over the picture, forming long, inky-black streaks. "Will not these stains destroy the negative altogether?" I asked. "They will soon become equalized," was the curt reply of the operator; and, so saying, he rapidly turned the plate round, and poured on the liquid from the opposite end; the negative was then lifted up and examined by transmitted light, and afterwards again treated with the mercury solution, the latter being allowed to rest for a short time on any parts where the film did not appear to be sufficiently intense. "Water!" was then ordered. "Water over the hands!" "Wash the back of the plate!" And the finished negative was then placed in my hands for inspection prior to its despatch to another part of the building.

If it had been my express desire to produce a negative of the most fogged description, it would, perhaps, have been

possible for me to have performed the different manipulations with the same nonchalance and disregard of all established rules and precautions; and I must frankly avow, that I deemed it an impossibility, by such means as I have described, to produce a negative without the presence of innumerable spots and blemishes. I was therefore already beginning to congratulate myself on being able to point out the evil consequences inevitable to such an extraordinary manner of carrying a photographic process. But, notwithstanding the most diligent and searching examination, I was unable to discover therein any faulty appearances whatsoever.

(To be continued.)

## THE PRINTING PRESS.—ITS USE TO PHOTOGRAPHERS.

BY THOMAS GULLIVER.

HAVING had one in use for several years, and found many advantages from the possession of one, I venture to recommend the addition of a printing-press to the usual stock of apparatus to be found in a photographic establishment. It need not be an expensive one, only such a one as would work off a neat circular, small handbill, list of prices, bill-head, carte-de-visite mount for landscapes, &c., &c.

I may be told that all this is a printer's business, not a photographer's; but it often happens that said printers have a large job on the press that they must work off first; and printers object to take small orders, for if you want only a hundred bills or cards, you will be strongly advised to have two. Now the press I have has cost only £3, and the type, &c., about £4 more, and it is surprising what can be done with this small outlay.

The press in question is of the kind called the people's printing-press, and the type can be had at any of the London type-founders. The working of it is easily acquired, and it serves as an agreeable change after working in the studio among the chemicals. Two or three lessons from a practical printer will be as well when beginning, as starting the right way at first is half the battle won. Some little difficulty will no doubt be experienced with the ink roller, which, like the nitrate bath, in some hands is always getting out of order; but by keeping mine in a close, air-tight box, I have used the same roller without renewing for over three years. I enclose a specimen of my work done on my little press; this was set up and worked off after tea one dull day, and the type washed and distributed before breakfast time next morning.

## DRY PLATES.—HINTS.

BY M. CAREY LEA.\*

*Washing before Developing.*—The systems of operations used by different photographers vary a good deal. The plates may either be moistened with weak alcohol and washed, or be simply washed, or be thrown into a developing bath without any washing.

This last plan, which is certainly the least trouble, may be used with some plates with impunity. But I have observed that where any sugar has found a place in the preservative solution, a good washing is needed to get rid of it; otherwise there will be a tendency to irregularity and spot-tiness in the development. When an acid pyrogallie development is used, this tendency is materially less than with the alkaline. When a preservative solution is used with as much as twenty grains of sugar to the ounce, an alkaline developer used without previous washing off sets up a sort of repellent action, and may even collect in pools, developing unequally, and spoiling the picture.

The best conclusion is, therefore, that although a previous washing is not always necessary, it is best and safest to apply it. The foregoing applies, of course, to developing in a pan; if the plate is developed in the hand, on a holder,

\* Philadelphia Photographer.

or on a levelling-stand, the developer cannot be got evenly over it without previous moistening; and in such a case, if the preservative has contained sugar, not a mere moistening, but a careful washing will be advisable.

*Dark Slides.*—When plates are exposed at home, the chance of accidental exposure is very slight, and the loss of a plate not very important. It is far otherwise, however, when a plate is carried many miles: the danger of accidental exposure is greatly increased, and the loss of a plate much more annoying. When a number of dark-slides are rolled up together in a cloth, and taken in a carriage to a distance, they move somewhat, and rub against each other. Perhaps the button works round in this way, and lets the door open a little, or a shutter works by degrees, so as to let in a crack of light. Again, in drawing out a slide from the bundle, the button may catch and open, or may open the button of another slide adjoining, or a shutter may be a little withdrawn.

I have found the following arrangement very convenient and useful to avoid these troubles. To keep the shutter from accidental moving, an ingenious little catch has been contrived for me by Mr. Peace, of this city. A piece of brass, about one and a quarter inch long, and three-tenths wide, is bent across. A hole is drilled through the short part, and notch at one end of the long part. A screw passed through this hole secures it to the end of the slide close up by the shutter. Into the thick end of the shutter a pin is driven, which goes into the notch, thus locking the shutter most securely, and removing all danger of accidental exposure by sliding or disturbance of the shutters.

To prevent opening of the door, I have an extra button placed at the side. It thus becomes extremely improbable that both the buttons will be disarranged on any one slide, and with these precautions the plates may be considered as absolutely safe. The buttons placed on slides for ordinary home use are put on the door, turn under a bent wire on the edge of the frame, and have their other end turned up and rounded, in order the more easily to be taken hold of. This arrangement, convenient enough for the use for which it is intended, becomes a great nuisance if the slides are carried out. Slides for such use should have flat buttons only, and these should be placed on the frame, and not on the door. A screw at one end secures them to the frame, and they will round so as to pass over the edge of the door.

*Roughing the Edges of Plates.*—In the collodio-bromide process the collodion is, of course, somewhat thicker than in the ordinary modes, by reason of the bromide of silver held in suspension, and, therefore, a little more care is necessary in coating. If the filing of the edges of the plate has been carelessly and roughly done with too coarse a file, it may happen that deep notches will be made, and that the plate, after coating, will show irregular bands running down an inch or more into the plate, alternately thicker and thinner. These will show, of course, in the negative, as where the film is thicker it will develop more strongly. Such plates will, of course, be failures, and the appearance of such bands as I have described may be traced with certainty to careless roughing. In fact, it may be doubted whether any filing or roughing of the edges whatever is needed with dry plates, as these should always be edged with india-rubber benzine varnish, or have a substratum of dilute albumen.

*Blistering.*—In all dry processes in which albumen is used in the preservative applied to collodion films, there is a tendency to blistering. This blistering depends upon osmotic action. Liquids containing certain substances in solution have an extraordinary power of forcing their way through membranes, and many kinds of artificial films are capable of acting in this respect like natural membranes.

The nature of the cotton used has much to do with this blistering; some collodions blister much worse than others, some during development, some only in the fixing and subsequent washing.

It has seemed to me that the addition of sugar to the preservative, in the proportion of about 10 grains to the ounce,

had a tendency to diminish this evil. I suppose its tendency to be to keep the collodion film in a more porous condition, and so to allow the liquid which has passed in to escape again. The film, when just made, and still moist, is in a very plastic condition, and has not undergone the powerful contraction which takes place in drying. If, whilst in this soft and plastic condition, its pores be filled up with a preservative containing a substance like sugar, the sponginess of the film seems to be better preserved, and, when wetted again, it returns more to the state of an ordinary wet plate than is the case with dry plates made without sugar in the preservative. In some cases this quality is very valuable; other forms of dry plates do not need it.

But I wish to place on record here the opinion that the action of sugar in the preservative is to keep the film in such a condition that, on wetting it, it will return to nearly the condition it had when it left the bath, and especially that by adding sugar to a preservative, and then washing it well out before applying the developer, the development will always take place with much greater rapidity than if the sugar had been omitted: not in the least that the sugar gives enhanced sensitiveness, but that its function is to fill up the pores, keep the film spongy, and, on its removal, to leave it in such condition that the developer penetrates instantly, and acts at once on every particle that has been impressed by light.

#### MEANS OF EQUALIZING EXPOSURE WITH WIDE-ANGLE LENSES.

BY JOHN M. BLAKE.\*

THE effects of the inequality of exposure over different parts of the sensitive plate, when using a wide-angle lens, are well known. The gradual diminution of light, as we pass from the centre to the borders of the plate, may give, in our collodion film, all gradations from an over-exposed negative where the light is at a maximum, to a well-exposed ambrotype at the extreme limits of the field.

This difficulty can be to some extent overcome by giving the best average exposure to the whole field, and shading the borders of the plate in printing; but we thus sacrifice other important points, and imperfectly accomplish our object.

Let us now consider the various causes which tend to diminish the amount of light as we go from the centre of the field. I will mention five.

First, and most important, the increasing distance of the plate from the diaphragm.

Second, the oblique position of the diaphragm to any but the central portion of the plate.

Third, the obliquity of beams of light towards the limits of the field, causing them to spread over more surface than their square section.

Fourth, loss by reflection from the surface of the wet film before reaching the sensitive particles below. This increases in amount as the incident rays make a less angle with the collodion surface.

Fifth, loss by interference of light, which may be supposed to increase in some ratio to the whole amount passing through the diaphragm, as the latter becomes in effect narrowed by its increasing obliquity.

From the first cause the light will vary as the square of the cosine of the angle included between lines drawn from the diaphragm to the centre of the field, and to any point at which we wish to compare the illumination with that at the centre. From the second and third causes the variation will be as the cosine of the same angle in each case.

The variation from loss by reflection must be determined by experiment. The light reflected would probably exceed that from water alone, owing to the greater density of the silver solution.

The loss from the fifth cause is probably of little account, except when using a very small diaphragm, or with a lens of very wide angle.

\* Philadelphia Photographer.

Combining the first three causes, and giving the result in a convenient form, we have, the intensity of light at the borders of a field, including a given angle, is to that at the centre as the fourth power of the cosine of half this angle to one; and we deduce that at the limits of a field of  $81^{\circ} 6'$ , the light is one-third that at the centre; of a field of  $65^{\circ} 32'$ , one-half; of  $52^{\circ} 6'$ , two-thirds; and of  $37^{\circ} 56'$ , four-fifths.

This result is about what we would have expected from the appearance of an under-exposed plate after development. Such being the case, we cannot expect to obtain the highest degree of perfection in detail over the whole surface of a wide-angle picture, unless we adopt some plan for properly equalizing the exposure.

It occurred to me, about the time of the first appearance of the Harrison globe lens, that any sort of approximation to equal illumination of field it might possess, must be due to the use, either by accident or design, of a kind of crown glass, partially obstructing actinic light. As the crown lenses are much thicker at the centre than towards the edges, the effect would be to retard chemical action near the centre of the sensitive plate to a degree depending on the kind of glass selected. The flint lenses in the combination, although thickest at the edges, probably do not have an appreciable contrary effect on the distribution of the light, since this kind of glass is usually whiter than crown.

Not having an opportunity to examine and use a lens of this kind, the matter was forgotten for several years, when the subject was forcibly recalled to mind by the appearance of negatives taken with a Zentmayer lens.

Some preliminary experiments were made with thin wedges of coloured glass placed over sensitive paper, and a kind selected which, at the thickness of the centre (about  $\cdot 03$  inch) of one of the lenses in the Zentmayer combination of the size it was proposed to construct, obstructed two-thirds of the actinic light.

At this time another plan was thought of, which could be more easily tested, and did not have certain disadvantages inherent to the first. Thus, if we intend to use our lens with the full angle only, at the best there will be an unnecessary loss in that portion of light passing near its edges, over what would be transmitted were the lens made of the whitest glass. And, again, if, as is often the practice, we wish to use our lens for a smaller plate than it is capable of covering, we will find it seriously and needlessly injured for this purpose, as regards quickness of working.

(To be continued.)

### THE USE OF PARAFFINE IN PHOTOGRAPHY.\*

PHOTOGRAPHERS are not generally aware of the value of paraffine in their business. Its more general use has probably been retarded for the reason that it is difficult to find a good article of it in the market. That which is best is very hard—so hard that the finger-nail can barely make an impression upon it. When it can be found of that kind, it makes an excellent preservative for prints, and can be safely used as such. If the softer kinds be used, they are apt to turn the print yellow, and aid in its destruction rather than otherwise. The reason of this is, says Professor Bottger, that when melted and exposed to the action of the air, oxygen is absorbed, and the melted fluid becomes brown gradually but surely. So much care need not be taken, however, in selecting paraffine to be used for coating the various articles of wood used in photography, although the best is the best.

In a letter to us some time ago, our esteemed co-worker, Mr. Charles Waldeck, writes:—"I think paraffine can be of great use to photographers. Nothing surpasses it to coat wooden dishes with. I prefer such dishes to hard rubber, porcelain, or photographic ware. A good coating of paraffine for the inside, and two or three of white-lead

paint on the outside, will make a wooden dish perfectly water-tight. A very good silver bath-holder may be made in the same way. The dish or bath is well warmed, the molten paraffine poured into it and made to move all over the inside surface. Then, if possible, if the vessel be put in an oven just hot enough to keep the paraffine melted, it will penetrate more deeply in the wood, and improve its water-tight qualities. Plate-holders made of wood, without glass or composition corners, by being put in the molten paraffine, will for ever after refuse to absorb the silver, and will never produce stains. Manufacturers of camera-boxes would do well to consider this; and all of the wood-work of the camera-boxes would be improved by immersion in this useful protection. A camera-box made of dry wood, as it should be, and well coated in this way, would never warp or corrode by the nitrate of silver. If I ever go on another tour to the Mammoth Cave, I shall previously coat everything I use, made of wood, with it. In coating an object, it should be observed that the *hotter* the paraffine the more perfectly will it penetrate the wood."

In our experience, we have found one objection to the use of paraffine for coating the inside of the nitrate bath. Except with very careful manipulation, the corners of the plates are apt to remove particles of it, which, floating in the bath, cause pin-holes, or adhere to the film. For the other purposes named, however, its advantages cannot be overrated.

### Proceedings of Societies.

#### NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Society was held in Myddelton Hall on the evening of Wednesday, December 2nd, Mr. W. W. KING in the chair.

The minutes of a previous meeting were read and confirmed, after which Mr. Tilly, Mr. Jewell, and Mr. Newbury were elected members.

Mr. W. BEDFORD exhibited a couple of very fine 12 by 10 landscapes, which were, he stated, printed on the back of albuminized prints, as had been recently suggested in the PHOTOGRAPHIC NEWS. The prints were rich and vigorous, and excellent in colour.

A conversation on the subject followed, in the course of which Mr. BEDFORD explained that the prints were treated with Mr. Thomas's encaustic paste, which answered well, and gave great richness to the shadows.

Mr. WHARTON SIMPSON exhibited some prints, by Mr. Carl Meineth, he had received from America. The prints were styled "photo-mezzotints," and were produced by interposing a medium between the paper and the negative, so as to remove extreme sharpness, and soften harsh lines. The specimens he exhibited displayed various degrees of modified sharpness, from slight diffusion to entire want of definition. He called attention, also, to the peculiar resemblance to printing on porcelain produced in some instances.

Some conversation on the subject followed, in the course of which admiration for many of the effects was expressed.

Mr. J. T. TAYLOR exhibited some exceedingly fine slides for the magic lantern, produced by Mr. Stewart, and in the course of the conversation which followed, it was suggested that on an early occasion the slides should be exhibited to the members by means of the lantern, the Chairman undertaking to say something on the subject from an architectural point of view.

Mr. HART exhibited a convenient light tray for fixing or washing prints. It was made of wood varnished with some waterproof varnish, probably a solution of marine glue. It was fitted with a siphon arrangement. Besides being light and not easily broken, it was said to be moderate in price.

After some further desultory conversation, it was announced that there would be no meeting of the society in January, the time coming too near the period for Christmas festivities to render it convenient. In February Mr. King promised to read a paper on neglected art and scientific subjects in connection with photography.

As the CHAIRMAN declared the meeting adjourned,

\**Philadelphia Photographer.*

Mr. DAWSON requested permission to ask Mr. Bedford one or two questions about the prints exhibited. Had he compared the results obtained by printing on ordinary plain paper with those obtained on the back of albuminized paper? and, if so, was there any difference?

Mr. BEDFORD said he had made such comparison, and found that he obtained a better and richer print on the back of albuminized paper.

Mr. DAWSON did not see how the presence of albumen on one side of the paper could affect the quality of the print on the other side.

Mr. SIMPSON said the presence of albumen on one side of the paper was not supposed to affect the character of the print on the other; but as all papers absorbed a certain portion of the albumen and salt with which they were coated, it was the presence of as much of those substances as were absorbed and passed through the paper, and then combined with the silver, when on the exciting bath, which gave the prints some amount of superiority over ordinary plain paper prints. It was, in short, a very simple and easy method of imitating in some degree the result produced on amorphous albuminized paper.

Mr. DAWSON thought that it would be better, if a little albumen gave an advantage to plain paper, to experiment and find out in what proportion and in what manner it would be best applied, and prepare paper on the right side, instead of using it in this somewhat indefinite manner on the wrong side.

Mr. SIMPSON said the object here was to save the trouble of experiment or especial preparation. Plain paper prints were only very occasionally required, and when, by chance, one or two were wanted, it would be very troublesome to the photographer to have to get special material and make special preparation. But he always had albuminized paper at hand, and he simply needed to float it, plain side downwards, on his ordinary silver bath to get an approximately good result, with little trouble. If the best plain paper results were required, and a demand existed for them—which, with the large rich class of pictures especially recently come into vogue, would be desirable—no doubt it would be worth while to make special preparations, and produce finer results.

A conversation followed, in the course of which commendatory reference was made to the fine plain paper prints of Mr. Hennah, familiar to photographers some years ago, and an expression of a conviction of the superior artistic effect of plain paper prints.

In the course of the conversation Mr. G. HOOPER stated that he had obtained good plain paper prints by means of a formula he was proceeding to describe, when it was suggested that he should introduce the subject by a short paper at an early meeting; and this was agreed to.

The proceedings then terminated.

#### LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in the Architectural Gallery, Conduit Street, on the evening of Tuesday, December 8th. Mr. J. GLAISHER, F.R.S., in the chair.

The minutes of a previous meeting were read and confirmed, and the following gentlemen elected members of the Society: Messrs. Louis Bing, Jewell, Twyman, H. Baden Pritchard, and Archibald Irvine.

THE CHAIRMAN read the seventh rule of the Society, relating to the nomination and election of officers; after which he said that during many years the Society had been honoured by the presidentship of Sir Frederick Pollock, ex-Lord Chief Baron. He regretted to say that the time had come when they could no longer have the pleasure of his able presidency. In a letter forwarded to the Council their President said that being in the eighty-sixth year of his age, and being compelled to abstain from all evening meetings, he regretted that he could no longer discharge the duties nor hold the office of president of a society which afforded him the pleasure of being associated with so many of the most enlightened practical and scientific men of the day. He also had to announce, with regret, that another officer, who had been eleven years their Secretary and thirty years a photographer, had felt, from the state of his health and pressure of other duties, he must resign his office, and Dr. Diamond would at the end of the Society's year cease to be their Secretary. The Council had appointed a gentleman (Mr. John Spiller) in his place, by whom they felt assured the duties of secretary and editor would be ably discharged. The gentlemen nominated by the Council for election were, for the Presi-

dency, himself (Mr. Glaisher), an office he had consented to hold for the following year; retiring from the Vice-Presidency, Mr. Glaisher and Mr. Durham; nominated for election, the Earl of Caithness and Dr. Diamond; retiring from the Council, Messrs. W. M. Brown, Joubert, Sedgwick, Spiller, John Williams, the Earl of Caithness, and Dr. Wright; nominated for election, Messrs. Durham, Dallmeyer, Dr. Arthur Farre, Professor Wheatstone, Dr. Mann, Wm. Mayland, and Mr. Whiting, Junr.

THE CHAIRMAN then announced that the Annual Report of the Patent Office of the United States had been presented by the U. S. Government to the Society, which they accepted with thanks. He also called attention to some coloured specimens of the "Emolliotype" process, by Mr. Notterville Briggs, and some fine carbon prints by Mr. Blair, of Perth, some without transfer at all, and some by a single transfer process, exhibited by Mr. Wharton Simpson. The specimens were examined with much interest.

Mr. H. BADEN PRITCHARD then read an interesting paper on the photographic operations in the Abyssinian War, and exhibited specimens of the photographs produced. He also stated that Sergeant Harrold, who had had charge of the photographic operations, was in the room, and would have pleasure in answering any questions on the subject.

THE Rev. J. B. READE congratulated the Society on the interest and importance of the first paper of the session. Such a paper seemed literally to transport us to the field of operations, and vividly illustrated the importance of our science in this new and important application of it. Mr. Pritchard had referred to cases in which the intensity of the light was so great that it was almost impossible to give sufficiently short exposures. This reminded him of some of his experiments in photographing the sun with the enormous telescope erected by Mr. Craig, at Wandsworth, giving an image of from 9 to 10 inches diameter. He had then to interpose a plate of yellow glass, to diminish the intensity of the light, and so obtained good negatives. Possibly a similar course might be found useful under the circumstances to which Mr. Pritchard had referred. He had pleasure in proposing a special vote of thanks to Mr. Pritchard and to Sergeant Harrold for this interesting paper.

Mr. MAYALL referred to some pupils to whom he had taught photography by the request of Lord Panmure, in order that they might practise the art during the Crimean war. He suggested that in such expeditions some dry plates—either by the simple albumen process or the collodio-albumen, both of which gave great certainty—should be taken, as well as wet plate apparatus. Such plates would often give facility for obtaining subjects when the time for preparing wet plates might not be available. The albumen process—which had not, he thought, received nearly sufficient attention in this country—would give plates which would keep twelve months. He had recently tried some prepared in 1855 which still gave an image. He would be very happy to show Sergeant Harrold his very simple process of preparing such plates. After some reminiscences of the experiences of Mr. Fenton in the Crimean war, and some remarks on the advantage of slit stops, Mr. Mayall cordially seconded the vote of thanks.

Mr. SPILLER, after some remarks on his experiences in connection with military photography, said that several suggestions occurred to him as arising out of the paper read: first, the importance, when working in a tent under a hot sun, of covering it with white; next, he thought the advantage of printing direct upon linen, as suggested by Mr. Pritchard, for purposes of this kind, must be manifest, especially after examining the excellent results which Mr. Pritchard had shown them of his own production. Referring to Sergeant Harrold, who had received a medal for bravery in the field, he thought it was satisfactory to find that he was as good a man before the enemy as behind the camera.

Mr. BEDFORD said that when he was photographing in the East he found it a valuable plan to stretch above his tent, not quite in contact, a white sheet, and when water was plentiful to wet that sheet. Such a plan was very valuable in securing coolness: indeed, during the last summer, whilst working in North Wales, he found that such a plan was very valuable in keeping cool the interior of his photographic carriage. Referring to the question of intense light, he should like to ask Sergeant Harrold how he found it in Africa. His own experience in the East was, that although the light was intense, the shadows were very dark, and exposures, except for distant

views, were not lessened by the intense light. His own average exposures were from ten to twelve seconds for 12 by 10 plates.

Sergeant HARROLD had generally found the exposures long rather than short.

Mr. V. BLANCHARD asked Sergeant Harrold what was the average temperature, as he had a vivid recollection of the difficulties in working in the almost tropical heat at Wimbledon. He had found that a wet covering to the vehicle was very valuable in securing coolness, but water was almost as scarce at Wimbledon as in Abyssinia.

Sergeant HARROLD said the temperature averaged about 100°.

Mr. SEBASTIAN DAVIS, referring to the packing of collodion, said that stoppers alone, without some extra covering, would certainly be insufficient to prevent evaporation. A box lined with felt was useful for packing such bottles.

Mr. BEDFORD said, when he went to Egypt he had each collodion bottle packed in a tin case with sawdust, which effectually prevented evaporation.

The CHAIRMAN, in putting the vote of thanks, referred to the "Norwegian Kitchen," which had such non-conducting powers that many hours elapsed before the interior was changed in temperature, and said that such an arrangement might be found valuable in packing substances like collodion. The suggestion of Mr. Bedford, of the wet white sheet, was most important, as a temperature of 30° lower than that of the atmosphere might be so secured. During last summer's experience they had the thermometer at 90°, and the dew-point at 60°. He had pleasure in putting the vote of thanks. The photographers with the expedition had conducted their photographic operations under the greatest difficulties, but with the greatest success.

The motion was carried by acclamation.

Mr. FRITCHARD, in responding on behalf of Sergeant Harrold and himself, said that the photographers were prepared with dry plates both by the coffee and collodio-albumen processes, but had no opportunity of using them. Once they attempted it in one of the Abyssinian churches, but the high priest interposed, and although Sergeant Harrold tried to hold him in parley until the plate was sufficiently exposed, he did not succeed, for the priest kicked over the camera. Regarding the light he had been slightly misunderstood. He had said that under certain circumstances short-focussed stereo lenses might be found too quick in the stroug light.

The CHAIRMAN, referring to the late exhibition, said he was informed by the attendants that no exhibition of any kind in those rooms had excited so much interest or had so many visitors, not less than about five thousand persons having seen the pictures. It was clearly a great success, and showed that there was no diminution in public interest in photography, nor any reason to fear declension in the progress of the art.

The CHAIRMAN then announced that at the meeting on the 12th of January Mr. Nelson K. Cherrill would read a paper on Combination Printing, illustrated with examples.

The proceedings then terminated.

#### AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE adjourned meeting of the Council of the Amateur Photographic Association was held December 1st, at 12, York Place, Portman Square, Col. the Hon. DUDLEY FITZGERALD DE ROS in the chair.

The minutes of the last meeting having been read and confirmed, the two following members were elected, R. C. Walker esq. and Miss Jane Hamilton.

Mr. GLAISHER then read a report upon the present condition of the Society, and the pictures for the present year, of which the following is an abstract.

It was my agreeable duty last year to notice the steadily increasing prosperity of the Amateur Photographic Association, and it is a source of no small satisfaction to find those remarks more than ever applicable to the present state of the Society, and that the pictures contributed by the members this year greatly exceed in number those of any previous occasion. The number of pictures of sufficient excellence to be specially noticed, are as follows.

*Class 1 contains 90 pictures, contributed as follows:—*

Lt. Senior 13, Capt. Bankart 7, W. Bailey esq. 7, F. Beasley esq. 6, J. W. Richardson esq. 5, Major Gresley 5, Dorabjee Pudumgee esq. 4, W. D. Howard esq. 4, W. Church esq. 4,

Capt. Taylor 3, F. E. Curry esq. 3, A. Booty esq. 2, J. H. Ravenshaw esq. 2, Dr. Hemphill 2, R. Murray esq. 2, J. G. Hydo esq. 2, E. Milson esq. 2, J. S. K. Moss esq. 2, E. R. Hall esq. 1, W. H. Harton esq. 1, R. B. Bowman esq. 1, T. Brownrigg esq. 1, Dr. Wilson 1, L. Ashburner esq. 1, Rev. J. Freke 1, J. H. Ritchie esq. 1, R. Hassard esq. 1, J. Richardson esq. 1, F. S. Schwabe esq. 1, Mrs. E. Daubeny 1, J. A. Jobling esq. 1, J. C. A. Bones esq. 1, A. Suzanno esq. 1, B. Jones esq. 1.

*Class 2 contains 185 pictures, contributed as follows:—*

Lt. Senior 26, J. H. Ravenshaw esq. 13, J. W. Richardson esq. 12, F. Beasley esq. 10, E. Milson esq. 9, Capt. C. Taylor 7, Dr. Hemphill 6, W. D. Howard esq. 6, Capt. W. Foster 6, Major Mason 6, A. Booty esq. 5, W. Church esq. 5, J. Richardson esq. 5, Col. Holder 4, Capt. Bankart 4, J. S. K. Moss esq. 4, Capt. C. M. Layton 4, F. S. Schwabe esq. 4, J. G. Hydo esq. 3, J. H. Hutchison esq. 3, W. Bailey esq. 3, Mrs. Daubeny 3, R. E. Chidley esq. 3, F. E. Curry esq. 2, F. K. Barclay esq. 2, J. A. Jobling esq. 2, J. H. Ritchie esq. 2, R. Grace esq. 2, R. B. Bowman esq. 1, R. Murray esq. 1, T. Bell esq. 1, W. G. Hunter esq. 1, T. R. Lane esq. 1, D. Pudumgee esq. 1, M. Guyton esq. 1, F. H. Tanner esq. 1, J. C. A. Bones esq. 1, G. H. Wood esq. 1, R. Hassard esq. 1, T. Brass esq. 1, J. S. Holden esq. 1, J. Richardson esq. 1, F. S. Schwabe esq. 1, T. Samuels esq. 1.

*Class 3 contains 282 pictures contributed as follows:—*

Lt. Senior 28, Major Mason 15, L. Ashburner esq. 13, Capt. W. Foster 13, J. W. Richardson esq. 10, F. Beasley esq. 9, A. Booty esq. 8, F. K. Barclay esq. 8, J. A. Jobling esq. 8, J. Richardson esq. 8, H. Day esq. 7, K. E. Chidley esq. 7, R. Murray esq. 6, J. A. C. Bones esq. 6, J. H. Ritchie esq. 6, W. G. Hunter esq. 5, D. Pudumgee esq. 5, J. Middleton esq. 5, G. H. Wood esq. 5, J. G. Hydo esq. 5, Col. Holder 4, Capt. Bankart 4, Capt. Taylor 4, F. H. Tanner esq. 4, R. Grace esq. 4, E. Milson esq. 4, W. D. Howard esq. 4, Dr. Hemphill 3, Capt. Layton 3, L. W. Williams esq. 3, J. Guyton esq. 3, T. Brass esq. 3, J. H. Hutchison esq. 3, M. W. Wemyss esq. 3, Capt. Arbuckle 3, F. S. Schwabe esq. 3, W. H. Harton esq. 2, T. Bell esq. 2, H. Maxwell esq. 2, T. R. Lane esq. 2, Rev. J. Freke 2, R. Hassard esq. 2, T. Samuels esq. 2, Major Gresley 1, T. Turpin esq. 1, C. Stephens esq. 1, W. Church esq. 1, B. Jones esq. 1, R. B. Bowman esq. 1, F. E. Curry esq. 1, T. Brownrigg esq. 1, Rev. T. Hervey 1, Dr. Wilson 1, J. S. K. Moss esq. 1, W. S. T. Sinclair esq. 1, J. H. Craigie esq. 1.

*Class 4 contains 209 pictures, contributed as follows:—*

Lt. Senior 27, L. Ashburner esq. 18, Major Mason 13, J. Richardson esq. 12, E. Milson esq. 11, J. S. Holden esq. 8, A. Booty esq. 6, S. Samuels esq. 6, Capt. W. Foster 6, R. Murray esq. 5, T. R. Lane esq. 5, C. Stephens esq. 4, F. Beasley esq. 4, T. Bell esq. 4, Rev. T. Hervey 4, Capt. C. Layton 4, T. W. Richardson esq. 4, F. H. Tanner esq. 4, O. J. Jones esq. 3, A. Suzanne esq. 3, R. B. Bowman esq. 3, Dr. Wilson 3, H. Maxwell esq. 3, J. S. K. Moss esq. 3, J. Middleton esq. 3, H. Day esq. 3, R. E. Chidley esq. 3, F. S. Schwabe esq. 3, B. Jones esq. 2, J. H. Ravenshaw esq. 2, W. H. Harton esq. 2, Capt. Taylor 2, Mrs. Daubeny 2, Rev. J. Freke 2, J. A. C. Bones esq. 2, J. H. Ritchie esq. 2, M. W. Wemyss esq. 2, Capt. Grimston 2, Col. Holder 1, F. K. Barclay esq. 1, W. G. Hunter esq. 1, D. Pudumgee esq. 1, W. S. T. Sinclair esq. 1, S. W. Williams esq. 1, J. Guyton esq. 1, J. A. Jobling esq. 1, J. H. Carriage esq. 1, G. H. Wood esq. 1, R. Hassard esq. 1, T. Brass esq. 1, J. H. Hutchison esq. 1, W. Bailey esq. 1.

The whole of the remainder of the pictures are comprehended in Classes 5 and 6, but it is unnecessary to mention them separately.

*The following prizes were awarded:—*

J. W. Richardson esq. for three pictures, Nos. 26, 30, and 50 a large silver goblet; Lieut. Senior for a pair of pictures, Nos. 263 and 272, a silver goblet; ditto for a pair of pictures, Nos. 273 and 287, a silver-mounted claret jug; Capt. Bankart for a pair of pictures, Nos. 121 and 124, a silver-mounted claret jug; W. D. Howard esq. for a pair of pictures, Nos. 125 and 126, a ditto; Dorabjee Pudumgee esq. for a pair of pictures, Nos. 12 and 14, a silver goblet; W. Bailey esq. for a pair of pictures, Nos. 1 and 8, a silver goblet; A. Booty esq. for a picture, No. 94, a silver-mounted claret jug; E. R. Hall esq. for a picture, No. 7, a ditto; F. E. Curry esq. for a pair of pictures, Nos. 42 and 43, a ditto; Major Gresley for a picture, No. 31, a large album, elegantly bound in morocco, with silver name-plate; J. G. Hydo esq. for a pair of pictures, Nos. 18 and 19, a ditto.

E. Milsom esq. for a pair of pictures, Nos. 19 and 25, a ditto; J. H. Ravenshaw esq. for a picture, No. 6, an album elegantly bound in morocco; F. S. Schwabe esq. for a picture, No. 1, a ditto; Rev. J. Freke for a picture, No. 25, a ditto.

#### Dry Plate Prizes.

F. Beasley esq. for a pair of pictures, Nos. 87 and 100, a silver goblet; J. H. Ritchie, esq. for a picture, No. 4, a large album elegantly bound in morocco with silver name-plate; R. Murray esq. for a picture, No. 12, an album elegantly bound in morocco.

#### Stereoscopic Prize.

J. S. K. Moss esq. for a pair of pictures, Nos. 63 and 66, a large revolving stereoscope.

*Certificates of Honourable Mention were awarded to the following gentlemen:—*

W. Church esq. jun., B. Jones esq., A. Suzanno esq., Dr. Hemphill, W. H. Marton esq., R. B. Bowman esq., T. Brownrigg esq., Dr. Wilson, Capt. C. Taylor, J. A. Jobling esq., Mrs. Daubeny, J. C. A. Bones esq., R. Hassard esq., J. Richardson esq.

The Council were gratified to find that Capt. Bankart, who was prevented from exhibiting at last year, has again sent a large number of his fine 12 by 10 pictures. Capt. Taylor, though he has not succeeded in taking a prize this year, has contributed some remarkably interesting life studies taken in India, amongst which his portrait of the "Great High Priest of Brahmin," is particularly worthy of notice.

Lieut. Senior has sent from India a very large number of most interesting pictures, amongst which there are no less than thirteen of the highest class. Mr. W. D. Howard still holds his place in the very highest rank, both as regards artistic arrangement and excellence of manipulation.

Dr. Hemphill, for the first time for five years, has failed to carry off a prize, though one of his pictures, "Lady in Antique Dress," is quite equal to some of the prize pictures of former years.

Mr. E. R. Hall has sent another of his unequalled engraving copies, the original print of which cost nearly two hundred guineas.

Mr. Milsom has sent from China some 10 by 8 pictures of considerable merit, illustrating the architecture and scenery of that distant land.

Major Mason has forwarded a series of native Indian portraits, which are quite an acquisition to the Society.

Amongst our later members are several who bid fair to hold a high place in the Association, foremost of whom may be mentioned Mr. J. W. Richardson. Several of this gentleman's pictures possess that combination of "crispness" with extreme softness and delicacy of tone which, though always sought after, is so seldom attained. Mr. W. Bailey, too, has contributed some pictures of game, which, in delicacy of detail, leave nothing to be desired.

The Secretary reported to the meeting the result of an interview he had had with Mr. H. Cole, C.B., of the South Kensington Museum, relative to the "British Museum of Portraits," but in consequence of the examination of the pictures having occupied so much time, the subject was adjourned for the consideration of the next meeting.

Dr. ARTHUR FARRE proposed a vote of thanks—which was passed by acclamation—to Mr. Glaisher for his valuable report, and for the vast amount of time and attention which he had bestowed on the examination and classification of the pictures.

The proceedings then terminated.

A. J. MELHUIS, Hon. Sec.

## Correspondence.

### CLEANING THE HANDS.

SIR,—It is generally admitted that the use of cyanide of potassium for the above purpose had better be avoided, though I have used it for many years, until recently, without inconvenience, and have only given it up even now because many have suffered from it.

It appears Mr. Carey Lea has introduced a formula for removing silver stains from the hands, in which bichromate of potash is a prominent ingredient; I suppose, under the impression that no injury can result from its application. If I am not greatly mistaken, bichromate of potash is quite as dangerous as the cyanide, having a very deleterious action on

the system when its solution is frequently brought in contact with the skin, producing sores, which, like those caused by fluoric acid, are very painful and difficult to heal. It is true the solution is dilute, but, unless I am proved to be in error, I shall be very unwilling to "wash" my hands in so suspicious a mixture.—I remain, &c., J. H. JOHNSON.

*The Vicarage, Tilshead.*

[Bichromate of potash is by no means an innocuous agent, although not such a violent poison as cyanide of potassium. It has no directly injurious action on a healthy skin which is free from cut or abrasion. If it come into contact with the mucous membrane or an abraded skin, great inflammation will result, and, in some instances, serious sores follow. Any agent, however, which can be used to remove silver stains will be more or less injurious, if brought into contact with an abraded skin.]

M. Gaudin's mixture is very effective, either applied to the fingers (not cut) or linen. It is—Alcohol 1 ounce, iodine 24 grains, nitric acid and hydrochloric each 20 drops. The stain, having been treated with this preparation, is next sponged with strong hypo, which at once removes it.

We repeat the following, communicated to our pages, two or three years ago, as an excellent means of cleansing the fingers from silver stains, by Mr. M. Whiting, Jun.:—

"Put half a pound of glauber salts, quarter a pound of chloride of lime (the sanitary disinfectant), and 8 ounces of water, into a small wide-mouthed bottle, and, when required for use, pour some of the thick sediment into a saucer, and rub it well over the hands with pumice-stone or a nail brush, and it will clean the fingers quite equal to cyanide, but without any danger. This will do to use over again until exhausted, and should be kept corked up. The disagreeable smell may be entirely avoided by the liberal use of lemon juice, which not only removes the smell, but whitens the hands. Rotten ones may be used, and answer well."—Ed.]

### PHOTOGRAPHERS' RELIEF FUND.

SIR,—Many as the suggestions that have been written in your Journal of late respecting the organization of a Relief Fund, I think none of the correspondents have set forth such a good, sound theory as that mentioned by yourself last week. I am strongly disposed to believe that any attempt to classify would end in failure, for the fund does not want dissension to contend with at its birth; assuredly there will be enough difficulty to surmount without touching upon that theme. Let all who think of doing any service to the cause put aside all ill-feeling, and should they have a prejudice against any certain classes, this should never enter into affairs of aid and support.

Now I am of opinion that whatever a man may be as regards social position, and he conducts himself as a respectable member of society, and connected in any way with photography (from apparatus-maker to albuminizer), he should be considered an eligible candidate, for it must not be forgotten that "unity" is strength.

Without interfering with selections, every member should be compelled to give some guarantee as to his respectability; for instance, employes could do this until the society was formed, then the new members be introduced similar to the method now in practice with photographic societies. Would it not be as well for those gentlemen who have so kindly promised support to deposit their money and form a committee for the purpose of thoroughly investigating plans for future management? My humble opinion is, that there should not be simply one fixed entrance fee and annual subscription, but several, and the benefit received to be in like proportion; by so doing those in indifferent circumstances would not be excluded from making some provision for their unfortunate days; whereas, should the subscription be great, it would deter them.

All who really and sincerely have the good of their brethren in misfortune at heart will never raise cries of inequality, for those who may now be high up the social ladder may one day find themselves at the bottom.

The above remarks are not written with the idea that they are faultless, but simply in the hope that those who criticise them may bring forward some more efficient plan.—Yours, &c., A. M. B.

[For the purposes of a benevolent fund all sums, either as subscriptions or donations, will be acceptable, and all persons properly recommended would be eligible for relief, the validity of their claims being decided by the committee in office for the

time being. We are not anxious that any deposit of funds should be commenced until arrangements are quite ripe.—ED.]

SIR,—In your last week's paper, in reference to the Photographers' Relief Fund, you call "narrowness" to professional photographers objecting to make a mixed fund. Now I, for my own part, call your doing so disinterestedness, no matter from what quarter it may come; and the average of professional photographers had to labour hard to weed out such rubbish before, or nearly so, and not to commence now to sow a second crop. You also call it industry to join photography with other business, and I call this idleness; and being actuated with a notion of making an easy livelihood is what makes us have such a number of muffs in the trade. Professional photographers are never jealous of each other, neither are they uncharitable towards relieving their distressed brethren; but they wisely and prudently disown any relationship or brotherhood with an intruding hand hedging on the borders of their province. Let me not be misunderstood. I by no means allude to respectable amateurs educated in the science—I believe some of them to be gentlemen worthy of admiration—but I allude to an idle, niggardly lot, no matter whether they be professional or amateur, who are ruinous to the trade, and who style themselves photographers, which nature never intended them for. *Longa est in iuria longæ ambagis.* Let professional photographers know that photography, as a science, should not be coupled with business of a dissimilar nature, and that when respectably carried on in competent hands it affords its followers a livelihood quite adequate, if not superior, to the generality of other respectable professions. So, then, why should not any body of men be at option to exercise their own discretion, and not throw their weapons into their enemies' hands?

I am a sufferer to an extent beyond description by this objectionable spoil-trade style of business, and had to suspend my profession for some time through its means, though being a portrait and general painter before I knew what a camera was. Photography, in a measure, having paralysed painting, and afterwards having taken the disease itself, discouraged many others at the time as well as me. Still, during my suspension of the black art, I viewed its progress and studied it all through with unwearied interest, and have continued doing so to the present moment; and if those persons who are working in the idle system were to work for improvement by laying a good foundation to base their success on (by at first undergoing a due course of training, and afterwards their own practice, if well studied, is about the best means of improvement, together with the many valuable hints from time to time in the journals from several able photographers, both professional and amateur, which they can have for a mere trifle), they would very soon, if possessed of anything in the shape of artistic genius, turn their labour into gold; while in their present state their work is a disgrace to them, and they may not take more than six tolerably good photographs in a year, and these by mere chance. Consequently, their work is not deserving of an ordinary price, perhaps 5s. or 6s. per dozen and less; whereas, if competent to do better work, they could charge from two to three times the price, and please their customers far better.

So, Mr. Editor, lest you may think I am intruding too far on your valuable space, I shall conclude by requesting of you not to crop my letter this time as you did the last, and I shall not appear again. Though I may be a passable hand at my work, I know that I am a bad statesman, and will leave the subject in future to the more learned.—I am, sir, your obedient servant,  
Clonmel, December 7th, 1868. PATRICK O'CONNOR.

[We excised from our correspondent's last letter some passages which were somewhat strongly worded in reference to what he regards as the "spoil-trade" hangers-on. We shall not be suspected of sympathy with any who degrade the profession by bad work or low prices; but in a benevolent undertaking we deprecate a narrow spirit and any attempt to draw a line which might unintentionally exclude some worthy persons from interest in such a fund.—ED.]

## Talk in the Studio.

CARRIER'S SENSITIVE ALBUMINIZED PAPER.—We have recently received from Mr. Solomon an example of Carrier's permanent sensitive albuminized paper, for which he is the

English agent. Our readers will remember that we gave a tolerably full report of the result of some trials we made some months ago with paper which had then been prepared several months. We have, within the last few days, again tried the sample which we received some time ago, and which has been prepared nearly twelve months. We found it perfectly unchanged in all respects, without a trace of discolouration; and printed and treated throughout side by side with that just received from Mr. Solomon, there was no difference in result, both being perfectly clean and pure. The unchangeable character of this sensitive paper is thus proved beyond a question. Its qualities remain just the same as we before described them. It gives an exquisitely delicate and soft print, but lacks a little vigour, unless a negative with full contrast be employed. A special toning bath is recommended, which we before tried with success; this time we used an old sulphocyanide of gold bath, made some months ago, with perfectly good results.

THE EX-PRESIDENT OF THE "CONFEDERATE STATES."—We have received from Mr. Netterville Briggs some portraits of Mr. Jefferson Davis, who is now resident in Leamington, where, amid the magnificent Midland scenery, and the grand historic associations of the district, he rests in comfort after the years of terrible struggle which he so bravely—whether wisely or well it is not necessary to say—conducted in behalf of Southern independence. The portraits are admirable photographs of a grand face: a purely nervous temperament, a broad, massive, thoughtful brow, keen, well-cut features, a powerful but not coarse jaw, a firm mouth, and thoughtful eyes, all contribute to present a man of mark. These portraits, without robbing the face of the traces of what it has passed through in thought and feeling, give it much more refinement than we have seen in any of the American portraits of Mr. Davis. We have here the intellectual, cultivated gentleman, as well as the man of daring enterprise and indomitable will. Mr. Briggs has secured really fine and artistic portraits, photographs worthy of his worthy subject.

MEMBERS OF BRITISH ASSOCIATION.—Mr. Sawyer, of Norwich, has favoured us with a selection of the card portraits of the distinguished members of the British Association who sat to him during the recent meetings in Norwich. The photography is good, and the portraits are excellent.

PERSONAL LUGGAGE.—A correspondent calls our attention to a decision, on the subject of "personal luggage," directly opposite to that we recently recorded in the case of Mr. Owen Angel. An action was brought before Mr. Spooner, Judge of the North Staffordshire County Court, by Mr. Collis, a commercial traveller, against the North Staffordshire Railway Company, for the removal of his luggage at a wrong station, causing him delay and loss, precisely as Mr. Angel suffered loss. Instead, however, of taking the luggage to Derby, the guard put it out at Uttoxeter, and conveyed it to Stoke-upon-Trent, Mr. Collis thus being deprived of the use for two days. He accordingly sued the company for damages for the inconvenience thereby occasioned. The defence was, that the luggage ought to have been labelled or addressed by the plaintiff, and that as the claim for damage was mainly based upon the temporary loss of price lists and account books, which were in one of the packages, and which were not in the nature of "personal luggage," the company were not liable. The judge held that it was the duty of a railway company, either by a uniform system of labelling, or by some other effectual way, to guard against the possibility of such mistakes. The articles in question were not such as to divest the portmanteau of its general character as "personal luggage," and he decided in favour of the plaintiff.

PHOTOGRAPHIC NUISANCES.—The *Tomahawk* says:—"We do not intend to follow the example of some of our elegant contemporaries, and puff the reigning Lais or Phryne of the day. But we wish to enter a strong protest against a custom, which has now extended to shops in the most fashionable localities, and which are much patronized by the mothers and daughters of society; namely, the custom of exhibiting, in the most conspicuous part of the windows, portraits of the most notorious courtesans of the day, amongst the Royal Family, the Bishops, and Prime Ministers, and other celebrated personages. We can readily believe that the young ladies of moral England may have some curiosity to see authentic portraits of those whose manners, but not whose morals, they so perseveringly copy; but such a morbid curiosity it is to us a sign of the gross degradation of society. It sickens us to see the course, idiotic,

sensual features of these goddesses promoted from the scullery to reign over the Casino, impudently smirking and leering side by side with the pure gentle faces of those whom all Englishmen justly love and honour. Is it come to this, that we wish publicly to confess our shame? to declare to all the world that we have so degraded fame to the level of notoriety that a great philosopher, a venerable bishop, or a well-beloved princess, is but on a par with the last 'lady of the ballet,' who has perpetrated the most popular feat of clumsy indecency at one of our theatres, or the favourite pet of the hour, whose pockets are filled with the money and the love letters of our gay youth? Shame on all respectable tradesmen who thus turn their shops into an advertising mart for unblushing profligacy!"

## To Correspondents.

**E. D. S.**—The film dissolving when the varnish you describe is applied arises from two causes: it is probable that the methylated spirit you have used is somewhat strong, or possibly contains an unusual proportion of wood spirit, in which case it would act as a solvent of a collodion film; it is also probable that the collodion is of that character which is easily dissolved by means of strong alcohol or methylated spirit. The mastic varnish, or gum mastic and turpentine, would not produce such a result. There are two remedies: one consists in coating the negative before it is dried, after fixing and washing, with a weak solution of gum; this will protect the film from the solvent action of the varnish; the other is to add a few drops of water to the varnish: this will cause it to be turbid at first, but it will clear with standing. Try, on a small quantity, to ascertain the amount of water necessary.

**EON.**—If you had sent us an example of your failures we could better have advised you. The bad yellow colour of which you complain in the whites of your eburneum prints may arise from the gelatine not being of good or suitable quality, or from using insufficient of the oxide of zinc, or from using that article impure. Pure oxide of zinc should be used, not that at 3d. per pound; for if the latter be pure, it would not be sufficiently fine, and the proportions stated in the formula would not be sufficient to give the gelatine a good colour. If it contain any impurity, that may also account for the blacks turning a bad colour. 2. Zinc white is sometimes called Chinese white. 3. Gum kowrie is a fine white Australian gum, analogous in appearance to fine sample of copal. At one time high hopes were entertained of its probable value for varnish purposes, but its imperfect solubility has rendered it comparatively useless.

**J. C. (Morice Town).**—The lens of which you speak ought to have given you better definition than you describe, especially if used with a suitable stop. Either of those you name will, we believe, be good; but we should prefer A.

**A SUBSCRIBER.**—Write to Mr. Blanchard, 12, Camden Cottages, Camden Road. It is very probable that he will give you satisfactory particulars.

**AN OLD FOLKESTONE SUBSCRIBER.**—The photographs of many of the continental galleries are taken direct from the paintings; but in the Dresden series to which you refer, the negatives are taken from monochrome copies drawn for the purpose. 2. We believe that they are not protected by copyright law. 3. An old and ripe collodion which has lost a little sensitiveness is often useful to add to a newly-mixed sample, and, to some extent, anticipates the effect of time upon the new. 4. Collodion kept mixed with nitrate of silver is apt to undergo decomposition, and become brown, as you describe. In our experience, collodio-chloride of silver keeps better mixed than the collodion with nitrate of silver does. Nevertheless, it is not quite certain that it is useless. Mix the two solutions in their due proportions, and, after a day or two, try the collodio-chloride of silver formed. We have at times found that the addition of the chloride restored the colour, or nearly so, and that the product might be used without serious disadvantage. In any case, the solution containing the chloride is good, and might, by the addition of a few drops of an aqueous saturated solution of nitrate of silver, be converted into collodio-chloride of silver.

**G. AVERY.**—If your pictures were sent in a packing-case, they would be packed and sent back to you; but if they were left at the gallery by hand, we presume they will remain until called for. An answer to your enquiry was written a fortnight ago; but, by an oversight of the printer, was omitted to be inserted.

**A BEGINNER.**—An analysis of the kind you state would require more time than we could devote to it at present, and would be of very little service to you when done. State your object in requiring such information.

**W. J. A. G.**—We do not wish for—nor, indeed, could we take charge

of—subscriptions now. We simply desire to know what amounts photographers are willing to contribute, so as to form some estimate of the propriety of forming a committee to administer the promised amounts. The dry-plate view is very excellent indeed. The comical portrait of the little dog is very good. Thanks. We hope the YEAR-BOOK will meet your anticipations.

**A LEARNER.**—Almost all the chemicals used by photographers are poisons; but those in which he is chiefly concerned, to which the restrictions of the new Act refer, are cyanide of potassium and bichloride of mercury. The distilled water obtained as you describe will be pure if the vessels are clean.

**W. G.**—The Liverpool dry plates are prepared by a collodio-bromide process, but the precise details of their operations are not published. Sugar-candy will not answer the same end as grape sugar. You can get the right article of photographic chemicals. You will find details surely in any work on organic chemistry. What work of the kind have you consulted which contains no allusion to grape sugar? Look for it in the index under "glucose" or "nitro-glucose;" if you do not find it, under grape or sugar; but it will certainly be treated under the head "sugar." 2. We prefer carbonate of ammonia to liquid ammonia in alkaline development. 3. No: the mixture does not keep.

**CANADA.**—The piece of print you enclose bears no trace of imperfect fixation, but seems rather impoverished by excessive action of the hypo bath. A fixing bath with one ounce of hypo in one ounce of water is too strong. We prefer a strength of 4 ounces of hypo in a pint of water for general purposes, and an immersion of fifteen or twenty minutes. Taking the print out of the fixing bath for a minute or two to examine it, and then returning it, would not be injurious.

**EDUCATOR.**—Add a little of a 10-grain solution of common salt to your discoloured silver bath, and shake well. The precipitate will generally take down with it the colouring matter.

**J. C. B.**—When you use the back of albuminized paper for producing plain paper prints, select a thin paper, through which, to some extent, the albumen may have permeated; for remember that the albumen is the element of vigour and warmth of tone. You have used a thick paper, and have not printed deep enough. A weaker toning bath is also generally required. Your examples are over-toned.

**AN AMATEUR (Cheltenham).**—Make a 10-grain solution of carbonate of soda, and add a few drops to the bath, just sufficient to make it turbid after shaking it well; then place the solution in a clear bottle for a few days, and expose to the best sunlight which the season affords; then filter, and try the bath. It may possibly require a drop or two of nitric acid, but will then probably work all right.

**OXONIENSIS.**—There is little doubt that both letters were taken out of that "imaginary letter-box" to which you refer, and that self-consciousness of unverity led to the insinuation of bad faith in others. The person to whose criticism you refer appears under many aliases, and supplies most of the contributions to the said "imaginary letter-box." The matter is not worth serious notice from any one. *Quos Deus vult perdere dementat prius.*

**J. W. SMITH.**—We shall have pleasure in proposing you as a member at the next meeting. You can send post office order for 10s. 6d., the amount of subscription, to the treasurer. You will be entitled to the presentation prints of this year.

**H. S.**—Your card lens will be the most suitable to employ with a magic lantern; better than any of the others, or any combination of them. As to the gas-bags, the manufacturer of whom you will buy them can give you the most efficient advice.

**VENATOR.**—The prints arrived too late for acknowledgment in our last. They are both very excellent.

**J. MARTIN.**—Received. Thanks. In our next. We see the blunders you point out in other pages; but we do not care for the task of pointing them out or correcting them. The range of influence is too limited to be seriously mischievous.

**CYANIDE.**—We have several times called attention to the fact that after this year photographers will not be able to procure cyanide of potassium of their regular dealers; it can only be then obtained of a qualified pharmaceutical chemist.

**W. SAWYER.**—Received. Thanks.

**G. B. SHEPHERD.**—Thanks.

**J. CARBUTT (Chicago).**—The *Art Journal* duly received. Thanks.

**PHOTOGRAPHERS' RELIEF FUND.**—A copy of the rules of the "Artists' Amicable Fund," and two letters containing suggestions for a Provident Fund, duly received, and shall shortly have attention.

**D. WINSTANLEY.**—Received. We will answer shortly. Several Correspondents in our next.

## DECLINE IN PHOTOGRAPHIC BOOK ILLUSTRATION.

THE extended application of photography to the purposes of book illustration which has prevailed during the last few years has been a feature of considerable interest and importance in connection with the progress of the art. For some years past there was a steady growth in this branch of the art. Photographs from nature, photographs from drawings made for the purpose, photographs from paintings and engravings, have variously been employed in taking the place of engravings in illustrating new works or choice editions of standard works. This form of illustration has of late years been especially chosen for Christmas books, and, at this season of the year, it has always been a matter of interest to us to examine the advertising pages of literary journals for announcements relating to photographic illustration.

We have more than once, however, felt it necessary to put on record a protest against the quality of much of the photography we have met with in this branch of the art. It has frequently been far below or far behind the standard of the day: sometimes poor and unartistic in result, often so careless in execution as to give no promise whatever of permanence. The explanation has been a very simple one: it has been done by contract, at a low price, and often under great pressure for time. We have feared, however, that such facts, which were the only things coming under the attention of the public—the explanation being neither known nor cared for—must eventually seriously damage the art, and we now fear that a decline rather than an extension in this branch of the art is taking place. We have been struck with the singular paucity at this period, when they should be plentiful, of the advertisements of books illustrated with photographs. But this alone might not necessarily indicate a falling off in the actual issue. A singular but significant fact, however, was recently brought under our attention. In conversation, a few days ago, with the reviewer-in-chief of one of the principal daily papers, he informed us that of nearly one hundred and fifty volumes of Christmas books now on his table for review, there was not one illustrated with photographs, a circumstance unprecedented in his experience for many years past.

We wish to draw no sweeping or general conclusions from insufficient premises; but such circumstances as those to which we have just referred are sufficiently significant to suggest some grave thoughts on the subject, and especially to give emphasis to the importance of adopting permanent printing processes, and of conducting silver printing processes with all attention to the best known conditions of permanency.

## "WATCHING THE LARK."

WE have refrained from noticing the charming picture presented to the members of the London Photographic Society by Messrs. Robinson and Cherrill until copies were ready for distribution. A specimen print was exhibited at the Society's meeting in May, and received general admiration; and another formed a great source of attraction at the recent exhibition in Conduit Street.

The subject and treatment combine to render this picture one of the most charming, and, we think, one of the most popular subject-photographs ever issued. The scene is a landscape in Borrowdale: seated on a knoll in the foreground, surrounded by wealth of wild flowers, weeds, and ferns, is a pretty little child. She has been gathering the wild flowers, and her little basket, filled with them, has just dropped from her hand, which still lingers resting upon the handle. But the basket and flowers are no longer absorbing her attention; the upturned face is filled with wonder and delight as she watches the circling flight of the lark, and listens to its song. Every feature of the face, every muscle of the body, expresses rapt attention and childish ecstacy. The scene, we said, is in Borrowdale, and Wordsworth's lines, written on the spot, accompany the picture,—

"Up with me! Up with me, into the clouds!  
For thy song, lark, is strong;  
Up with me! Up with me, into the clouds!  
Singing, singing,  
With all the heavens about thee ringing."

Beyond the knoll on which the child is seated, forming the foreground, stretches a fine landscape with woodland, and stream, and bridge in the middle distance, and the grand hills of the English lake district in the distance, surmounted by a fine sky. The picture is so full of life and thought, and so perfectly harmonious, and has so much the feeling of spontaneity and naturalness, that it is not until the student examines it to gain a lesson that he will think of the composition, or even imagine that it has been composed at all; and then he will be struck with the admirable pictorial and technical skill involved in its production. Pictorially, the composition of the lines is excellent, the figure and immediate accessories forming an irregular pyramid. The head thrown back to watch the soaring chorister, and the position of the body which naturally follows, would give the figure an uncomfortable, imperfectly balanced effect; but the little arm, resting on the basket, forms a line which supports the body, and the basket and the little hat, which is carelessly thrown down, complete the pictorial balance. As in a hilly county it should do, the horizon line is high, being not less than a third of the depth of the whole from the top of the picture. The result is, that the tender but atmospheric nicely graduated greys of the distance and middle distance form the practical

background to the figure, and are most effective in giving it relief. A perfect sensation of light and air pervades the whole picture, and the lighting of the figure is in admirable keeping. The exquisite variety, gradation, and balance of tones complete an admirable pictorial result. The technical management of the printing from two negatives is a marvel of success.

Whilst we recommend the careful examination and analysis of the composition of this picture as affording an excellent lesson to the student, we especially direct his attention to the charming expression of thought involved. Balance of lines and tones, gradation, harmony, and other pictorial qualities are necessary elements in a picture; but these should be subsidiary to thought and its perfect expression. Whilst a group of persons were eagerly examining the copy hung in the recent exhibition, one remarked: "What a pity that the lark itself could not be introduced into the picture!"

"But it is there," rejoined another discriminating observer.

"Where?" was the response: "I don't see it."

"Probably not; but the child does, and I can see the expression in her face which proves it."

The criticism embodied here was excellent and true, and of a character we commend to the thoughtful art student.

Other presentation prints to the members of the society, from Mr. Claudet, Mr. England, and Mr. Mayall, will follow in due course, and will each, doubtless, illustrate different phases of excellence and photographic interest. We are glad to notice that the distribution of presentation prints seems to have become a feature in societies as universal as it is pleasant; and it is worth note that Mr. Robinson—or, more correctly, Robinson and Cherrill—have supplied presentation prints of different kinds to no less than four societies this year.

#### PHOTOGRAPHY IN THE THEATRE.

AMONGST the curiously-varied applications of photography, its aid to the scene-painter is not one of the least interesting. At the annual dinner of the South London on Saturday evening last, Mr. Jabez Hughes recalled an incident illustrating strikingly the value of photography in decorative art, a form of art in which, more than in any other, conventional modes of treatment take precedence of the literal truth of nature. Upwards of twenty years ago, Mr. Hughes being at the time engaged with Mr. Mayall, Mr. Telbin, the well-known scene-painter, called at the studio in the Strand, and wished to have a series of Daguerreotypes taken of a quantity of white satin, fresh from the draper's shop, the widths sewn together, and suffered to fall into its own natural folds, without arrangement or design on the part of the artist. To secure a record of the design in anything like useful proportions it was, of course, necessary to take a portion at a time of the satin, the complete effect being comprised in a series of five by four plates. The purpose of Mr. Telbin was to paint a drop-scene for Drury Lane Theatre, and his aim was to produce the most perfect literal transcript of a beautiful curtain of white satin, with all its little sharp accident folds and creases, as well as its general masses. Every one who has visited Drury Lane Theatre is familiar with the scene, and knows how complete is the illusion. So perfect and satisfactory is the result, that whatever other changes have been made in the decoration and scenery of the house, this remains through every management in constant use, and continues until now a perfect and most illusive presentment of a white satin curtain.

At the Haymarket, Mr. O'Connor, the accomplished scenic artist of that theatre, has used photography in another form. When scenes of an architectural character are required, representing actual places, he has found useful a transparent photograph of the subject, the image

of which is projected by means of a magic lantern on the canvas, and this image serves as a perfect guide in securing accurate proportion and perspective correctness. In both these applications photography does yeoman's service to the painter.

#### NEW STYLE OF MOUNT FOR PHOTOGRAPHS.

Mr. Fox has recently brought under our attention a new style of tinted mount for photographs which, under some circumstances, is very effective. For a long time the mount with an Indian paper tint, or a delicate grey, in immediate contact with the picture, has been a favourite with photographers. It had the especial advantage of giving value to the whites of the photograph, which, especially in the days of the old toning and fixing baths, if in contact with a pure white mount, often appeared a little degraded. Perhaps for a fine portrait print, printed fully out, nothing is more effective than the kind of mount we have just described. But there are circumstances in which such a mount ceases to be suitable or effective, and to meet these cases Mr. Fox's new style of mount is designed.

The new mount, instead of having a tint for immediate contact with the picture, surrounded by a broad white margin, is printed with a broad tint, which constitutes the margin, with a space of plain white in the centre, leaving a margin of white to come into contact with the picture itself. This effect with many pictures is very pleasing. For instance, in landscapes where the sky has printed through to a delicate tint, the print, if mounted on an India tint, would appear to have a white sky; mounted, however, in contact with the white portion of a board having a tint beyond, the atmospheric tint of the sky receives its full value, and the picture becomes effective. The same is true of vignetted portraits in which the background softens into a grey tint instead of into white, and in a number of other cases the new style will produce a more pleasing result than any yet devised.

The new style exists in various tints, and having centres of various shapes and sizes to suit all pictures.

#### WASHING SENSITIVE PLATES.

AT the last meeting of the South London Society an interesting discussion arose as to the causes of pinholes in dry plates. The subject was not, we think, by any means exhausted, and we do not intend to renew it here; but we wish to call especial attention to one important observation made by Mr. Sebastian Davis, who opened the question.

Dry-plate photographers have often been warned of the dangers of washing a plate fresh from the nitrate bath with any kind of "common water," as the chlorides, carbonates, &c., in such water would precipitate on the plate insoluble silver salts, which, becoming firmly attached to the spongy surface of the film, would result in spots, stains, &c. It has become, therefore, a tolerably generally recognized canon of dry-plate photography, that the first washing of the plate after it leaves the nitrate bath should be effected with distilled water. But Mr. Davis pointed out another danger, obvious enough when once indicated, but which has, singularly enough, been generally overlooked. He showed that the use of distilled water was not a certain means of avoiding a precipitate of an insoluble silver salt. The nitrate bath, containing a certain amount of iodide of silver in solution, would precipitate a portion of this if diluted, and as the first application of distilled water in washing is a practical dilution of the free nitrate on the plate, a precipitate of iodide of silver was thrown down, and, unless especial care were used, this would become attached to the film and prove a source of pinholes. He suggested, therefore, that the plate should be kept in motion, and the water so applied as to check the risk of a precipitate settling on the film. To aid this we suggest

the importance of using a dipping bath of distilled water for such washing, and the frequent moving of the plate whilst in the bath. By a little care, and a knowledge of the danger, it is obvious that the precipitate in question may be prevented from exercising any detrimental influence on the plates.

### AN AMERICAN EXAMINATION OF MR. McLACHLAN'S DISCOVERY.

A COMMITTEE having been appointed by the Photographic Section of the American Institute to examine the propositions put forward by Mr. McLachlan, Mr. Newton, an able New York photographer, recently reported on the subject. He said that the committee had not entered into any concerted examination of the subject, but had experimented independently, and compared notes. We extract from *Humphrey's Journal* some of the remarks of the experimentalists:—

Mr. Newton stated that he did not follow Mr. McLachlan's directions, either in the mode of making the bath alkaline, or in the proportions of silver and water. Mr. McLachlan exposes one ounce of silver dissolved in one ounce of water to the sunlight for three months. Now as the solution, to make it suitable for the negative plate, must have added to it ten or eleven ounces of water which has not been subjected to the influence of the sun's rays, it appeared to him that a much longer time would be required to prepare a bath by Mr. McLachlan's process than by mixing the silver and water of the proper strength at the commencement.

It would appear evident that the action of light is on the solution, and not on the silver, for if it were on the latter you would get the same effect by exposing your nitrate of silver crystals to the action of sunlight.

To prove the correctness of this theory I added to a 40-grain bath, containing 54 ounces of solution, 1 ounce of crystals of nitrate of silver. The working properties of the bath were not perceptibly changed by the addition. This bath had previously been worked down from 45 to 40 grains to the ounce.

Mr. Newton, therefore, made his bath of the strength he wished to use it, then added to it one half grain to the ounce of cyanuret of potassium, and one drop to the ounce of concentrated ammonia, and exposed several baths for different periods of time.

He found that a bath thus prepared and exposed two weeks required the addition of a few drops of nitric acid, leaving it, however, decidedly alkaline, when it would make beautiful negatives, leaving nothing to be desired.

A bath prepared in the same way, and sunned six weeks, worked perfectly clear and brilliant, without the addition of any acid; from which fact he concluded that the longer such a bath was sunned the more alkaline it can be used,\* and the more intense would be the negatives.

Mr. Newton, fearing that there would be some considerable scepticism manifested by members of the Society, came prepared to silence all such scepticism. He brought with him eight or ten negatives, and also a small bottle of the negative bath in which they were sensitized, and some red litmus paper which he introduced into the bottle containing the bath, when it instantly turned a deep blue colour. The negatives which he exhibited as made in-doors were portraits, and made by Mr. S. A. Thomas, one of the committee; those made out-doors were made by Mr. Newton. They were all very brilliant and of a beautiful intensity.

Mr. Newton stated that nothing had been done to any of them further than developing, fixing, and varnishing; no redeveloping or strengthening of any kind had been necessary.

Mr. Thomas prepared his bath in the same way as did Mr. Newton, except in making it alkaline; he followed Mr. McLachlan's directions by using caustic of potash.

Mr. Thomas stated that he had used the bath in which the negatives on exhibition were sensitized very much longer than he had ever been able to use an acid bath, and, up to the present time, it had shown no signs of disorder.

Mr. Newton stated that the results were so contrary from what he had expected, and differed so widely from the universal experience and theories of photographers, that he hardly expects photographers to be fully convinced except by actual experiment. He believed it to be a subject of more importance to professional photographers than any which had been presented to them for a long time; and when all of the committee have completed their experiments, and are prepared to present a full report, the subject will be so definite and fixed that there can be no possible mistake made by any one wishing to adopt the use of the alkaline bath.

### PICTURES BY THE ACTION OF COLD.

BY D. WINSTANLEY.

THE terms heat, light, and electricity, are terms used to indicate three of the great divisions under which a vast variety of phenomena are classified by writers on natural philosophy. In the pages of scientific encyclopædias photography finds its place under the heading of "light," the force upon which the science of optics is entirely based. This science, as its name implies, explains the various phenomena which appear for recognition to the organ of sight. Since, however, the emissions which produce the photographic effect are not necessarily such as may be seen, it is scarcely correct to say photographs are produced by the action of light, and, indeed, the word "photograph" itself is not altogether a proper term. The force of actinism, as we now call the chemical power of light, is scarcely yet sufficiently well understood to warrant the substitution of the term "actinography" in place of the firmly grounded and almost irremovable word "photography," which latter term forcibly calls up in the mind of every one the idea of pictures produced by the action of light. The production of pictures by the influence of electricity—electrotypes, and the telegraphically transmitted autographs of Mr. Bakewell, for instance—are also familiar to readers of works on natural science; but the production of pictures through the influence of heat—or, as the writer has more incorrectly worded it above, the action of cold—as a possibility by no means so generally known.

Between the months of November, 1863, and March, 1864, it was the writer's fortune to winter in Wisconsin, U. S. The weather was exceedingly severe, the thermometer falling frequently to as much as 38° degrees below zero (Fahrenheit.) Cold like this, especially when accompanied by a strong wind, tries human powers of endurance to a much greater extent than they ever are, or perhaps, than they ever have been, in England. During the winter alluded to, Lake Michigan was frozen as far as the eye could reach, and when the ice broke up in the harbour of Milwaukee it was twenty-six inches in thickness. The snow in the districts round about the town was fourteen feet in depth; and on New Year's day, 1864, eleven persons were frozen to death within the city limits. At the commencement of these "cold spells," as those period of intense cold are termed, the thermometer frequently falls more than fifty degrees in a single night. Under these circumstances, all the moisture floating about in the atmosphere of a room is congealed to the form of a thick coating of ice upon the windows, which ice is crystallized in a more or less opalescent form, according to the rapidity of the condensation. One morning, upon entering the drawing-room of the house where he resided, the writer's attention was arrested by the beautiful and regular design given, in different degrees of opacity, by the ice upon the windows. These windows descended quite to the floor of the room, opening on to a verandah on the outside. The design alluded to upon the frosted glass was vague and indistinct at an elevation of fifteen inches above the floor, but became more sharp as it descended, until quite at the bottom the leaves and flowers of the carpet were distinctly and unmistakably traced upon the glass. The writer called the attention of several others to this interesting phenomenon, which all were able to see without difficulty was, as the writer has stated, a representation of the design upon the carpet. The different degrees of facility with which radiation was possible from the various colours forming the design on the carpet affords no doubt of the true explanation to be given for the production of the design upon the window.

The writer has attempted to repeat the production of pictures by the action of cold upon the table of his laboratory, but, so far, without success. It may, however, be worth while to mention the method adopted in this attempt. An aqueous solution of iodine and iodide of potassium, strong enough to emit a powerful odour of the elementary body

\* Mr. Newton overlooks the fact that the continued action of light on a silver solution would reduce silver, and liberate nitric acid.—Ed. F. N.

(thereby proving its existence in a state of vapour), was made. This mixture was then poured into a shallow porcelain vessel, and covered with a plate of glass upon the under side of which was a film of uniodized collodion, and on the upper side of which was placed a piece of white paper having large black letters printed upon it. Over this paper a clear plate of glass was placed, upon the upper surface of which ether was continually dropped for several minutes. The idea of the writer was that the cold produced by the evaporation of the ether would absorb the heat from the sheet of paper beneath, and consequently from the collodionized glass under it, with different degrees of facility, varying with the radiating power of the black letters and their white ground. The collodionized plate was then removed from beneath and plunged into a silver bath, the writer hoping that the amount of iodine condensed upon the collodion surface would vary with the radiating power of the letters and their ground. The plate, after removal from the silver bath, was exposed for a few seconds to the action of daylight, after which a common iron developer was poured over its surface. The whole developed up almost black, but the writer was enabled to distinguish upon its surface any semblance to the letters whose image he expected to obtain. Some of the readers of these pages may perhaps see the error committed in this experiment, and, if so, indicate a means by which it may be avoided, thereby enabling us to repeat the experiment of producing pictures by the action of cold.

### PHOTOGRAPHY IN CONNECTION WITH THE ABYSSINIAN EXPEDITION.

BY H. BADEN PRITCHARD,

OF THE GENERAL PHOTOGRAPHIC ESTABLISHMENT OF THE WAR DEPARTMENT.\*

THE purposes for which photography was used with the army in Abyssinia were very different to those for which it is generally employed by professional followers of the art. Photography in that campaign fulfilled all the duties of a printing-press in the field, and rendered unnecessary, in many ways, the employment of skilled draughtsmen and lithographers. Maps, plans, and sketches of routes were by its means elaborated and put together, and afterwards multiplied with unerring exactitude and great rapidity. This was the principal function performed by the art, and for the fulfilment of which the photographic equipment was sent out; the taking of pictorial views and sketches of the country, although forming an important part of the photographer's duties, was a matter of secondary importance, and partook more of a semi-official character.

In moving an army over an enemy's land, especially if that land be an untravelled and unknown one like Abyssinia, it is imperatively necessary for the commander-in-chief to obtain correct information of the nature of the surrounding country, the state of the roads, &c., over which his troops will have to pass. For this purpose *reconnaissances* are frequently pushed forward to the front and on the flanks of the army, to examine and survey the adjacent ground; and staff officers, who have previously received special instruction in their duties, carefully sketch out a plan of the district visited, which they forward, together with such information as may have been collected, to the Quartermaster-General's Department. A scale is of course attached to every plan sent in, but this need not be the same in all maps; for when the latter, after examination and verification, are forwarded to the photographers to be copied, an enlargement or reduction of them is easily made to one uniform scale. The copies are printed upon salted paper, and mounted upon linen; and the work is done so rapidly that it frequently happened that thirty prints were produced and distributed within twenty-four

hours of the receipt of the original plan. In order that officers might be acquainted with the method of working adopted by the photographic staff, and likewise with its resources, General Simmons, C.B., R.E., prior to the despatch of the equipment, carefully drew up a memorandum relating to it, for the information of all concerned. According to this document it was stated that whenever a plan was forwarded to be reproduced, the first copy might be expected in about two hours, after which copies would succeed each other at the rate of about four per hour of sunlight. To so great an extent was photography used in this connection during the late American war, that within the period of one month, during General Grant's advance to the Rapidan, no less than 1,200 maps of this kind were circulated. Thus it will be seen that at the present day photography plays a most important role in aiding the movements of troops, often furnishing the several commanding officers of the different branches of the army with details of a *reconnaissance* taken only the day before.

Seeing the importance of the services to be rendered and amount of work to be performed, it was necessary to furnish a very ample photographic equipment; and the collection of instruments and materials sent out was therefore a bulky affair. The selection and arrangement of the stores and apparatus was entrusted to Captain Stotherd, R.E., and Lieut. Anderson, R.E., the Instructor and Assistant Instructor in Photography at the Royal Engineer Establishment at Chatham, gentlemen, therefore, possessing considerable experience in the art, and well acquainted with the necessities likely to be required for a campaign; and the general success which attended the working of the equipment was in great part attributable to the excellent manner in which these officers acquitted themselves of their onerous duties. Two separate outfits were supplied, each contained in eighteen boxes; but only one of these was used and taken forward with the army to Magdala; the reserve outfit remained at Senafe, and was returned to England intact. The equipment may at first sight appear far too extensive; but when it is remembered that the nature of the work to be performed involved the employment of a large camera, the supply of other necessities was of course also requisite of corresponding size and quantity; it must likewise be borne in mind that the duties of the photographers were not confined to taking negatives only, but that the greater part of their labours were devoted to the processes of sensitizing, printing, and mounting, operations which had mostly to be conducted within the limits of the dark tent with which they were provided. A large copying table, mounting boards and material, washing utensils, a portable still, &c., were found to be almost indispensable, and helped to swell the list of incumbrances to a notable extent, not to mention the glass plates for the negatives and paper for the positives, of which sufficient was provided in each equipment for taking 200 large *cliches* and 1,700 prints.

On any future expedition of this kind the application of photography will no doubt receive even more extended employment than at present. It would afford the most invaluable information to commanding officers if the mechanical *reconnaissance* sketches were always accompanied by an actual photograph showing the nature of the ground surveyed. If a small stereoscopic view were thus attached to the map drawn to scale, one would immediately be able to understand the true character of the district; all the mountains, ravines, rising ground, declivities, rivers, lakes, &c., would be shown at a glance, and their position at once comprehended. The negatives might easily be taken by the staff officer making the *reconnaissance*, who would be provided with a small camera and a couple of dark slides containing dry sensitive plates. He would require at the most but five minutes to perform the duty, and would simply need instruction as to the approximate time necessary for the exposure of the plates; on his return he

\* Read before the London Photographic Society, December 8th.

would hand the negatives over to the photographic staff, who would develop and print them. The stereoscopic cameras would also be useful for ordinary manipulation, as the negatives produced are of sufficient size for most purposes, and are always capable of being enlarged if necessary.

The personnel of the equipment consisted of one chief photographer, Sergt. John Harrold, R.E., and seven assistants, all of whom belonged to the 10th Company Royal Engineers; besides photographers, the Company included men skilled as telegraphers, signallers, well-sinkers, &c., all of whom were under the orders of Lieut.-Colonel Pritchard, R.E.

The difficulties of working were sometimes very great, especially near the coast, and the experience gained will, in many cases, be of great value. The dark tent seems to have been the *bête-noire*; although no doubt very suitable for employment in a temperate climate, it proved for Abyssinian service exceedingly hot and close, and also very unsteady. Sergeant Harrold suggests that it would be a great improvement to furnish the same with guy ropes, for the purpose of rendering it firmer and more solid. The tent was several times blown down, and the covering continually flapping about from the effect of the sand-storms and strong mountain breezes, so that some difficulty was experienced in drying the pictures and in conducting the operations connected with printing. The fine sand blowing about was a most serious annoyance, as it was quite impossible to prevent it from penetrating the boxes, camera, and utensils; even the photographic solutions became contaminated with it, although the tent was kept so close and tight as almost to prevent breathing, the effect of being shut up in a confined space without light or ventilation on the glaring shores of the Red Sea being a sensation more easily conceived than described. For hot climates it would no doubt be better to construct the dark tent with a white or yellow outside covering, which would fail to absorb the heat rays in the same degree as an ordinary black tent. At Annesley Bay and Senafe especially, the heat was very intense, and great vigilance was necessary to preserve the collodion of the proper consistence, and to avoid the desiccation of the plate when taken from the bath.

The manner in which the collodion and iodizing solutions were stoppered was one which the chief photographer found to be very faulty; in some cases as much as half of the solutions had evaporated, and the remainder therefore required judicious doctoring. The best plan to secure these liquids would be to cork and seal up the bottles, a glass stopper being tied round the neck for employment after the vessel has once been opened.

The collodions sent out were of the usual descriptions at present in the market, and, on the whole, answered very well. For hot sunny climates, however, there can be no doubt that a liquid collodion should be selected especially rich in alcohol, and sensitized with salts which exert a liquefying action upon the material, as, for instance, the iodide and bromide of ammonium. It would appear, moreover, that a collodion which is not so very highly sensitive is best suited for employment in the tropics, and, if required for landscape purposes, it should contain a goodly proportion of bromide, in order to secure as much detail and half-tone as possible. To prepare a material of this kind it would be necessary to diminish the amount of sensitizing salts, as the rapidity with which a collodion works is governed mainly by the quantity of these salts contained in it; the proportion of bromide and iodide to be employed might soon be ascertained by a few experiments undertaken in the sunshine, but, according to Dr. Vogel, five equivalents of bromide to one of iodide may be used with good effect, provided an acid bath be employed to prevent the fogging of the negative.

(To be continued.)

## A VISIT TO THE PHOTOGRAPHIC STUDIO OF THE IMPERIAL MILITARY GEOGRAPHICAL INSTITUTE IN VIENNA.

BY ALOIS NIGG.\*

I WAS subsequently informed that in working with large plates it was quite impossible to coat the glass with collodion in the same manner as that adopted for those of a smaller description; if such a method were adopted, the glutinous mass would, by reason of its own weight, hang in folds towards the lower part of the plate, while it would be torn off altogether from the upper portion. For this reason the margin of the glass is roughened all round, so that a more perfect adherence may be effected; at the same time, a collodion is selected for employment which dries very slowly, and is likewise of not too thin a consistence, so that during the time it remains upon the plate in a horizontal position an equal distribution of the mass takes place.

The rest of the operation requires merely special skill in its performance, for it does not matter so much by which method one works, as what are the nature of the results obtained. The quality of the productions turned out by the Imperial Institute furnish the most satisfactory proofs that with the talent available, and the opportunity for continual practice in the most difficult operations, together with the efficient superintendence bestowed, success is sure to attend the labours of the staff, whatever may be the method pursued.

M. Fink works in a pair of india-rubber gloves, examining the plates in the light by holding them flat in his hands at the two opposite edges; by this means he but seldom soils the fingers during the elaboration of a negative.

During my visit at the Institute, Colonel Schopf was engaged in examining some proofs in the photo-zincographic department, and I regret, therefore, that I am unable to make known any of the important details relating thereunto. Without the quaintness of manipulation which characterizes M. Fink, M. Schopf works in a more quiet and precise manner, which always seems to suggest the most agreeable expectations of his continual researches. He was good enough to inform me that the employment of cyanide of potassium had been totally superseded in the Institute, by reason of the injurious vapour and poisonous smell to which it gives rise when used upon large surfaces. Even for the removal of silver stains upon the hands, cyanide of potassium has ceased to be employed, a concentrated solution of corrosive sublimate being found much more efficacious for the purpose.†

He informed me, likewise, that the positive paper used for printing is not rendered sensitive by floating upon nitrate of silver solution, but that the latter is applied to the surface of the paper by means of a brush, thus effecting a considerable saving in the preparation of so costly a liquid when dealing with prints of large size. A soft camel's-hair brush, not less than four inches broad, is used for the purpose, and at the lower margin of the paper are attached a few pieces of blotting-paper. The brushing over of the silver solution is repeated a second time as soon as the paper has become slightly dry, but while it is yet tolerably moist. This mode of operating would seem especially suitable for adoption by photographers whose work consists chiefly in the production of enlargements, for the results obtained by the method certainly leave nothing to be desired, provided care is taken that the sheet is washed over with the sensitizing solution to a sufficient degree.

During a recent discussion in photographic circles on the merits of the method of coating and preparing the plates just described, it was mentioned that this original manner of operating, although yielding good results in negatives where contrast is very great—as, for instance, in maps composed of black lines upon white ground—could scarcely be

\* Continued from p. 593.

† We cannot but think that a strong solution of bichloride of mercury would be quite as injurious for application to the hands as cyanide of potassium.—Ed. P. N.

employed where delicate gradation or soft half-tone is required. To confute this argument I exhibited, at the last meeting of the Vienna Photographic Society, a large 30-inch negative, being a life-size portrait of the Baron v. Wertheim, which was prepared at my request from a print of equal size, and which proved in the clearest manner that the method might with advantage be adopted for the production of ordinary negatives.

When in any of the map-negatives there are found large empty spaces which print too transparently, or, in plates of coloured plans, certain portions which do not possess sufficient density, the glass in these cases is made more opaque by gumming upon the reverse side of the finished negative pieces of tracing-paper, which are cut by means of a sharp knife to the required outlines. In this way negatives of insufficient density are made to furnish prints of a very clear and even character. This method of increasing the opacity of the film I have modified somewhat for employment with large portrait negatives: I accurately cut out a piece of straw-paper on the back of the negative, according to the outlines, and afterwards attach it to the front of the plate over the varnish.

The composition of the solutions and formula used at this Institute have already been given in the *Correspondenz*. Not less important than the work performed in the photographic studio are the labours undertaken in the photolithographic and galvanoplastic departments; so that the establishment may be regarded in the highest sense as the cradle of multiplying arts.

### ON INTENSIFYING NEGATIVES.

BY GEORGE H. FENNEMORE.\*

A NUMBER of negatives have been shown me lately representing the work of some ten or fifteen different photographers. I was struck with the many different modes adopted to bring these negatives up to what was supposed to be the proper density for printing, by the use of intensifying agents. And I was both surprised and pained to see many negatives that really had a great deal of merit in them completely spoiled by the indiscriminate use of such agents as sulphuret of potassium, bichloride of mercury, iodide of mercury, &c. It seems to be that the one idea of a perfect negative was clear glass for the dark parts, and complete opacity for the whites. When will photographers learn that the only merit in intensifying is to produce tone; that is to say, a well-graduated balance between the highest points of light on the face, and the deepest shades on the drapery, the remainder being half-tone? The face of no picture should be white, because there is no pure white in the face of a living human being. When we see a person in a strong light there are certain spots of light on the face which appear to us to be nearly white; for instance, on the point and slightly extending up one side of the nose; one bright spot on each eye, and another on the forehead, if it be smooth. It follows, therefore, that the only points of pure white in a portrait should be (for instance, of a man with dark clothing) the shirt collar and bosom, the cuffs, and the catch-lights of the eye. Consequently, they should be the only parts showing perfect opacity in the negative. Suppose, for example, you have for a sitter a lady with a black velvet sacque and brown merino dress: do you think you can secure the proper negree of tone between the sacque and the dress, if you bring your negative anywhere near perfect opacity in those parts representing the face and hands of your sitter? Assuredly not. A brown merino dress will be quite dark in a picture, because it has not much power to reflect white light; but if taken in conjunction with black velvet, it will look comparatively light, because the velvet represents perfect black, and the dress does not. For making a negative of such a subject, the object should be to place the sitter in

such a light as will give a harmonious rendering of light and shade; expose sufficiently long to allow the developer to bring out the finest detail; and then, if necessary, intensify until the highest points of light in the face are sufficiently dense to keep the paper white until the printing is deep enough on the velvet to represent pure black. A print from such a negative will be bright and vigorous, and, at the same time, full of the most delicate detail and half-tone.

The question, then, arises, What is the best method of producing the desired result? Unquestionably the best negatives are those that have had a full exposure, and the proper amount of density brought out by the first development; but this cannot always be done, because, with the practical photographer, the conditions necessary to produce such a result are continually varying. With the amateur photographer it is somewhat different, because he can generally choose the time best calculated to give him the desired result; but those who have to make their living by the aid of the camera are obliged to manipulate at all times during the day, and under all conditions, which, as I said above, are continually varying. The light varies, and the subjects vary: first, perhaps, a full-grown person, then an infant a few months old; or you may have a young girl with a round face and pearly complexion, and afterwards an old man from the country, full of wrinkles, and sun-burnt and tanned almost to the colour of an Indian. This is no exaggeration; and I candidly ask those who tell us that after-intensification is only an excuse for bad manipulation, if they can come into a gallery and produce, from morning till night, perfect negatives with a single development? My experience tells me No; but I may be mistaken. But while I believe redevelopment and intensification necessary in many cases, I also consider that every endeavour should be used to produce a perfect negative without it.

One great fault among many operators is, that they do not stop to consider whether a negative requires to be redeveloped or intensified. This becomes such a confirmed habit with them that it is the general rule, and not the exception, and they are apt to abuse it. This is a great mistake, and will have much to do with making or marring the beauty of the print. For the sake of illustrating this point, let us begin an imaginary day's work. Our first sitter is a young girl with a fair complexion. We expose our plate, and get a good negative, perfect in light, shade, and half-tone. The next is an old man, wrinkled, and with a sallow complexion. We sit him the same time as the other. Do we get as perfect a negative? No; for the face lacks sufficient density, and the wrinkles show with painful distinctness. The proper remedy for such a negative is to try again, and give more time in exposing. This will allow the weaker radiations of light from the face to impress themselves upon the sensitive plate, thereby softening down the wrinkles, and making a much more pleasing picture. The negative is now very soft, but weak, and must be strengthened or intensified, the best mode of doing which I will explain below. Our next subject is an infant. We try two or three plates, perhaps, before we succeed in getting it still, even for a few seconds; we develop the plate, and find but little more than an ambrotype, but we feel satisfied to think we have got that much. But how shall we bring it up to something like-printing quality? By sulphuret of potassium or bichloride of mercury? Many of you will say, Yes. But I say, No: because the negative is still capable of having more of the detail brought out; and this can be done by taking a portion of your bath solution, and, after well washing the plate from the first development, flood it evenly with the silver solution, allow it to permeate the film thoroughly, drain, well, and then flow over your iron solution again, or pyrogallie acid solution, which latter I prefer. Do not keep it on too long, or it may fog the plate. If it does not come up sufficiently, wash the plate well, and repeat the dose. In this way many a good negative may be made from short exposures.

The chief trouble in intensifying is caused by the impa-

\* Philadelphia Photographer.

tience of the operator, who aims at getting it through in a hurry. To redevelop or intensify a negative properly, it should be done slowly, producing a fine, even deposit, only upon those parts already acted upon by the developer. This is done by adding a very small portion of silver to the pyrogallic acid, or iron, as the case may be. But many operators throw in the silver without much regard to quantity, thereby producing a very coarse and uneven deposit, and not unfrequently covering the whole negative with a red veil of reduced silver. Intensification, therefore, in careful hands, may be made to beautify, and, in careless hands, to destroy, the negative, according as it is properly or improperly practised.

In conclusion, I give my plan for redevelopment and intensifying. In the first place, I make my solutions as follows:—

*Solution No. 1.*

Pyrogallic acid	...	...	16 grains
Citric acid	...	...	24 "
Water	...	...	8 ounces.

*Solution No. 2.*

Nitrate of silver	...	...	25 grains
Water	...	...	1 ounce.

*Solution No. 3.*

A very weak solution of sulphuret of potassium, to be used as directed below.

For slightly under-exposed negatives I take half an ounce of solution No. 1, and add to it three or four drops of silver solution No. 2. This will remain on the plate a long time without decomposition. If the plate is fully exposed, I fix first, and, after well washing, intensify the same as above. If the plate is slightly over-exposed, or very weak and flat, I use, after fixing and washing, the weak solution of sulphuret of potassium, because that is an intensifier alone, and has no redeveloping qualities, and, consequently, is the best for over-exposed negatives. The above only applies to negatives that really need after-intensification, for, as said before, I never use any if I can get along without it.

I hope what I have written may benefit some of the less-experienced of my brother photographers.

## MEANS OF EQUALIZING EXPOSURE WITH WIDE-ANGLE LENSES.

BY JOHN M. BLAKE.\*

THE plan finally carried out in practice may be thus described:—In front of a Zentmayer lens a disk is suspended by means of fine wires stretched across a frame. This frame can be drawn out parallel to the axis of the lens. The object is to shade the centre of the field while the borders are receiving the necessary amount of exposure. Now, provided we know the time required for each portion of the field, and can give the disk a steady and regulated movement, finally removing it altogether from before the lens, we can control the distribution of actinic action as we desire.

On trial, the steady movement of the disk was found unnecessary. Four separate adjustments gave no visible ring on the plate when using the Zentmayer lens, provided that in the first position the disk was as near the lens as the mounting would admit.

The first object sought in deciding on these positions was to make them answer to times which would be simple fractions of that required for central exposure. In case we wish to expose the limits of a field of 85° three times that which the centre requires to give the best results, we may take such successive positions for our disk that, first, its shadow shall cover a circular field of 74°, and expose the annular portion outside this once the time required for the centre. Second, move the disk until its shadow on the plate subtends 58°. The illuminated ring outside this is now ex-

posed one-half, as above. Third, the shadow measuring 44°, time, one-quarter. Fourth, shadow 20°, time one-quarter. Fifth, the disk is removed altogether, and the whole plate given the time of central exposure.

The above adjustments and times may give as good an equalization of exposure as the necessities of the case require. If we include a less angle at the corners of our plate than given above, we may commence with the second or third position, and, of course, shorten the whole time accordingly.

If it is thought three times the central exposure is not sufficient for the borders, we may arrange for four times this, as follows:—Shadow of disk, 76°, time one; 64°, one; 48°, one-half; 34°, one-quarter; 15°, one-quarter; whole plate, one. This makes six adjustments, if we count the removal as one.

The above estimates are only given as approximations, sufficiently exact for practical purposes. A curve was plotted, representing the calculated times required for different parts of the field, and the best adjustments of the screen for the given intervals of time found by measurements from this curve. The tendency to form a ring on the plate is greatest when the disk is farthest removed from the lens, since its shadow is then more sharply defined, and, also, because the intervals are shorter, and more exact timing is necessary.

The centre can be exposed first or last, as is most convenient, and, provided we succeed in locating objects liable to move in the centre of the field, we actually increase the efficiency of a wide-angle lens in respect to quickness in working; for the centre of the field can actually be exposed a less time when this method of equalizing exposure is employed than is possible when we would get the best general effect over the whole field in the ordinary way.

As an additional refinement, it may be suggested that the disk should be inside the camera between the lens and plate. In this position it will not itself become, to some extent, a luminous object, for it will be effectually shaded. Further than this, when it is outside and shading the centre of the plate, this portion is unnecessarily subjected, during the whole exposure, to light reflected between the two lenses of a double combination. Although, in the lens used in my experiment, this reflected light was so distributed by the arrangement, of curves as not to come to a focus on the plate, and thus form a central spot, and was as small in amount as it is, perhaps, possible to attain in any combination, there was a slight fogging near the middle of the plate, visible on an otherwise perfectly clear negative, when viewed by reflected light, the effect of which was to make negatives taken with an equalized exposure print more slowly near their centre than negatives produced in the ordinary way, having equivalent central exposure. This unwelcome light, which, with my lens, I consider mostly due to the luminosity of the disk, was isolated by exposing the outer portions of the plate the amounts above given, omitting the final exposure of the whole plate, thus leaving a circular spot at the centre of the latter, which ought to have been clear glass, but by reflected light it showed fog. Measures were taken to prevent blurring, and all other sources of fog were absent, for the borders of the plate showed perfectly clear glass on several repetitions of the experiment. At the most, this fog is slight, to be discovered only under favourable conditions. The lens gave no detectable fog in an ordinary exposure (for instance, over a dark interior, near the centre of the plate). The front of the lens and disk were shaded, as much as practicable, by a box. This box was necessarily shallow, on account of the wide angle.

An internal central screen would reduce this fog to a minimum, if due to the operation of either cause. The mechanical difficulties in the way of adjusting and removing it are, however, much increased in this situation.

I have not yet completed an arrangement by which I hope to accomplish this object. A large plate can be rotated back of the lenses in a stereo-camera box. This plate is provided with a double set of disks of different sizes, suspended in apertures which are brought in succession opposite the

\* Continued from p. 595.

lenses. While this should accomplish the same object as the plan actually used, and have the advantages mentioned, there will be an additional gain, inasmuch as the shadow of the screen will be less sharply defined; and hence we may do with fewer adjustments than above given, so far as the formation of a visible ring on the plate is concerned.

The difficulties in the way of perfecting the last-mentioned arrangement are tenfold greater than in case of the external screen.

### THE CAUSE OF PINHOLES IN DRY PLATES.

BY SEBASTIAN DAVIS.

[The following remarks were made by Mr. Davis in introducing a subject from the "Question Box" at the last South London meeting.]

At a recent meeting of the Committee of this Society it was deemed advisable to proceed with the discussion of the several "queries" which have been proposed and accepted for consideration. In order to give a more useful character to their discussion than would be likely to follow from their casual introduction, it was decided that different members should be deputed to introduce them to the attention of the Society, with remarks upon the general subject to which they respectively refer. By following this method, it is hoped that many technical questions of practical photographic interest may receive elucidation, and means of avoiding difficulties that militate against success devised.

The subject that I have to bring before you this evening is that of the causes that lead to the occurrence of "pinholes" in dry-plate photography. It is quite certain, however, that the question cannot be regarded as having an exclusive connection with dry-plate practice, but has also an intimate association with similar appearances that are occasionally met with in the wet. It is possible, however, to have plates in which this annoyance occurs abundantly, arising from causes confined to the after preparation of the films, when, with the same collodion and bath, it would not occur if the plate were immediately exposed upon removal from the nitrate of silver solution. The subject is especially vexatious in either instance, because it is almost impossible to remedy the defect in the finished negative by the most skilful hand treatment. If the pinholes be examined under a magnifier they will generally be found to present two distinct characteristic features: the one, a circular transparent ring around a small opaque spot; and the other, irregular patches of transparency.

The causes which produce these pinholes are doubtless manifold; some understood, others yet to be explained. One of the first for consideration, and to which I have distinctly traced their occasional appearance, consists in the existence of small particles of insoluble matter in the collodion itself, which refuse to deposit even after prolonged standing, and cannot therefore be eliminated by simple decantation. In this case it is necessary to filter. To accomplish this with the smallest possible loss from evaporation, and through ordinary filtering-paper, I have designed and constantly used a simple apparatus, which I find so efficient and useful that I do not hesitate to introduce it to your attention. It consists of a funnel with a large and short stem, over which is fitted an elastic flat ring, so as to secure an air-tight connection through the neck of the bottle which is to receive the filtrate. Into this funnel is placed a smaller one with a longer stem, and held in its place within the larger by a circular disk of wood with grooves cut in its outer surface, in order to maintain a communication between the space below and above the inner funnel. Over the surface of the outer funnel is placed an air-tight removable cover, or its upper edge can be ground flat, and a piece of plate glass be placed thereupon, with a small weight to keep the two in contact. By this inexpensive arrangement, collodion or any other ethereal liquid can be efficiently filtered without sensible loss from evaporation, and its use will oftentimes prove valuable in ensuring an immunity from pinholes.

I now come, in the second place, to that which I regard as a more general cause of their existence, and the one which has an immediate bearing upon their appearance in dry-plate photography, viz., the method employed for removing the free nitrate of silver solution from the film. The process generally adopted is to allow the plate to remain in ordinary or distilled water for a certain length of time after it has

been rocked to and fro therein, until the liquid freely flows over its surface. The use of ordinary, or even filtered rain-water has been condemned for this purpose, in consequence of the insoluble salts of silver produced by the reaction, and which naturally adhere to the surface of the film. My own observations lead me to conclude that when once this has taken place, no amount of subsequent washing, even with water falling upon the film with considerable force, will entirely detach the insensitive particles deposited. But I am desirous of especially calling attention, at this stage of the enquiry, to the fact that the use of distilled water, even if chemically pure, does not prevent the formation of a precipitate, and consequently that the plate, even when treated with such, should not be allowed to remain at rest until the whole of the free nitrate of silver bath solution has been removed. The precipitate to which I allude is produced by the simple dilution of the nitrate bath holding iodide or bromide of silver in solution. The disregard of this reaction has been, I feel convinced, a fruitful source of difficulty, and has led many to the conclusion that the use of distilled water in preparing a dry plate is unaccompanied with any corresponding advantage. My recommendation is, therefore, that when the free silver is to be removed from an excited collodion film, the plate should be washed once or twice in pure water with constant agitation, and that on no account should the plate remain stationary therein until the whole of the free bath solution has been removed.

In the last place I have to refer briefly to the action of a prolonged treatment of the film with a developer containing citric acid upon the darkened salts of silver, as a fruitful source of pinholes. This prolonged development is sometimes rendered necessary in consequence of under-exposure, and the result is that the superficially deposited salts upon the denser parts of the negative are displaced by the solvent power of the developer itself, or the subsequent action of the fixing solution. The pinholes so produced are those of an irregular outline, referred to in my earlier remarks. There are doubtless other causes connected with the presence of pinholes than those to which I have referred—such as the condition of the bath, the microscopic texture of the plate glass, &c.—but my experience leads me to infer that if, as recommended, the collodion be once filtered, some little time after it has been sensitized, the free silver be removed from the plate with distilled water constantly agitated, acetic acid be substituted for citric in the developer, and the necessity for its prolonged action be avoided, the principal causes of pinholes in dry-plate photography will be evaded.

### Proceedings of Societies.

#### EDINBURGH PHOTOGRAPHIC SOCIETY.

A popular meeting of this Society was held in Queen Street Hall, on the evening of Wednesday, December 9th, at which a very large attendance of members and their friends were present. A number of Mr. Stuart's, of Hammersmith, fine transparencies of English cathedrals and abbeys were exhibited by the Society's oxyhydrogen lantern; and the subjects were described and explained by the president of the society, Sheriff Hallard. At the close of the meeting an enthusiastic vote of thanks was passed to Messrs. Stuart and Hallard for their services to the Society.

#### SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held in the City of London College on the evening of Thursday, December 10th, the Rev. F. F. STATHAM, M.A., in the chair.

The minutes of a previous meeting were read and confirmed, and Mr. J. Gale was elected a member of the Society.

Mr. WHARTON SIMPSON exhibited a number of Mr. Blair's fine specimens of carbon printing by the single transfer process, and without any transfer whatever, both possessing good half-tone. They were examined with much interest, and some conversation thereon followed. Mr. Simpson also exhibited a fine example of M. Salomon's portraiture, which excited much admiration. He also exhibited some examples of Carl Meinerth's photo-mezzotint printing, an example of Dr. Liesegang's paper pyroxyline, and a collodio-chloride print, the collodion of which was made from this pyroxyline. After some further conversation on the various specimens,

Mr. SIMPSON further called attention to some examples of a new style of mounting-board just introduced by Mr. Fox (see p. 602). After some conversation, and approval of the effect of the mounts,

Mr. COCKING exhibited a number of interesting specimens containing fine cloud effects. The subjects were chiefly in Lahore, taken by Major Bamfield.

Mr. How exhibited a fine frame of photographic magic lantern slides. The subjects were various, many of them being very beautiful, and all excellent in execution. Mr. How stated that, with a view to introduce photographic transparencies for the lantern in place of the less perfect painted slides, he was enabled to issue these at a much lower price than such things had ever been published before.

After some conversation on the subject, Mr. How promised to give an exhibition of these slides by means of the magic lantern at the January meeting of the Society.

Mr. GAMMAGE exhibited Mr. Browning's new economic electric lamp, a good steady light being obtained by means of six cells of a Grove's battery. He explained and illustrated the working of the automatic arrangement by which the proper position of the points was maintained during the combustion.

Mr. SEBASTIAN DAVIS then introduced for discussion a subject from the "Question Box," in which the cause of pinholes in dry plates was discussed (see p. 608). In the course of his remarks he exhibited a very simple and efficient collodion filter.

Mr. HOWARD said that his experience confirmed that of Mr. Davis as to the impropriety of washing the prepared plate without keeping it in motion, so as to prevent the deposit of chloride or insoluble salt of silver precipitated in washing adhering to the film. He thought the immunity of collodion-albumen plates from pinholes arose from the character of the albumen surface, to which particles precipitated did not adhere as they did to a collodion film.

Mr. TAYLOR asked Mr. Davis if he had considered the action of excess of nitro-iodide of silver in the bath as a cause of pinholes.

Mr. DAVIS said he had not done so especially. He presumed that at the outset the bath would be properly filtered.

Mr. HART described a sample of nitrate bath brought to him to test, which registered 36 grains to the ounce by the argentometer, and was found, by means of his volumetric apparatus, to contain 53 grains. He could see it full of fine needle-like crystals floating about, but it was stated that no pinholes resulted.

Mr. SIMPSON remarked that if the floating crystals were nitro-iodide of silver, it must have been singularly surcharged, as a bath of that strength would keep a large quantity in perfect solution without crystallization.

After a desultory conversation on the subject,

Mr. DAVIS said he felt that especial attention was due to the effect of washing in distilled water, occasionally precipitating iodide of silver on the film by the dilution of the free nitrate it produced; and most persons imagined that if they used distilled water they were quite safe from the risk of precipitating insoluble salts.

Mr. SIMPSON said that this observation was clearly important, and he believed that it had not been made before. The use of a dipping-bath would, however, be valuable, as it would tend to remove all precipitates from the plate, whilst horizontal washing might aid in attaching them to the film.

After some further conversation the proceedings terminated.

#### FRENCH PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held on the 6th ult., M. BALARD, president, in the chair.

M. CONSTANT-DELESSERT placed at the disposition of the Society several copies of his recently published pamphlet, entitled "Researches on the Dry-Collodion Processes."

M. VINOIS read a short communication on the renovation of glass in studios. He said, Much has been written respecting the lighting of photographic studios, but nobody has, as far as I know, studied the alterations produced upon glass by sun and rain, or suggested a means of repairing the bad effects caused by the same. It is well known that when glass is exposed to the influences mentioned, it undergoes a certain change, which occurs more or less rapidly, according to the greater or less amount of potash or soda in its composition, the surface presenting a matt appearance, which much resembles ground

glass. To restore glass of this description to its pristine translucency, it is simply necessary to clean the surface with ordinary muriatic acid, diluted to a more or less degree with water, according to the extent to which the glass has become discoloured; the latter being subsequently treated with Spanish white mixed with water, and finally thoroughly cleaned. By this means I have cleaned glass, and rendered it again as good as new, which was so opaque that it was impossible to see through it; the method may also be used for renovating glass plates which have suffered much from frequent employment.

M. PELIGOT stated that this was, no doubt, the first time that muriatic acid had been proposed for cleaning photographer's glass, but its employment was suggested for similar purposes by M. Bernard, who patented its application, and exhibited results at the recent Paris Exhibition.

M. DAVANNE reminded photographers of the fact that muriatic acid attacks and dissolves metallic substances, such as iron and zinc, which are generally used for framing the glass.

M. VINOIS also communicated a formula for making a negative varnish, which he had used for upwards of ten years with great success. The varnish must, it is true, be applied upon a warm surface, but it possesses the advantage of resisting a very high temperature, and does not affect the transparency of the negatives. It is composed of—

Alcohol ... ..	100 cub. cents.
Gum sandrac ... ..	10 grammes
Benzoin ... ..	10 "
Gum elemi... ..	10 "

The materials are dissolved upon a water bath, and the solution clarified by standing, and decanted; the negative is slightly warmed before application, and afterwards dried at the fire.

M. DAVANNE feared that the proportion of gum elemi, which had a softening effect upon varnishes, was somewhat large.

M. JOAQUIM INSLEY PACHECHO addressed a communication from Rio Janeiro, calling attention to the appearance of some prints which he forwarded, and which were covered with minute white spots. M. Pacheco had read in the *Bulletin* an account of these disagreeable appearances, which were stated to be due to the presence of fine particles of bronze powder upon the mounting-board. To this M. Pacheco demurred, inasmuch as the imperfections observed by him were upon cards bearing no gilt ornamentation, but upon mounts with coloured borders. He was disposed to believe the effect was due to something injurious contained in the colouring matter, or in the paper pulp, for his large prints, which were mounted on Bristol board supplied to him by the same manufacturer, were free from any of these injuries.

M. DAVANNE adhered firmly to his opinion as to the origin of the spots, and believed that, inasmuch as many manufacturers preserved their gilt and coloured cards in the same workshop, it was not unlikely that some of the bronze dust became detached, and adhered to the other ornamental boards.

M. DESPAQUIS exhibited a collection of carbon prints mounted as transparencies, and produced by means of his collodion-cuir. He likewise read a short note on the subject.

M. DESPAQUIS suggested that in M. Marion's method of transporting the carbon print by means of an albuminized surface coagulated by heat, it would be an improvement to use a more impermeable basis, to prevent staining; as, for instance, tinfoil, dioptric paper, tracing-cloth, &c.

M. CONSTANT-DELESSERT forwarded an interesting paper on dry plate processes, accompanying the same with specimens.

The PRESIDENT stated that he had been requested by Mr. Warren de la Rue to say that certain photographs obtained in natural colours by M. Edmond Becquerel, eleven years ago, had been left to Mr. de la Rue by the late Professor Faraday, and that the colours were still perfectly vivid, although Faraday had frequently exhibited them and exposed them to light.

MM. GEYMER and ALKER exhibited the process of producing photographic enamels, starting with an unsensitized glass plate, and finishing with the perfect enamel. A solution composed of honey, sugar, gum, and bichromate of ammonia, dissolved in water, was poured upon a well-cleaned glass plate, and dried. On this dry plate a good *positive* was placed, and exposed to a magnesium light for a few seconds; the enamel powder was then brushed over the surface, attaching itself to those parts which had been preserved wholly or partially from the light. The print, thus developed, was covered with ordinary normal

collodion, and then plunged into a very dilute bath of sulphuric and hydrochloric acid; after immersion for several minutes the plate was placed in pure water, when the pellicle with the image became detached, and was transferred to a solution of sugar. Under the film was placed the material which was to be heated, in such a manner that the enamel-powder was undermost, and the whole was then drained and thoroughly dried; subsequently it was placed in a sulphuric acid bath, to destroy the collodion, and, after a few minutes, withdrawn, washed, and again dried. After the image had been somewhat touched up, it was put upon a piece of baked clay, placed to warm for a few moments before the muffled furnace, and afterwards introduced therein when the latter was at a red-heat. In a minute or two the enamel became brilliant, and was then withdrawn and allowed to cool gradually.

M. GEYMER likewise read a paper describing the process, and pointing out the difficulties and liabilities of failure; he also alluded to several modifications which might be made in the method. The production of photographs, either upon enamel, porcelain, or glass, could be undertaken without the aid of any special appliances with the exception of an enamel-furnace, which might always find place in a corner of the studio.

The proceedings then terminated.

## Correspondence.

### LUX GRAPHICUS ON THE WING.

THE REFUNDING OF THE BALANCE OF THE GODDARD FUND—THE PHOTOGRAPHER'S PROVIDENT SOCIETY—A FEROCIOUS DOORSMAN—THE SOUTH LONDON DINNER—A CHRISTMAS CAROL.

MY DEAR SIR,—Now that the balance of the Goddard Fund is returned to the contributors, and all the trials and vexations the administration of the fund brought upon the chief promoters are known, I think the very best thanks of the whole body of subscribers to that fund are due to the committee for their firm and sensible determination to provide for the wants of the poor imbecile recipient in the manner they did, and for their withstanding the attempt made by a person who was not in the least related to the late Mr. Goddard to obtain possession of the balance in hand. I, for one, a subscriber to the fund, return them my most hearty acknowledgements, not for the money returned to me, but for the straightforwardness of their report, and the wise and judicious manner in which they dispensed the funds. While congratulating myself and confreres on seeing the money not required for the relief of the late Mr. Goddard returned to the subscribers instead of going into the possession of a person for whom it never was intended, I think it is to be regretted that no responsible party had foreseen that much of this returned money would have been gladly placed to the credit of some benevolent or provident institution connected with photography. The whole amount, or even the half of it, would have made a very handsome nucleus for the commencement of such a fund. I have heard several wishes to that effect expressed during the last few days. Doubtless the committee did the very best thing they could have done for their own credit and the entire satisfaction of the whole of the subscribers; but I am afraid an opportunity has been lost in the interest of the incipient relief fund by not having had a receiver for these stray and unexpected sums appointed. The praiseworthy act of Messrs. Ross and Pingle, as noticed in another journal, confirms this impression.

While the subject of a photographer's provident or relief fund is before me, I may mention that in the Report of the Friendly Societies recently issued by Mr. Tidd Pratt, he speaks in the highest terms of those societies which are managed by the members themselves without salaries, and condemns the extravagance exhibited by the societies of a similar nature which are conducted by salaried officials. Now, as it is a friendly society pure and simple that sick or needy photographers ought to look to for future help, in

my opinion the former is the kind of society that should be established. The movement is not to be started as a business speculation, and there should be no salaries attached to any of the offices. Each member joining the provident society should be prepared to submit to the tax on his time and energies, if elected to office, as part and parcel of the amount he subscribes for the general welfare of the body and relief of individual members. For my part, I object to the contemplated society taking the form of a relief fund depending upon donations, collections at dinners, &c., for its support. Such means for raising the necessary funds to start the society may be allowable; but, after it is commenced, every individual connected with it should be a subscribing member, and not allowed to receive any benefit, except under the most urgent necessities, until he has paid a certain number of subscriptions.

During one of my peregrinations about town lately I stumbled upon a very ferocious doorman. My attention was suddenly arrested, while passing one of those photographic establishments which keep a kind of two-legged hyena prowling up and down before their doors, by hearing the somewhat startling and cannibalistic exclamation of "I'll eat yer!" Looking round, I saw that one of those prowling bipeds had fastened upon two quiet-looking young gentlemen, evidently strangers in town and to town ways, and had so importuned them to sit for "a correct likeness," until they turned upon him, and threatened to give him in charge if he did not desist; when he retaliated by threatening to eat them, and used a great deal of sanguinary and abusive language as a substitute for more palatable suavity. Is such an "outsider" or hanger-on a fit and proper person to join a photographer's provident society, or be the recipient of a benevolent relief fund?

The South London Photographic Society's annual dinner came off on Saturday evening last at the "Salutation Tavern," Newgate Street. Twenty-three members and friends, all told, sat down to dinner, and enjoyed a thoroughly English repast. After the cloth was removed, the pleasantest part of the evening commenced. The worthy and honoured president, who occupied the chair, was all geniality, and gave the toast of the evening—"The South London Photographic Society"—in his usually felicitous style. To Mr. Jabez Hughes was allotted the task of proposing the next important toast—"Photography"—which he did in the most glowing and eloquent terms, dwelling on the rise and progress of the art in England, its position in a competitive point of view at the Paris Exhibition, interspersed with some racy and facetious remarks on the different modes and kinds of rewards, from the bronze, silver, and gold medals, to the paper certificates, which he considered the most honourable mentions that could be given by a discerning public. From that he soared into the higher aspirations of photographers and sublime regions of photography, giving, with thrilling effect, a description of the social joys, scientific pursuits, and human ameliorations to which photography administers. Mr. Baynham Jones, being the oldest photographer present, had the honour of replying on behalf of the art. Mr. G. Wharton Simpson, in very appropriate terms, gave the toast, "Art Photography," which was responded to by Mr. O. G. Rejlander. Mr. Johnson, of the Autotype Company, had the honour of proposing the toast "Professional Photography," which was responded to by Mr. Valentine Blanchard, who occupied the vice-chair. Other toasts of a professional and semi-professional character were given and responded to. The intervals were filled up with part and instrumental music by members of the Society. Mr. Cooper contributed greatly to the evening's enjoyment by giving two charming performances on the cornet-à piston, which were admirably accompanied by Mr. Henry Cooper on the piano. Taking it all in all, it was one of the pleasantest and merriest evenings I have ever enjoyed at the convivial meetings of the South London Photographic Society, and formed a delightful introduction to the season of universal festivity which is close at hand.

Christmas, all over the civilized world, is not only a period of festive réunion, but, according to the only rational interpretation of the word, a time of good will towards men, and peace upon earth. Photographers, like other men, have had their little differences of opinion, which have produced partial estrangements during a portion of the year which will so soon expire; but let the approaching season, which is held in commemoration of the birth of the greatest Peacemaker that ever came among men, be looked upon by all as the fittest time to forget and forgive all slights, injuries, or insults, real or imaginary; and let not the great festival of our common faith be clouded or eclipsed by an angry thought, nor the immeasurable charity of true Christianity be dimmed by one unforgiving feeling. The light of the Christian faith is a light that should penetrate to the dark cells of our hearts, and dispel all the gloomy and corrosive accumulations of controversy that may have lodged there, and unconsciously eaten away any part of our better nature. Few of us—none but the most presumptuous—can lay his hand upon his heart and say, "Mine is immaculate!" None of us are without sin, and charity and forgiveness are the greatest of the Christian virtues; and they should be the more carefully studied and practised by all who live in, and by the Light of the world.—Yours, very truly,

December 15th, 1868.

LUX GRAPHICUS.

### Talk in the Studio.

THE SOUTH LONDON ANNUAL DINNER.—The South London Photographic Society is, we believe, the only photographic organization which indulges in the enjoyment of an annual dinner; but the complete satisfaction and success which attend these social réunions each winter are sufficient to warrant a recommendation of the example as worthy of imitation. On Saturday evening last, the members of the South London dined together at the Salutation Tavern, where they had a capital dinner, and a delightful evening. The Rev. F. F. Statham, M.A., occupied the chair, and Mr. Blanchard the vice-chair. Some excellent speeches were made, and some fine glees, songs, and instrumental solos, materially added to the pleasures of the evening. The speech of Mr. Hughes, in proposing "Photography," was a grand piece of oratory, and Mr. Baynham Jones, whose name was associated with the toast, interested the meeting by a reminiscence of his efforts to take a Daguerreotype in the first year of the discovery, before he had seen a specimen; in the absence of Daguerreotype plates he had to polish a portion of a silver waiter, to make a plate for his experimental operations; Mr. Howard responded ably on behalf of the South London Society; Mr. Wharton Simpson proposed "Art Photography," and Mr. Rejlander responded; Mr. Johnson proposed "Professional Photography," and Mr. Blanchard responded; Mr. Cocking proposed the "Photographic Press," by which he said he wished especially to be understood as referring to the respectable and trustworthy portion of the photographic press, and not the disreputable and untrustworthy, and Mr. Simpson and Mr. Taylor responded; Mr. How proposed the "Guests," and Mr. Greenwood, Mr. Whiting, Mr. Pritchard, and Mr. Mills responded. The officers of the Society, the musicians, and some other toasts, all received due honour, and midnight closed a very happy evening. A photographic comic song, composed for the occasion, was sung, which we shall probably print when occasion serves.

NEW WHITE PIGMENT.—The *Times* states that a new pigment has been discovered in some lead mines in New Jersey, United States, which consists of an intimate natural mixture of zinc and lead, and is termed plumbate of zinc. A certificate of its qualities has been obtained from the School of Mines, Columbia College, some of which are entirely wanting in the artificial mixtures. In comparison with the other pigments in general use, it is stated to possess the following peculiarities:—1. Owing to its great opacity, it covers much better than pure oxide of zinc, or the best white lead; 2. it covers more surface, weight for weight; 3. it makes a harder and more durable coating; 4. it will wear much longer when exposed to the weather on outside work; and, 5. it resists for a greater length of time the action of sulphuretted hydrogen and other dele-

terious gases which so quickly discolour white lead. At the same time its cost is considerably less.

CHEAP MAGNESIUM.—A writer in the *Builder* says:—"There is now a fair prospect of a reduction in the price of magnesium through some recent improvements in its manufacture, and it is probable that in the course of next year we shall see the metal retailed at or under one shilling per ounce."

PHOTOGRAPHIC PAPER.—A contemporary states that a prize of 2,000 fr. has been offered in France for the production of the best photographic paper. The prize will be awarded in 1869.

A NEWLY-DISCOVERED PROPERTY OF GUN-COTTON.—It has been found that the explosive force of gun-cotton may, like that of nitro-glycerine, be developed by the exposure of the substance to the sudden concussion produced by a detonation; and that it exploded by that agency the suddenness and consequent violence of its action greatly exceed that of its explosion by means of a highly heated body or flame. This is a most important discovery, and one which invests gun-cotton with totally new and valuable characteristics; for it follows, as recent experiments have fully demonstrated, that gun-cotton, even when freely exposed to air, may be made to explode with destructive violence, apparently not inferior to that of nitro-glycerine, simply by employing for its explosion a fuze to which is attached a small detonating charge.—*Pall Mall Gazette*.

A HINT TO LECTURERS.—Many lecturers have felt how unsatisfactory it is to write or draw, or in any manner attempt to illustrate their ideas, in a large room. Professor Albert R. Leeds, of Haverford College, Pa., suggests that this difficulty may be overcome thus:—A plate of glass is placed in the lime-light or magnesium lantern, and an inverting prism is put in the forward part of the draw-tube of the objective. If, now, while lecturing, writing is done with an ordinary pen and Indian-ink upon the glass plate, proceeding from left to right upon the plate, it will advance correspondingly upon the screen, and will be read in greatly enlarged characters by those present. The square prism inverts with respect to bottom, and the writing being actually reversed by the writer in reference to the other direction in which the lantern is pointing, the crossing of the rays produced by the lens becomes in this case an advantage, and corrects the letters upon the screen. A collodion film, blackened by exposure to the sun's rays, may be substituted for a naked glass plate with great advantage. On such a film chemical and mathematical formulae, drawings of apparatus, machinery, and so on, may be cut with delicacy, and appear as intensely bright white lines on a black ground, and with something of the appearance of an immenso copper-plate engraving.—*The Builder*.

### To Correspondents.

TO AGENTS AND ADVERTISERS.—Next Friday being Christmas Day, the PHOTOGRAPHIC NEWS will be published on Thursday December 24th. Advertisers should send in their Announcements not later than Wednesday, the 23rd.

OXONIENSIS.—We do not belong to the Amateur Photographic Association, and cannot speak with authority of its internal economy. The classification, so far as we believe, is regulated by the size of the pictures, not by the subjects. Members subscribe a guinea a year, and send in for printing not less than half a dozen negatives. They are entitled for this to two guineas' worth of pictures, and to half the profits on any sales of prints from their negatives. There is a rule that negatives which receive the prizes become the property of the Association; but there is also a condition that the owner of a valuable negative may decline to part with it on such terms. Whether by so doing he would forego all chance of a prize or not we cannot tell. As an outside observer, our impression is that, on the whole, the working of the Association has been beneficial to photography. 2. The object of the instruction that the plate should remain ten minutes at least in the bath is to ensure the perfect change of the extra proportion of bromide the collodion contains into bromide of silver. The double decomposition between bromides and nitrate of silver is not so rapidly effected as between iodides and nitrate of silver; hence, in any process in which a large portion of a bromide is employed, it becomes desirable to use a strong nitrate bath and give a long immersion. The use of two or three baths would economise time. If varnishing round the edge do not secure the film, a preliminary dilute coating of india-rubber, either in pure benzole or chloroform

may be used. In such case it is important to give full exposure, or the preliminary coating will act like a dirty plate, causing markings to appear in development. 3. We have seen many pictures produced by the lens you name, and have heard the opinions of many able photographers. They all state it to be one of the most valuable lenses ever introduced, and, for the class of lens, very rapid. Our own trials have only been experimental, but they were very satisfactory.

**C. COLLODION.**—The amount of soaking in warm water necessary to unmount prints from cardboard should not reduce the tone or brilliancy of the pictures. We know of no better plan than soaking in warm water. Placing a piece of wet blotting-paper over the print will sometimes serve to soften the adhesive material sufficiently, but more time is required. 2. The lens to which you refer will serve for 10 by 8 pictures, and, with a very small stop, for 12 by 10. 3. Either is good; we cannot with certainty say which is best for landscape work.

**W. G.**—In separating grape sugar from honey by means of alcohol, it is simply necessary to wash the honey with the spirit to remove the soluble syrupy substance, the hard crystalline residue being the grape sugar.

**A. LEARNER.**—Hypo-sulphite of soda may, of course, be used for fixing instead of cyanide, and is in many respects best. For collodion positives cyanide is preferable, as giving a better colour. 2. A porcelain pan is better for most purposes than one of gutta-percha; the latter has the advantage of permitting, by its colour, the progress of fixing collodion positives to be watched. If a negative (or positive) be left long in a cyanide bath, the image will quickly be dissolved; in hypo-sulphite of soda there is no danger. 3. The guide for determining when a plate has been a sufficient time in the silver bath is generally its appearance. When the solution flows freely over it without greasy lines, and the plate looks even and creamy, it is judged to be ready for use. As a rule, 2 or 3 minutes in summer, and 3, or 4, or 5, in winter, are sufficient with ordinary materials. Various evils result from leaving the plate too long in the bath: sometimes a portion of the iodide of silver formed is redissolved; sometimes crystals of iodo-nitrate of silver crystallize on its surface, and cause pinholes; sometimes fog is the result. 4. Under-exposure of the negative is the common cause of the face being too dark; sometimes, of course, it arises from over-printing.

**SUBSCRIBER FOR YEARS.**—We do not know anything better than a good magic lantern condenser for using for enlargement with artificial light.

**P.**—The print you enclose is a very bad sample of a very troublesome defect, cases of which are frequently brought under our attention. We cannot arrive at any absolute certainty of the cause. We have often been inclined to believe that the formation of minute air-bubbles on the paper whilst in the fixing bath, causing imperfect fixation, is the cause; but, not having met with the defect in our own practice, we cannot with certainty trace the defect to that cause.

**J. MAYCOCK.**—The prints seem good; but whether they are absolutely perfect reproductions we cannot, of course, say, without a comparison with the original. No. 3 seems as if the negative were just a little under-exposed. 1. A thick lac varnish is very excellent. Repeated applications of wax or paraffine have been recommended. 2. The use of a strong bath is conducive to the formation of matt silver stains, and weakening the bath a little is often a cure. Take care to wash the inner frames of the dark slide frequently. 3. A small portion of bromide of silver is soluble in bromo-iodized collodion; the collodion should be decanted from any insoluble residue. 4. Members of the Amateur Photographic Association pay a guinea a year, and receive two guineas' worth of prints. 5. The pinkish purple tone to which you refer is best obtained with a bath of sulphocyanide of gold. We have not tried the addition of chlorate of potash. Thanks, and reciprocation of kind greetings. We shall doubtless hear of the working of the oxymel process.

**K.**—The name and address of the proprietor, and the date of publication, are necessary on an engraving, to secure the copyright. Copyright in illustrations in books goes with the copyright of the book, and permission to copy them should be obtained. There are many Copyright Acts relating to different things; some for engravings, some for books, some for paintings and photographs. All of them can be obtained at the publishing office for Acts of Parliament in New Street, E.C. There are no means of determining what is copyright and what is not, without much research. Some publishers will give permission for their engravings to be copied for the lantern, and some will not. A black tone for transparencies is often obtained by using a sulphide. See our last and the forthcoming YEAR-BOOKS. All aniline colours are derivatives of coal tar, and consist of different compounds of aniline and some other body, and each requires different treatment.

**W. J. A. G.**—It is unfortunate that your prints have been spotted-

out before mounting, as that not only renders it dangerous to use dampness as a means of making them lie flat, but will cause risk of injury in mounting. Try rolling them in the other direction, and keeping them in that position for a few hours.

**ARCHER CLARKE.**—We shall have some remarks on the subject shortly. It will be much more difficult to form a Provident Society than it will be to form a Benevolent Fund. 2. We do not know personally the gentleman you name.

**X. X.**—Your negative requires a little more intensity; but the print you enclose would not be bad if the background were clean. To get a fine tone you require a more forcible negative than that you have been using.

**LANDSCAPE.**—Our time is too closely occupied to permit us to answer photographic questions privately. 2. We prefer No. 1. 3. A is most suitable for landscape and general work. 4. After this year photographers can obtain poisonous chemicals only of a pharmaceutical chemist.

**D. O. N. E.**—To succeed in producing opal pictures by camera printing requires experience. The defects you describe are due, probably, to over-development. Either over-exposure or over-development will produce such a result; but it is most commonly due to the latter. The development should be much more rapidly effected than the operation of developing a negative. Read the article which appeared in our pages on the eburneum process, last September. All the manipulations of producing the picture should be the same for opal glass. You will find it easier, in working with opal glass, to get good pictures by the collodion-chloride process.

**PATRICK O'CONNOR.**—We perfectly understood your motives, and never object to correspondents speaking plainly and courteously. We can readily appreciate your view of the case.

**H. R. S.**—The conditions of relief in any organization which may be formed will be determined by the committee, we presume, who may be appointed; we cannot, of course, lay down conditions. We will, however, shortly make some general suggestions on the subject. If a Benevolent Fund be formed, all kinds of donations and subscriptions will be accepted, and relief granted according to the urgency of the need, the worthiness of the claimant, and the state of the funds. If a Provident Society be established, definite payments and definite relief, under definite conditions, will prevail.

**J. B. M.**—As a rule, about 4 grains of gallic acid will dissolve in an ounce of distilled water at 60°. If a stronger solution is required, the addition of alcohol is necessary. As a rule, an aqueous saturated solution after filtration is an excellent developer.

**JAMES KEANE.**—The YEAR-BOOK will be ready shortly. Our Publisher will supply you the NEWS direct. The terms are 4s. 4d. per quarter in advance.

**AMATEUR.**—Received. Thanks. The communication shall appear shortly.

**J. ASHMORE.**—The YEAR-BOOK is not yet published, but shall be sent when ready.

**SUBSCRIBER.**—Thanks: it is scarcely necessary, however, to publish your remarks, however flattering to the committee. On the subject of the disposal of your balance, see another answer to several subscribers who make a similar suggestion. In answer to your general question: most of the statements, or all of them, are as absurdly untrue as those which you have pointed out in your letter. In answer to your definite questions: 1. The treasurer has Mr. Goddard's receipt for all the money charged to him in the balance sheet. 2. We believe that there is no truth in the statement as to a £20 annuity; Mr. Goddard himself told us that he had nothing but the casual contributions to which we referred; the only relatives he had were in very humble circumstances. 3. We know nothing of Mr. Hardy, and do not even remember hearing his name; but, of course, no matter how trustworthy a person he might be, the committee could not honestly delegate to him duties which the subscribers had entrusted to them. The only vote of thanks which the committee could receive has been conveyed in almost every acknowledgment of the balance. Not one of the subscribers has expressed any dissatisfaction with their course.

**YOUNG.**—We do not usually undertake to express any opinion on the characters of individuals as expressed in their portraits. In case of criticising a portrait of a public man such a course is sometimes natural; but in case of private portraits, such as you enclose, it would be obviously an inconvenient and undesirable course. As photographs, they are pretty good.

**SUBSCRIBER.**—The letter was addressed and forwarded.

**THE GODDARD FUND.**—Several subscribers have expressed a wish that their balance could be devoted to a general fund, We would suggest to all so disposed that, as it is not improbable that such a fund will be established, their balance of contributions may be easily retained for a while in anticipation of this possibility.

Several Correspondents in our next.

### PICTORIAL EFFECT IN PHOTOGRAPHY.

THE chief interest in photography amongst the greater number of its devotees must ever centre in its capacity as a pictorial art. During the brief years of its existence the number of its branches has become legion, and its applications increase almost beyond count; but by far the most important of them, in the interest it excites, in the extent to which it is practised, and even in its commercial results, is that which belongs essentially to the region of pictorial art. Photography had its parentage in art, not less than in science, and in its earliest days its chief patrons and admirers were found in art circles. And it was only when its technical disabilities and the limitations of its capacity and appliances were found to interfere with its plasticity for art purposes that it was abandoned by the *dilettante*, and relegated into the hands of the scientific experimentalist, by whom its powers have been educed, its capacity developed, and its range of action altogether modified and extended.

All that belongs to the technics of photography has for some years past been acquiring a high state of perfection: chemical processes, mechanical operations, and optical appliances have acquired a degree of practical perfection which has tended materially to remove the disabilities for art purposes which at one time seemed inherent in photography. For some time past the one thing needful to extend the domain of photography in the region of pictorial art, and to furnish indisputable credentials to its adherents to be recognized as legitimate subjects in that region, has been a higher culture and a more perfect knowledge of pictorial conditions. Aids to art study of a general kind have not been lacking, but they have, for the purpose in question, seriously wanted special photographic application. Desultory art instruction of a more special kind has been found in photographic journals; but this has lacked the systematic and progressive character necessary to give completeness to such instructions. We have, however, in the course of the present volume, endeavoured to supply the existing and deeply-felt want, and in the lessons on pictorial effect in its photographic application, we have, we believe, furnished the photographic art student, not only with more comprehensive and detailed instructions than have ever before been published, but with sufficient guidance, if carefully studied and honestly followed, to enable him to attain high excellence in the practice of pictorial photography.

One word in especial relation to the articles themselves. When, at the commencement of the present volume, we announced that a series of articles on pictorial effect in relation to photography should appear in our pages, we stated that contributions towards such a series had been sent in and promised from various sources, and that this

material would be placed in the hands of Mr. Robinson for arrangement, addition, or elision. This was the original programme. Mr. Robinson found, however, at the outset, that the plan proposed would materially limit the systematic and progressive character and consequent completeness and usefulness of the articles. He therefore preferred to commence unfettered by other material, producing just such a series of articles as his own art study and photographic art practice suggested would be most valuable to the earnest student of pictorial photography. As Mr. Robinson had not only long occupied a foremost position in the ranks of art photography, but had, previous to his introduction to photography, spent some years in the study and practice of art as a painter (his work in this direction having been exhibited at the Royal Academy and other exhibitions of paintings), we felt that his desire in this respect should be held paramount; and our readers have gained the advantage in the fulness, completeness, and admirable simplicity and perspicuity of the series of art lessons just completed.

But few words need be added on the subject of art study itself. It is perfectly true, that the greatest and grandest elements in pictorial art cannot be taught. No art teaching will confer the power to conceive a fine picture; but given the creative instinct, art culture can aid the student in giving to his conceptions pictorial form, and save him from much heart-breaking disappointment at the crudities which result from attempts to give pictorial expression to thought, without a knowledge of the conditions of pictorial effect. Art culture will often, too, stimulate conception, and a knowledge of conditions will often suggest the thoughts which may be expressed by their aid.

Further, a knowledge of the laws of pictorial effect is of emphatic importance to the photographer, because he is less called upon in his art to attempt to give a form to pictorial conceptions than to give pictorial embodiment to existing facts; and it is often only by arrangement of materials and management of light and shade that a pictorial character can be given to the representation of prosaic facts. To the painter who can give interest to his picture by the beauty of the subject, or of the thought represented, and to whose work the glamour of colour can add fresh charms, some disregard of the laws of composition may sometimes be permitted without pictorial loss. To the photographer who would excel as an artist, a rigid attention to all that can be reduced to rule becomes imperative, because it often forms his sole means of elevating his work beyond the rank of a mere diagram or plan and elevation of some very commonplace and unpictorial piece of nature's handiwork, whether animate or inanimate.

We urge the photographic art student, then, whilst in no degree neglecting the culture of the esthetics of art, to

614  
ground himself first of all in its simple framework by a study of rules, and assiduous practice, for practice' sake, of those rules. We have before quoted, and we now repeat, an admirable remark by Dr. Thompson, bearing on the question: "Every art, from reasoning to riding and rowing, is learned by assiduous practice; and if principles do any good, it is proportioned to the readiness with which they can be converted into rules, and the patient constancy with which they are applied in all our attempts at excellence." In the series of lessons just completed, recognized rules have been clearly stated, and principles have been, as far as possible, stated with the simplicity and precision of rules, and their application clearly pointed out and illustrated. It remains for the student to put them into practice.

## PHOTOGRAPHY IN CONNECTION WITH THE ABYSSINIAN EXPEDITION.

BY H. BADEN PRITCHARD,

OF THE GENERAL PHOTOGRAPHIC ESTABLISHMENT OF THE WAR DEPARTMENT.\*

THE greater part of the varnish (chloroform and amber) was found unsuitable for use in a hot climate, out of doors, as the film did not harden rapidly, and was frequently rendered tacky by the heat; this was the more annoying from the circumstance that whenever a negative was taken, copies of the same were required to be printed off immediately. For work of this description, Sergeant Harrold prefers to use Newman's Diamond Negative Varnish.

With but few exceptions, the chemicals and appliances were in first-rate order, and worked almost without a hitch. In copying plans—an operation which was, of course, conducted in the open air—much difficulty was experienced from the breeze which blew almost incessantly in the vicinity of the mountains. Often the maps were blown right off the copying-table; and during exposure it was frequently necessary to keep brushing the dust and sand from the original, a proceeding which sometimes militated against the sharpness of the reproductions.

Work had to be undertaken at all times, so that at any moment the photographers were ordered to fall out on the line of march, whatever might be the state of the weather, and the likelihood or possibility of success. When the duty had been performed, successfully or unsuccessfully, as the case might be, the boxes were packed, the mules saddled, and the head-quarters caught up again as soon as possible. Paper was sensitized over night whenever a halt was made, about sixty sheets being prepared at a time, occupying the staff between four and five hours. Early in the morning the prepared paper was rolled in sheets of blotting-paper, and stowed away as far from the light as possible; and on arriving at the next encampment printing was at once commenced. After toning and fixing, the prints were washed for two or three hours, and if water happened to be plentiful, which was very seldom the case, the same was changed several times during the night. When the pictures were urgently required, they received but an imperfect and hasty washing; but otherwise they were packed moist in blotting-paper, and again washed on the first opportunity; when the prints dried in contact with the paper, the latter required to be carefully moistened before a separation was attempted, as pictures in this condition are very liable to injury. The squaring and mounting operations were performed without difficulty.

It will be a question in future operations of this kind whether, instead of printing the plans on paper and mounting them afterwards on linen, it would not be better for field purposes if they were produced direct from the fabric. The material might be kept ready stiffened and albuminized; the sensitizing and printing operations would not be more laborious or time-taking, and the amount of washing required would be very small, as the

water readily permeates the fabric. The time gained by shortening the process of washing, and obviating altogether that of mounting, would be considerable.

A subject of regret is the fact that a great deal of useless work was sometimes performed on account of the ignorance of photographic matters on the part of staff officers who gave orders. This occurred the more frequently from the fact that Colonel Pritchard's command was so extensive that he was unable to give the photographers his undivided attention. Such a state of things would easily be avoided in future by sending an officer well skilled in photography in immediate charge of the party; it would then be possible to question the feasibility of an order upon its receipt, instead of vainly endeavouring to obey an impossible mandate, and wasting valuable time and materials unnecessarily. In many cases, in taking landscape pictures, a rough, imperfect sketch was frequently all that was required; but even this, under unfavourable circumstances, is sometimes quite as difficult to secure as a perfect picture. With soldiers there is, however, no appeal; and an order given must be obeyed if possible. So sometimes the mules had to be halted and the boxes unpacked during a long march in a drizzling rain, in order that a picture might be attempted of some mountain or other, the top of which was enveloped in a dense fog, simply because a staff officer had expressed himself to the effect that the whole would make a grand picture.

The scarcity of water on the line of route was a serious evil; several negatives had frequently to be washed in the same water, and the prints fared no better. Besides, the water was in general badly adapted to photographic purposes, being very hard and full of chlorides, involving, therefore, great waste of silver in its employment; a distilling apparatus had been provided for purifying the water, but the latter was always so scarce, and time so pressing, that the still was rarely resorted to. From the fact that the majority of negatives taken were those of maps requiring a lengthened and more varied treatment than ordinary plates, in order to produce a film of considerable density, the want of an abundant supply of water was felt more seriously than would have been the case in ordinary manipulations.

On inspecting the landscape and other negatives taken by the chief photographer and his assistants, it will be seen that they include many creditable productions; and when we remember that not a single one of them was specially selected for the camera by the photographers themselves, and that the series of sixty negatives has not been weeded out, but represent the whole number produced to order, sometimes with the sun shining directly into the camera, sometimes when the sun had gone down, sometimes with the camera in the sunlight and the object to be reproduced in a covered tent, at most unseasonable times, at all hours, after long marches, and by men who had besides to perform the duties of soldiers—I say, when we bear in mind the circumstances under which the operators laboured, the work they have performed is highly commendable. There is, however, one more picture which should have been included in the set our friends have brought home, and which is eagerly sought for by every examiner of the sketches; its absence is regretted, however, by nobody so much as by Colonel Pritchard himself, who was indefatigable in his endeavours to obtain interesting subjects for the camera, but who was unfortunately wounded at the storming of Magdala, and, therefore, unable to perform any active duties for some days after the death of King Theodore. An order was sent down by General Napier to obtain a picture of the fallen chief, but, owing to some delay, the instructions were not given to the Engineers until after the interment; the authority for visiting the body reached Sergeant Harrold one hour too late, and thus has been lost all record of those features, a delineation of which by photography, even of the crudest description, would have been of great

How eagerly should we all have scanned the portrait, in England, in endeavouring to read from the markings of the brow the character of the detestable traitor we had vanquished!

But, we must be contented with the pictures we had there are some among them possessing deep interest.

There is the conference tent at Durbagh, where the meeting took place between Napier and Kassai: it was alleged, but treachery was feared, and, accordingly, we see upon the field the troops and guns prepared for salute or for action; for it was deemed almost improbable that within half an hour of the firing that picture the landscape might be turned into a field, and the labours of the photographers rendered more serious purposes. There are the views of the late King Theodore's house; of Selassie, the height on the Good Friday, together with the rock from the Emperor's big gun first opened fire; groups of some of the captives, who are now probably scattered all over Europe, and whom, even within twenty-four hours of liberation, it required some energy on the part of the photographers to collect together to be photographed. Of the lakes of Abyssinia, there are views of those of Lake Tana, Magdala, Focada, and Antalo; pictures of the lake and of scenery on the banks of the Tella, the Djedda, and Bashelo rivers, besides representing all the principal points of interest and architectural details met with.

In the whole, therefore, I think we can congratulate the English Engineer photographers, and more especially the late Harrold, on the manner in which they performed their duties; to them the staff of the army was indebted for information obtained and circulated by the camera, their labours forming no unimportant part of the cog-wheel of administrative machinery, which, under the guidance of Sir R. Napier, worked so smoothly; to them we at home are indebted for a clearer view of the nature of the country, for presenting to us the various difficulties met with during the pilgrimage to release the prisoners, for giving us a true picture of King Theodore's stronghold, and for showing what the inside of Magdala was like. And I feel a will agree with me in the opinion that if ever a medal has been well earned by a photographer, it is which Sergeant Harrold now wears upon his breast, which was specially awarded to him for distinguished services rendered in the field before Magdala.

## EXTENSIVE PHOTOGRAPHIC PIRACY OF ENGRAVINGS.

of extensive piracy was last Friday brought before Mr. Alderman Allen and Alderman Sir Robert Carden, when Coleman, John Lawrence, and William Hooper were charged with conspiring together to sell and publish pirated copies of certain engravings of great value, contrary to law. Mr. Lewis said he appeared to prosecute the three prisoners, if of Mr. Henry Graves, for a conspiracy to injure his business, by publishing and selling pirated copies of his engravings, for the copyright of which he had to pay a large sum. The prisoner Lawrence, who appeared to be a realist, had supplied the copies to Coleman, who hawked about the streets of London after they had been mounted upon paper. The Act under which the charge was brought prohibited the sale of protected paintings, drawings, and photographs from and made it an offence punishable with a very severe penalty to sell or publish a copy without the consent or authority of the owner. Mr. Graves had spent enormous sums in engraving his copyright works. He sold copies of them for three or four guineas each, whereas those exhibited in the streets by the defendants might be had for £1 or 30s. Henry Graves gave evidence as to his copyright in the pictures, including the "Railway Station," &c., and as the piracies produced having been manifestly copied from

Mr. Alderman Allen, looking at a print, said: This photograph is not so perfect as the others.

Witness.—No, they all fade in a very short time. They should be all stopped in publication. I produce a certificate of the registration in February, 1865, of O'Neil's picture of "The Anxious Mother," with an impression from my plate.

Mr. Lewis.—Is the photograph produced a piracy?

Witness.—Certainly; and I may state that if this thing goes on they will have nothing to copy from, as publishers will not produce an engraving to have it copied the very next morning. I also hand in a registration certificate of Miss Edwards' painting, "The Last Kiss," and I produce a photograph which has been taken from my engraving. Every touch and every line of the original engraving is reproduced in that photograph.

Mr. Lewis.—I believe the original plate was destroyed in your great fire?

Witness.—Yes; in fifteen minutes I lost £40,000 worth of property. I produce a certificate of the registration of Millais' picture, "The Parable of the Lost Piece of Money," which was unfortunately destroyed in the fire at Baron Marochetti's studio. There are thousands of piracies now in circulation, and the effect is almost to annihilate my sale. I sell "The Railway Station" at five guineas a copy; the defendants at 21s. They probably get 19s. profit on each picture; in fact, it is to them all profit. Last week a package of them was stopped at the Custom House, and the importer was fined £60 or £70 at the Thames Police Court. I believe they are mostly manufactured at Birmingham. I have spent £500 or £600 on these prosecutions, after deducting the fines. I hope the time will soon come when engravings will be protected like banknotes, and the forgery of them punished with equal severity.

At the request of the prisoner Coleman, the charge against him was read by Mr. Oke, the chief clerk. He said, in answer to it, that it was totally untrue; that it was impossible for the photographs to have been produced at Birmingham, where the atmosphere was so dense; and that he obtained them from a man who told him that they grew in a nursery garden near St. Paul's Cathedral. (Laughter.)

William Henry Burgess was next examined by Mr. Lewis. He said: I am in the employment of Messrs. Graves and Co., publishers, Pall Mall, and I have known the prisoner Coleman as a hawk of photographs for about six weeks. (This was denied by the prisoner.) I have been watching him for that time, and have seen him almost daily selling pirated copies. He carried them in a box and exposed them for sale in the street. I saw him on the 24th and 25th, and sent for Mr. Graves, Jun.

The Prisoner.—You are a nice fellow. (Laughter.) You came to my house, learnt all about my business, and ended in taking my daughter to the theatre. You promised to send me yesterday two nice orders, and you kept your word by sending me the warrant. You can't call yourself a man.

Witness.—On the 25th of November I bought from Coleman, at his house in Banner Square, St. Luke's, the 41 cartes-de-visite produced for 3d. each.

The Prisoner.—You offered me £100 if I would tell you where I got them from; and you wanted to become my partner.

Mr. Lewis said Mr. Graves had not cared what money he spent in finding out the source of these piracies, and it was quite true the witness had suggested a partnership.

Witness.—On the 3rd of December I bought seven more cartes, and on the 14th four—all at 3d. each. I have watched the prisoner Lawrence for about six weeks. He occupies a room on the third floor of a house in Powell Street, Goswell Road. Coleman has been in the habit of going there night and morning and leaving his photograph box. He used to open the door with a latch-key.

The prisoner Lawrence.—It is an abominable falsehood.

Witness.—I have spoken to Coleman about his business, and I told him if he would give me the name and address of the person from whom he obtained the photographs I would find £50 to go into partnership with him. He said he would do his best, but the "old man" was a "screw," and very close-fisted. He added, "We have no right to sell them, as we are liable to a £5 penalty on each." On one occasion, while we were talking, a gentleman came up and asked Coleman for a copyright picture. He supplied him with one, afterwards saying to me, "He looks like one of Graves's men and a touter; what do you think of it?" I replied, "I don't know; he looks queer." (Laughter.) He then asked me my profession, and I told him

I was an architect—Coleman told me if he ever got a summons he should "make a bolt of it."

The prisoner Coleman.—I said I should go away in a balloon. (Laughter.) His evidence is a tissue of falsehoods. I have sold pictures, not knowing there was any harm in it.

Witness continued.—I was present when Lawrence's house was searched. There were 850 printed copies of Mr. Graves's pictures found, as well as hundreds of those of other publishers.

By Mr. Wontner.—Hooper keeps a shop in Jewin Street, and I believe he is a respectable man.

Edward John McDouall said he was in the employment of Mr. Graves, and had been engaged for the last month in watching the three prisoners. He went to Hooper's shop on the 3rd of December, and took a copy of Mr. Graves's "Monarch of the Glen" to be mounted. Hooper was not present. His wife opened a large paper parcel, and showed him copies of "The Railway Station," "The Second Sermon," and "A Piper and a Pair of Nutcrackers," among many others. They were all mounted, and witness afterwards saw Lawrence leave the house with a parcel like that shown him by Mrs. Hooper. A few days after he went back to fetch the engraving, and saw Hooper. He showed witness some copies of engravings, but declined to sell them, as they were copyrights, and as he had been engaged to mount them for a gentleman.

The prisoners Coleman and Lawrence both seemed anxious to exonerate Hooper, but were stopped in their statements with that view by Mr. Wontner, who defended Hooper.

Mr. Boydell Graves said: I am manager to my father, and saw Coleman selling pirated copies of his photographs in Lime Street Square on the 23rd of November. I purchased two copies of "The Last Kiss," one of "The Railway Station," and two of "A Piper and a Pair of Nutcrackers" on that day. He represented that only two copies out of every hundred manufactured were sent to London. I counted the pirated photographs found at Lawrence's house at Bow Lane Police Station yesterday, and found there were 700 cartes-de-visite and 150 of a larger size. They were all taken from Lawrence's bedroom.

The prisoner Coleman: If you saw me selling these things, you should have said, "My good man, you know you're doing wrong; just hook it." (Laughter.)

John Mark Bull, a city detective sergeant, said he received the warrant for the apprehension of the prisoners, and went on Thursday to the house of Lawrence, in Powell Street, St. Luke's, with the witness McDouall. He saw Coleman come out with a large black photograph case, and stopped him in Old Street.

Edward Funnell, another city detective sergeant, said he had acted with the last witness in the matter, and on Thursday sent a messenger to Lawrence's house in Powell Street. The prisoner opened the door, and witness told him the charge on which he would be taken into custody. He became very excited, and said no three men alive should take him. He was, however, arrested, and he then admitted that he knew Hooper, whom he had employed to mount photographs. Witness found 850 pirated copies of Mr. Graves's subjects at his house, with several hundred others. The prisoner told him they came from Scotland, but he could not tell where. Witness afterwards arrested Hooper, who acknowledged that he had mounted photographs for Lawrence, and produced his books, showing the work done. Two copies were found at his house, and he said he had supplied Lawrence with 28 that morning.

The prisoner Lawrence said he had been all over Scotland and England, and had bought them at different places.

At this stage, Mr. Lewis applied that the prisoners should be remanded.

Mr. Wontner submitted that there was no case against Hooper, who, it had been proved, absolutely refused to sell a single copy of the pirated photographs.

Mr. Lewis said it was part of the conspiracy to help to produce the photographs, and this Hooper had done.

Mr. Alderman Allen remanded the prisoners until Thursday next, and offered to admit them to bail in the meantime—themselves in £100 each, and two sureties in £100.

The prisoner Hooper at once left the court, having found the requisite amount of bail.

The other prisoners were conveyed to Newgate, Coleman, as he was leaving the dock, causing some laughter by offering to become surety for "his friend" Lawrence.

## Proceedings of Societies.

### EDINBURGH PHOTOGRAPHIC SOCIETY.

The ordinary meeting of this Photographic Society, being the fourth of the session, was held on the evening of Wednesday, December 16; Mr. NICOL occupied the chair.

The minutes of a previous meeting having been read and confirmed, the following new members were duly elected:—Mrs. John Peat, East Claremont Street, Edinburgh; Miss Wood, 130, George Street, Edinburgh; Mr. Finlay Anderson, 32, Moray Place, Edinburgh; Mr. E. J. Dallas, Princes Street, Edinburgh; and Mr. J. Macdonald, Lasswade.

The CHAIRMAN expressed his gratification to observe that ladies were beginning to join the Society, and would urge upon those present the desirability of inducing as many of their friends as possible to enter their ranks. He should like, in fact, to see the Society composed of as many ladies as gentlemen, and saw no reason why it should not be so.

Mr. NORMAN MACBETH then read a paper on the importance of a few of the leading principles of the art of drawing, and their bearing on photography, and exhibited drawings in illustration of the paper. This will appear in our pages in due course.

The CHAIRMAN thought it would be unnecessary for him, as well as impossible, to comment upon the paper, beyond remarking that it was, he thought, the most valuable paper they had ever had before them. It seemed to him to combine the practical with the theoretical in such a way as to make it useful to every photographer, both amateur and professional. Every one of them would, he doubted not, derive a great deal of advantage from it. At that late hour it would not be desirable to enter into anything like an extended discussion, the more so that it seemed to him that the whole of the propositions had been so self-evident, and the whole of the information so unobtainable, that the only thing they could do was to take what they had got, be exceedingly thankful for it, and make the best use of it they could. He would be glad, however, to hear the remarks of any gentlemen present, if they would promise to be judiciously brief in their observations.

Mr. GEORGE CAMPBELL suggested that it would be well if they could devote an entire evening to the discussion of the subject of such paper, if they had courage to take it up and do it justice.

Mr. DAVIES (Secretary) remarked that, in that case, it would be better to wait till the paper was printed.

The CHAIRMAN heartily approved of the idea. If they had the paper printed and in their hands, it would be of very great benefit carefully to study it; and seeing that Mr. Macbeth had kindly volunteered to give any assistance to any one wishing a little more information, he had no doubt that gentleman would be present at the discussion and help them by information or explanation. The Business Committee would doubtless appoint an evening for the purpose of resuming the subject, after the paper had been published and in the hands of the members.

Mr. ROSS, in cordial terms, proposed a double vote of thanks to Mr. Macbeth, and remarked that he was only afraid the discussion would be tame, flat, and unprofitable, because there was very little in the paper that any one could contradict or gainsay.

Mr. SANDFORD, of London, then exhibited and explained an arrangement for using the magnesium light for enlarging purposes. The only apparatus at his disposal was, unfortunately, defective, and did not give a proper idea of the system. It was therefore agreed that at the next meeting two of the members who are in the habit of using Mr. Sandford's apparatus should give a practical demonstration of its capacity.

The proceedings then terminated.

## Correspondence.

### PRINTS ON APPROVAL.

DEAR SIR,—The question of "prints on approval" has, perhaps, an aspect overlooked by Mr. Cherrill. If pictures are to be so sent, what wonder if photographers bent on "business," when they have a difficult subject and take

several plates before a passable portrait is obtained, send prints from each plate taken, in hope that one, at least, may please, instead of washing off the bad ones on their own responsibility, and so get the "art" the bad name of making people look cross?

This is the custom with some, I fancy, as I have several times had this remark made me: "I suppose you will send me prints of both." Surely the better plan is to turn out only those with which the photographer is, at least to some extent, satisfied? But, ignoring this aspect of the matter, his paper seems to rest on this rather uncertain foundation: "The public is not so fond of having its portrait taken that it will reject pictures unless they are absolutely too bad. There are, indeed, many people who would sooner put up with a bad portrait than have the trouble of sitting again." "Many," there are, no doubt; but how about the rest? "May I come again to-morrow?" has been the request of merry little sitters who have occupied the best part of a bright morning; and children grown older in the use of the looking-glass have expressed an idea not altogether different. Must a photographer make his studio a chamber of horrors to avoid the impositions of those who, "now they see it, do not quite like the effect of the dress;" or, who "wish, after all, that they had sat down instead of standing?" &c.

To meet the difficulty, we put the following on our receipt form:—"To avoid disappointment, it is recommended that sitters should have one copy of their portraits before more are printed. If, for any reason, the first should not be satisfactory, another sitting will be given for half-price, provided the copy of the first be returned, when the negative will be destroyed."

Very few indeed object to that solution of the difficulty; even those who have been treated on the other plan, elsewhere, agree that ours is reasonable and fair.

Allow me to make two extracts for the benefit of those who prefer to follow Mr. Cherrill, that they may know how far they may have to go:—"To take a successful photographic portrait is a much more wonderful thing than many people seem to think. Persons who have known each other, and who have been constantly in each other's society for a long course of years, naturally know infinitely more of each other than those who meet only for a few minutes once, perhaps, in the course of a lifetime; and yet the photographer is often blamed if, after five minutes' conversation with a person whom he has never before seen, he cannot call up in the portrait he produces the very best expression ever seen by even the most intimate friend of the sitter." And: "It matters not how artistic the pose may be, it matters little how good the picture may be, it matters absolutely nothing how good the photograph may be, if the portrait is not approved of, its condemnation is complete; and if a picture is condemned, who is to blame, the sitter or the artist? Certainly, in nine hundred and ninety-nine cases out of a thousand, not the sitter."

Or, if I may put it in other words, "It is wonderfully difficult to take a successful photographic portrait, especially as you may not have an opportunity of seeing the expression you ought to get; but if you do not get it perfectly, it is entirely your own fault, and the "public has a right" to claim that you shall go on till you do; and you must consider your trouble paid for in your reputation." Let me ask Mr. Cherrill how often he is quite satisfied with his own work?

Some one (perhaps as good an artist in his way as some photographers) once said, that his genius was declining, because he was satisfied with his productions.—Yours, truly,  
ED. SEELEY.

#### PICTURES BY THE ACTION OF COLD.

SIR,—I cannot help thinking that, with some few modifications, Mr. Winstanley will succeed in his experiments in "cold printing." It seems to me that the causes of failure

were two; viz., a too great quantity of iodine in the vapour used, and much too short a time in the application of the cold. I reason thus:—In the original phenomenon of the radiant heat from the colours in the pattern of the carpet, I presume that no deposit of the vapour of the room would have taken place, except on a considerable lowering of the temperature, and that, by such low temperature being long continued—that is, for the entire night—an image was gradually built up on the portions of glass which received the less radiant rays. Again, the Wisconsin climate, with its 70° below our freezing point, would only have to act through one layer of glass, and that, as I said, for many hours continuously; whereas, the cold of the ether was induced only for "several minutes," and then, ere it could come in contact with the vapour so as to condense it, it had to penetrate through two thicknesses of glass, a thickness of paper, two thin layers of atmospheric air, and a thickness of collodion film. Now Melloni, as the result of his experiments on the diathermic properties of bodies, places glass as more unfavorable to the transmission of heat rays than even ice itself—that is, under certain circumstances. Air is a bad conductor, and the paper would represent a sort of cotton blanket. As this winter may afford an opportunity for a thorough and inexpensive repetition of the experiment, I should suggest it being conducted thus:—First of all, to ascertain the weakest iodized vapour which would remain for some hours in contact with collodion film at ordinary temperature without so condensing as to charge the film with iodine, and render it capable of forming a *general* layer of iodide of silver in the bath, and so, if presenting an entire sensitive surface to the light, which must blacken all over on the application of the developer. Having determined this, I should put my collodionized plate face down over the vessel containing the vapour; I should then take a rather deep dish quite flat at the bottom, and pasting the printed paper on to the reverse of the glass carrying the collodion, I should place the bottom of the dish firmly upon the paper while it was still slightly damp, then fill the deep dish with snow or pounded ice, which I should sprinkle with hypochloride of ammonia and common salt, and then leave it all night. I should expect, with this long-continued low temperature, that opposite the dark letters of the paper there would be a copious deposit of vapour charged with iodine, with, perhaps, a small amount from the cooling down of the layer of air in contact with the collodion surface; but I think that the after operations would show the difference between the radiant and non-radiant portions, and so produce the analogue of the original phenomenon.

I trust that Mr. Winstanley will see that I am not attempting to dogmatize, but only offering suggestions; and that if that gentleman should succeed in a future trial, to him will belong all the credit of a philosophical and beautiful experiment.—Yours, &c.,

JOHN ANTHONY, M.D.

Washwood Heath, nr. Birmingham, December 19th, 1868.

#### PACKING CASES.

SIR,—At this season, like many others, no doubt, I find a good many uses for the cases accumulated in the course of the summer's business. I have no doubt, too, that others have experienced the evil of which I complain. I find that the enormous nails used by the first senders to secure the cases so split the wood as to make the second securing of them, if not an impossibility, at least a matter of great trouble. Would it not be better to supply the cases with screws? I fancy it would be to the interest of the wholesale houses themselves, besides being, I am sure, a favour to the customer on whose hands the dilapidated remains are eventually cast.—I am, sir, yours &c.,  
Y.

Preston, December 15th, 1868.

# THE INDEX TO VOLUME XII.

## A

ABRIDGMENT of specifications relating to photography, 219  
 Abyssinian expedition, by H. Baden Pritchard, photography in connection with the, 604, 614  
 ———, photography and, 191, 206, 239, 251, 350, 455  
 ——— prince, photographs of the, 455  
 ——— scenery, 575  
 Academy of 1868, by Nelson K. Cherrill, 376  
 Accident in boiling down a bath, 443  
 Acetate bath, decomposition in the, 419  
 ——— of lead in the printing bath, 126  
 Actinic value of colour in negatives, by M. Carey Lea, 389  
 Actinism, the transmission of, by glass, 310  
 ——— *versus* illumination, 262  
 Actinometer, Mr. Bing's new, 422  
 Actinometry, by L. Bing, 416  
 Adhesive mediums, a word or two in favour of paste, by a Practical Man, 174  
 Africa, photographic difficulties of an amateur in South, by Dr. Mann, 134, 140, 152  
 Albumen, 345  
 ———, from a chemical point of view, by J. Spiller, 170  
 ——— opalotypes, 69  
 ——— prints, by M. Carey Lea, reaction of hyposulphites and sulphocyanides upon, 453  
 Albuminized paper and printers, 549, 561  
 ——— and brilliant prints, 563  
 ——— and printing, by N. K. Cherrill, 536, 542  
 ———, blistering of, 53  
 ——— ready for use, sensitive, 337  
 ———, salting formulae of, 525  
 ———, the proportion of salt employed in, 507, 514, 538, 573  
 ———, uneven drying of sensitized, 509  
 ——— prints, varnishing, 311  
 Alcohol in developing and fixing solutions, 51  
 ———, rectifying, by means of gelatine, 432  
 Amateur Photographic Association, 202, 560, 587, 597  
 ——— criticism, 566, 573  
 America, international copyright with, 143, 179  
 ———, photographic convention in, 180, 212, 228, 274  
 ———, prices of photographs in, 8  
 ———, studio and processes in, 495  
 American examination of Mr. McLachlan's discovery, an, 603  
 ——— Institute, proceedings of, 274  
 ——— patent office, photography at, 107  
 Amorphous albuminized paper, 586  
 Antidote to vegetable poisons, 407  
 Application of photography, another, 11  
 ——— of the camera-obscura to harbour defence, 510  
 Approval, prints on, 616  
 Aqueous varnish, by C. Meinert, 288  
 Archaeology, photography as an aid to, by J. Henderson, 163, 178  
 Art critic on the late exhibition, 589  
 ———, lectures on, 10, 56  
 ——— studies, photographic, 515  
 ——— teaching and art study, by Respice Finem, 487

Artificial light, by David Wiostanley, on the economical use of, 245  
 Artistic copyright, 587  
 ——— pictures photographically considered, by E. Dunmore, 19  
 ——— printing, Mr. Piercy's patent method of, 318  
 ——— process, patent, 311  
 Atmospheric effects in landscape photography, by Nelson K. Cherrill, on natural clouds and, 87, 208  
 Austria, photographic enterprise in, 122

## B

BACKGROUNDS and accessories, by James Martin, 531  
 ———, landscape, to portraits, 346  
 ———, some hints on, 278  
 Ball, William, photographs to historical and architectural notes, 399  
 Balloon photography, 240, 479  
 Bankrupt pirate, a, 275  
 Bath, accident in boiling down a, 443  
 ———, making a, 527  
 Baths, some experiences with, 155  
 ———, old, 179  
 Battery, chloride of silver, 83  
 Beattie, John, lighting the sitter, 511  
 ———, posing phenologically and psychologically considered, 567  
 Belgian volunteers, photographs of, 107  
 Bellows camera, making a, 11  
 Bell, William, mixture for retouching negatives, 333  
 Bensa, L. G., the photographers' reference table, 327  
 Best photographers, 383  
 Beverley, J., dry-plate photography, 247  
 Bichromate of potash, poisoning by, 299  
 Bing, L., on actinometry, 416  
 ———, new actinometer, 422  
 Biographical photographic albums, 287  
 Black tones, 491  
 ——— varnish, 359  
 Blake, J. M., means of equalizing exposure with wide-angle lenses, 594, 607  
 ———, means of equalizing exposure with the wide-angle lens, 607  
 Blair's carbon experiments, 443  
 Blanchard, Valentine, some remarks upon stereoscopes, 499  
 Blistering of albuminized paper, 53  
 Blisters in albuminized paper, 143  
 Bloede, Victor G., on a new method of recovering metallic gold and silver residues, 272, 331  
 ———, removing varnish from a collodion film without injury, 128  
 Blue glass in photographic studios, by M. Alois Nigg, on the employment of, 439  
 Blurring, with a new remedy, by M. Carey Lea, 234  
 Bockett, John, on some of the changes which take place in photographic materials and chemicals after lengthened disuse, 233  
 Bolton, W. B., on collodio-bromide, 149  
 Bordeaux, M. Omer, on the employment of mixed collodion, 546

Bovey, W. T., photographic printing in silver, theoretical and practical, 86, 122, 160, 157, 221, 256, 291, 304, 399, 511, 524  
 ———, fireside musings, 7  
 ———, mode of toning, 346, 574  
 Braun's collodion, 126  
 ——— reproductions, 395  
 Brewster, Sir D., the last words of, on photography, 139  
 ———, the late, 74  
 Brigandage, photography and, 11  
 Brine, a remarkable natural, 83  
 British Association for the Advancement of Science, 409  
 ———, members of, 599  
 Bromides in a collodion containing a potassium salt, 265  
 ———, test for, 218  
 Bromide patent, the, 347, 383, 398, 457  
 Bromine upon certain ethers, on the action of, by MM. A. Lulenberg and H. Wichelhaus, 343  
 Bromo-iodized India-rubber, 359  
 Browne, J. C., redevelopment by nitrate of silver and citric acid, 234  
 ———, view of New York, 5  
 Bruges and its belfry, 459  
 Burgess, studio at Norwich, 410, 422  
 Burke's photograph, Col., 180

## C

CABINET background, 22  
 ——— portraits, 203  
 ——— in America, 311  
 ——— with natural backgrounds, 432  
 ——— work in Egypt, 618  
 Camera-obscura to harbour defence, application of the, 510  
 ——— printing and collodion prints, 217  
 Campbell, W., an easy mode of obtaining the position and focus for field views, 314  
 Canvas for enlargements or direct printing, by J. M. Loewe, preparing, 212  
 Carbolio acid, 467, 479  
 ——— in the silver bath, 448, 515  
 Carbon and other tissues, a modification in transferring, 229  
 Carbon printing, 22  
 ———, by M. Carey Lea, 176  
 ———, simplified, 589  
 ———, progress of, 497  
 ———, simplified manipulation in, 277  
 ——— process, by Dr. H. Vogel, remarks upon the, 200, 308  
 ———, by M. Jeanrenaud, observations on the, 463  
 ——— not Braun's, 110, 242  
 ———, notes on the, 297  
 ——— reproduction, 156, 483  
 ——— tissue, modified, 99  
 Carbonate of ammonia in the fixing bath, 47, 53  
 ——— of lime in toning, 323  
 Carriage of photographic goods abroad, 331  
 Carrier's sensitive paper, 319  
 ——— albuminized paper, 599  
 Cases, packing, 617  
 ——— uses of spots in prints, 11

Luggage, what is passengers', 467  
 Lux Graphics on the wing, 154, 202, 263, 418, 456, 560, 610  
 — in defence, 588  
 —, the use of clouds as backgrounds in portraiture, 99  
 —, the use of clouds in landscapes, 27

## M

McLACHLAN, Mr., remarks upon the wet collodion process, 245, 259  
 McLachlan's discovery, Mr., 45, 58, 85, 181, 193, 202, 214, 229, 241, 253  
 —, an American examination of, 603  
 —, by Nelson K. Cherrill, 197  
 —, nitrate of silver, by J. Spiller, F.C.S., 254  
 —, process, by John Spiller, F.C.S., observations on, 195  
 Magic lantern and photography, by J. Martin, 9, 28, 69, 79, 100, 138, 161  
 —, development exhibited by, 107  
 —, gas or oil lamps for the, 154  
 Magnesia toning baths, 275  
 Magnesium, cheap, 611  
 —, light, enlarging by the, 37  
 Magnified photographic pictures, 309  
 Mann, Dr., photographic difficulties of an amateur in South Africa, 140, 152  
 —, Professor Smyth's "Great Pyramid" bath, 296  
 Manufacture of glass, Mr. Chance's lecture on the, 236  
 Marking ink, by H. Neale, 592  
 Marseilles, Photographic Society of, 284, 394  
 Martin, J., backgrounds and accessories, 531  
 —, the diamond, 281, 367  
 Masking prints, a new method of, 515  
 Mason, O. G., removing varnish and collodion film from old negatives, 487  
 Measurement of the luminous intensity of light, by William Crookes, F.R.S., &c., on the, 308, 391  
 Mechanical printing process, by R. Griggs, photography applied to, 199  
 Medals at the Cornwall Polytechnic Exhibition, 482  
 —, final, of the French Exhibition, 371  
 Memorial card mounts, 323  
 Mercury, the stability of negatives intensified by iodide of, 481  
 Methylic alcohol, artificial, 345  
 —, into ethylic alcohol, conversion of, 345  
 Micro-photography, by Jules Gerard, 572  
 —, stereoscopic, 10  
 Microscopic Society, soiree at, 215  
 Middleton, J. B., combination negatives, 282  
 Military school of photography at Chatham, the, 373  
 Mirage at Dover, remarkable, 251  
 Moist condition, by General Mongin, on the preservation of collodionized plates in a, 258  
 Monckhoven's, Dr., photographic optics, 146  
 Mongin, General, on the preservation of collodionized plates in a moist condition, 258  
 Monochromatic light as a means of detecting disease, use of, 228  
 Moon, photographs of the, 264, 278, 309  
 Monstre photographic group, a, 347  
 Morphine plates, insensitised spots on, 215  
 —, the moist process, 2  
 Morien, Prof., on a peculiar action of light upon the salts of silver, 419  
 Motive power, new, 345  
 Moulds for the galvanoplastic process, 335  
 Mounting-boards, sulphur compounds in, 189  
 —, cards, on the occurrence of hyposulphites in, by J. Spiller, F.C.S., 220  
 —, photographs and engravings, method of, 389  
 Mounts for cards and cabinet pictures, 96  
 Mount for photographs, new style of, 602

## N

NATURAL accessories, 432
